TAPERED STRUCTURAL MEMBERS: AN ANALYTICAL TREATMENT

By Walter H. Weiskopf[1], and John W. Pickworth[1], Members Am. Soc. C. E.

With Discussion by Messrs. Fred L. Plummer, LeRoy W. Clark, E. G. Paulet, J. Charles Rathbun, Halvard W. Birkeland, C. W. Dunham, Fang-Yin Tsai, A. A. Eremin, Austin H. Reeves, A. W. Fischer, L. Legens, and Walter H. Weiskopf and John W. Pickworth.

Synopsis

The object of this paper is to present a method of analyzing structures composed of members which are not uniform in cross-section throughout their lengths. The application to some of the classical methods of analysis is indicated, and as applied to the method of moment distribution a complete development is given. Formulas for variously shaped members under various loadings are given for design use.

Introduction

The tapered member, one in which the cross-section varies from point to point along the length, is the natural and, in every respect, the correct design for a beam with restrained ends. In fact, unless the members are tapered the full advantage of continuous beams and rigidly framed structures cannot be realized. With the marked present-day trend toward the use of such structures the need increases for a satisfactory mathematical treatment of this subject.

The term, tapered member, as used herein is not confined to members in which the upper or lower edge has a curvature or haunch. Broadly stated a tapered member is one in which the moment of inertia is not constant

Note.—Published in October, 1935, *Proceedings*.
[1] Cons. Engr. (Weiskopf & Pickworth), New York, N. Y.

throughout the length. In this sense a plate girder, in which the flanges are straight, but vary in area as certain parts, such as cover-plates, are added is a tapered member.

When one seeks to apply the usual theory of structures to a tapered beam difficulties appear immediately. It becomes necessary at the beginning to perform some operation, usually an integration, upon an expression of the form, $\frac{M\,dx}{E\,I}$, $\frac{M^2\,dx}{E\,I}$, or $\frac{M\,x\,dx}{E\,I}$. For a uniform member this presents no unusual difficulties since I and E are constant. In a tapered member, however, the moment of inertia, I, is usually a complicated function of x, subject to irregularities such as occur at haunches, or involving sharp discontinuities where parts of the flange begin. Although the moment of inertia, I, may be a simple function of x, it is likely to be one which will make the integration of $\frac{M\,dx}{E\,I}$ difficult or impossible.

The method explained herein for overcoming these difficulties introduces, for the actual I of the member, a function of x, the nature of which has the properties of: (1) Closely approximating the actual I-curve; and (2) being of such a form that the expression, $\frac{M\,dx}{E\,I}$, can be integrated easily. This function,[2] which is termed the substitute I-curve, is:

$$I_x = \frac{I_0}{1 + A\left(\frac{x}{l}\right)^n} \quad \text{.....................(1)}$$

in which I_x is the moment of inertia at any point; I_0 is the moment of inertia at the end where $x = 0$; and l is the length of the member. Constants A and n are determined so as to make the substitute I-curve fit closely to the actual curve.

Fitting the I-Curve

Fig. 1 represents a member above which are plotted the actual, and a substitute, I-curve. Obviously, the substitute I-curve (Equation (1)) agrees with the actual curve where $x = 0$, both having the value, I_0, for this point. The constant A, can be determined to make the two curves coincide at the other end of the member, $x = l$. Substituting I_l for I_x, and l for x in Equation (1) and solving for A:

$$A = \frac{I_0 - I_l}{I_l} \quad \text{.........................(2)}$$

Constant A then depends solely upon the moments of inertia at the ends of the member. From Equation (2) it is evident that the greater the taper,

[2] Similar formulas have been suggested by George E. Large, Assoc. M. Am. Soc. C. E., and Clyde T. Morris, M. Am. Soc. C. E., *Bulletin No. 66*, Ohio State Univ., Columbus, Ohio, and by Max Ritter, *Schweitzerische Bauzeitung*, Vol. LIII, No. 18.

the greater the difference between the extreme I-values, and, therefore, the greater the value of A. For this reason, A is termed the "taper modulus" of the member. For a member of uniform cross-section the taper modulus becomes zero.

Since the taper modulus, A, depends solely upon the end values of the I-curve, the constant, n, can only affect the path between these two values, or the shape of the I-curve between the ends. Therefore, n is termed the "shape exponent".

The effect of varying the shape exponent, n, is illustrated in Fig. 2. For the purpose of this illustration, I_o is chosen as 10, and I_l as 1. Therefore, by Equation (2) $A = 9$; and, by Equation (1):

$$I_x = \frac{10}{1 + 9\left(\frac{x}{l}\right)^n} \qquad \text{(3)}$$

For each value of n the substitute I-curve takes a different path between the ends of the member. As n approaches infinity, the substitute I-curve approaches that of a uniform member of moment of inertia, I_o, while as n approaches zero the curve approaches that of a uniform member, of moment of inertia, I_l. Theoretically, the shape exponent, n, can have any value between zero and plus infinity.

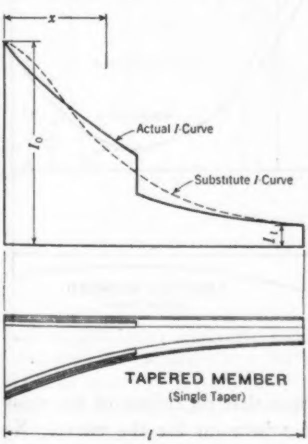

FIG. 1.

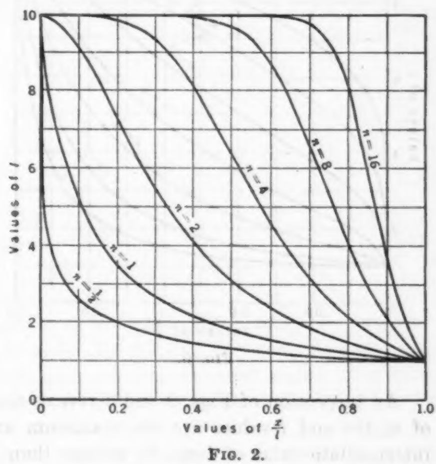

FIG. 2.

Although in Fig. 2, I_o is chosen greater than I_l, the method is equally applicable when I_l is greater than I_o. In Fig. 3 the curves are plotted for $I_o = 1$, and $I_l = 10$. In this example, A is negative and, by Equation (2), is equal to -0.9. By Equation (1),

$$I_x = \frac{1}{1 - 0.9\left(\frac{x}{l}\right)^n} \qquad \text{(4)}$$

As before, n can have any positive value. When it becomes infinity the curve again represents a uniform beam, of moment of inertia, I_0; and when n becomes zero the curve represents a uniform beam, of moment of inertia, I_1.

By properly choosing a value for n, the substitute I-curve can be made to approximate closely the actual I-curve. As an aid in selecting n, a value for it can be determined which will make the substitute I-curve pass through any intermediate point. Suppose it is desired that the substitute I-curve shall have a value, I_e, where $x = x_e$. Substitute I_e for I_x, and x_e for x in Equation (1), and solve for n; then:

$$n = \frac{\log \dfrac{I_0 - I_e}{A\, I_e}}{\log \dfrac{x_e}{l}} \qquad \text{.......................(5)}$$

By means of Equations (2) and (5) values of A and n can be determined, which will make the substitute I-curve coincide with the actual I-curve at the ends of the member and at one intermediate point.

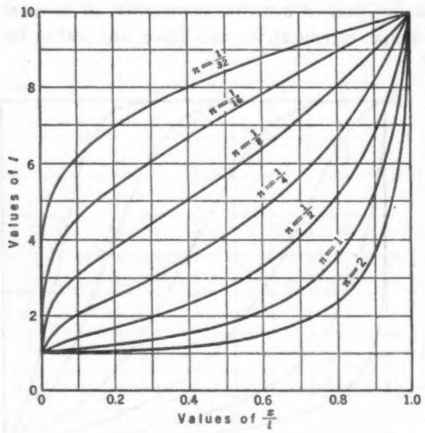

FIG. 3.

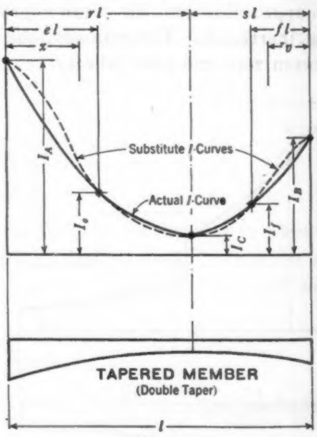

FIG. 4.

An inspection of Figs. 2 and 3 reveals the fact that regardless of the value of n, the end I-values are the maximum and minimum for the curve. No intermediate value of I can be greater than the larger end value, or less than the smaller. Since members in continuous frames very frequently have I-values at the center less than that of either end, this might appear at first to be a severe limitation to the method. The difficulty, however, can be overcome easily by treating such a member in sections. Thus, let Fig. 4 represent a member with end I-values, I_A and I_B, that are large, and with a minimum I_C, that occurs at some point a distance $r\,l$ from the left end. Such a member which can be defined as one of double taper, is divided into a left and a right

section. A substitute I-curve can be fitted to the left section of the member by substituting $r\,l$ for l in Equation (1), which becomes,

$$I_x = \frac{I_A}{1 + A \dfrac{x^n}{r^n\, l^n}} \qquad (6)$$

For this section of the member, Equation (2) becomes,

$$A = \frac{I_A - I_C}{I_C} \qquad (7)$$

The substitute I-curve can also be made to pass through another point in the section of the member, (I_e), by means of Equation (5) which becomes,

$$n = \frac{\log \dfrac{I_A - I_e}{A\, I_e}}{\log \dfrac{e}{r}} \qquad (8)$$

For the right section of the member take the origin of co-ordinates at the other end, using v instead of x as the ordinate. If B is the taper modulus, and m, the shape exponent for this section, the equations of the substitute I-curve become,

$$I_v = \frac{I_B}{1 + B \dfrac{v^m}{s^m\, l^m}} \qquad (9)$$

$$B = \frac{I_B - I_C}{I_C} \qquad (10)$$

and,

$$m = \frac{\log \dfrac{I_B - I_f}{B\, I_f}}{\log \dfrac{f}{s}} \qquad (11)$$

It is possible, of course, to divide a member into three, four, or more sections, and fit a substitute I-curve to each. Practically, however, it seems that dividing into two sections gives sufficient accuracy for most engineering purposes. Ordinarily, it is not necessary to obtain an extremely close approximation. The taper modulus can be obtained exactly, and then a variation in the shape exponent produces a surprisingly small change in the resulting stress distribution.

Applications

Many of the commonly used methods of analyzing structures composed of uniform members can be applied to structures composed of tapered members by using substitute I-curves. Some of these methods are: (1) Finding the elastic curve of a member; (2) finding the strain energy of a member and,

from the strain energy, the deflection; (3) the method of least work; (4) the slope deflection method; and (5) the Cross method of distributing fixed-end moments.

(1).—Finding the Elastic Curve of a Member.—By means of a double integration of the fundamental expression, $\frac{d^2 y}{dx^2} = \frac{M}{EI}$, the deflection, y, is obtained as a function of x.

(2).—Finding the Strain Energy of a Member and from This Energy, the Deflection.—This problem consists of integrating between the proper limits the expression for the strain energy, W:

$$W = \int \frac{M^2\,dx}{2\,EI} \quad \text{(12)}$$

(3).—The Method of Least Work.—To find a statically unknown force, H, this method consists in equating $\frac{\partial W}{\partial H}$ to zero and solving the resulting equation which is in the form:

$$\frac{\partial W}{\partial H} = \int \frac{M}{EI}\,\frac{\partial M}{\partial H}\,dx = 0 \quad \text{(13)}$$

(4).—The Slope Deflection Method.—The fundamental equations of this method are derived by integrating the $\frac{M}{EI}$-diagrams; thus:

$$\theta_A - \theta_B = \int_B^A \frac{M}{EI}\,dx \quad \text{(14)}$$

and,

$$y_A - \theta_A\, l = \int_B^A \frac{M\,x\,dx}{EI} \quad \text{(15)}$$

in which θ_A and θ_B are the changes in slope of the points, A and B, and y_A is the deflection of one end of the member with respect to the other end.

(5).—The Cross Method of Distributing Fixed-End Moments.—This method requires first finding the fixed-end moments, the stiffness, and the carry-over factors. By means of expressions of the form, $\int \frac{Mx\,dx}{EI}$ and $\int \frac{x^2\,dx}{EI}$, these moments and factors can be found for tapered members. A full development of these terms is given subsequently.

Integrating the $\frac{M}{EI}$-Curve

All the foregoing equations are variations and recurrences of the familiar expressions, $\int \frac{M\,dx}{EI}$, $\int \frac{M^2\,dx}{EI}$, $\int \frac{M\,x\,dx}{EI}$, etc. They can all be integrated according to the following general procedure.

The bending moment at any point in a member can always be expressed as the algebraic sum of the moment due to restraint at the ends, and that due to the loads acting on the beam as if the ends were simply supported. These moment diagrams are shown in Fig 5. If M_R is the moment at any point due to end restraint, and M_s is the simple beam moment:

$$M = M_R + M_S \text{..........}(16)$$

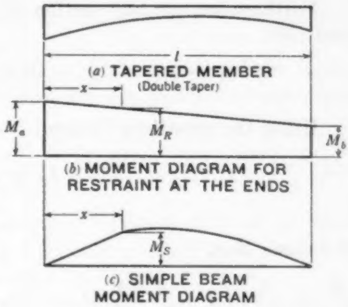

FIG. 5.

Since the moment diagram for end restraint is a straight line,

$$M_R = M_a \frac{(l - x)}{l} + M_b \frac{x}{l} = M_a + (M_b - M_a) \frac{x}{l} \text{.......}(17)$$

in which M_a and M_b are the end moments.

In treating the moment, M_S, the member is divided into sections between the concentrated loads. It has already been shown how the member can be divided into sections for a discontinuity in the I-curve. Each one of these can again be divided for a discontinuity in the M_S-diagram, so that sections are obtained over which both the I-curve, and the M_S-diagram are continuous functions of x. The integral of the entire member will then be the sum of the integrals of the separate sections. Subdividing the member into sections, although it increases the work, does not add to the difficulties encountered in any other respect.

For a complicated system of loading it is often easier to plot the influence line of the quantity desired for a single concentrated load at any point on the member, and then to sum up the effects of simultaneous loads. If there are no loads other than concentrations the M_S-diagram will consist of a series of straight lines, any one of which can be expressed by an equation of the form:

$$M_S = a_0 + a_1x \text{........................}(18)$$

If parts of the beam carry uniform loads, sections of the M_S-diagram could be expressed in the form:

$$M_S = a_0 + a_1x + a_2x^2 \text{.....................}(19)$$

For a uniformly varying load, there would be:

$$M_S = a_0 + a_1x + a_2x^2 + a_3x^3 \text{..................}(20)$$

When more complicated loadings occur they can be treated by the influence-line method. Therefore, it is plain that the M_S-diagram can always be divided into sections any one of which can be expressed by a formula not more complicated than Equation (20).

Furthermore, for any section of the member, from Equations (16), (17), and (20),

$$M = M_a + (M_b - M_a)\,\frac{x}{l} + a_0 + a_1 x + a_2 x^2 + a_3 x^3 \ldots\ldots (21)$$

Using the substitute I-curve:

$$I_x = \frac{I_A}{1 + \dfrac{A\,x^n}{r^n\,l^n}} \ldots\ldots\ldots\ldots (22)$$

it follows that,

$$\frac{M}{E\,I} = \frac{1}{E\,I_A}\left(1 + \frac{A\,x^n}{r^n\,l^n}\right)\left[M_a + (M_b - M_a)\,\frac{x}{l} + a_0 + a_1 x + a_2 x^2 + a_3 x^3\right] . (23)$$

Then,

$$\int \frac{M\,dx}{E\,I} = \int \frac{1}{E\,I_A}\left[M_a + (M_b - M_a)\,\frac{x}{l} + a_0 + a_1 x + a_2 x^2 + a_3 x^3\right] dx$$

$$+ \int \frac{A}{E\,I_A\,r^n l^n}\left[M_a x^n + (M_b - M_a)\,\frac{x^{n+1}}{l} + a_0 x^n + a_1 x^{n+1} + a_2 x^{n+2} + a_3 x^{n+3}\right] dx . (24)$$

In Equation (24) M_a and M_b are sometimes known (as is the case when a deflection is sought) and sometimes the unknowns which are to be found. In either case they do not vary with values of x, and are constants as far as the integration of Equation (24) is concerned. Since E, I_A, r, n, l, and the a-terms are constants, Equation (24) can be integrated term by term by the simplest processes of integral calculus.

For integrals of the form, $\int \frac{M\,x\,dx}{E\,I}$, all the terms of Equation (24) would contain values of x one power higher. For the form, $\int \frac{M^2\,dx}{E\,I}$, the terms would have still higher powers of x, but the integrations could be performed in the same general manner.

Application to the Cross Method of Distributing Fixed-End Moments

The method of moment distributions[3] introduced by Hardy Cross, M. Am. Soc. C. E., is so useful that its adaptation to tapered members will be developed in full. This will not only afford an illustration of the methods of integrating the various $\frac{M}{E\,I}$-functions, but will also furnish a set of formulas which will enable a designer to use the Cross method without integrating each time. Formulas will be derived that will give the fixed-end moments for various conditions of loading, and the stiffness and carry-over factors, for variously shaped members. Once values for these quantities have been found by means of the formulas, the designer can proceed to distribute the fixed-end moments

[3] "Analysis of Continuous Frames by Distributing Fixed-End Moments", by Hardy Cross, *Transactions*, Am. Soc. C. E. Vol. 96 (1932), p. 1.

according to the method of Professor Cross in the same manner as for uniform members.

First the expressions for beams in general will be derived. From Equations (16) and (17), a formula can be obtained for the moment at any point in a beam; thus,

$$M = M_a \frac{(l-x)}{l} + M_b \frac{x}{l} + M_S \qquad (25)$$

In Equation (25), M_a and M_b are any restraining moments at the ends. The values of these moments for fixed ends are those which would make the strain energy of the member a minimum. The strain energy is:

$$W = \int_0^l \frac{M^2\,dx}{2\,E\,I_x} \qquad (26)$$

Then,

$$\frac{\partial W}{\partial M_A} = \int_0^l \frac{M}{E\,I_x}\,\frac{\partial M}{\partial M_A}\,dx = 0 \qquad (27)$$

with a similar equation for $\frac{\partial W}{\partial M_B}$. For fixed-end moments, Equation (25) becomes:

$$M = M_A \left(\frac{l-x}{l}\right) + M_B \frac{x}{l} + M_S \qquad (28)$$

Then,

$$\frac{\partial M}{\partial M_A} = \frac{l-x}{l} \qquad (29)$$

and,

$$\frac{\partial M}{\partial M_B} = \frac{x}{l} \qquad (30)$$

Substituting Equations (28) (29), and (30) in Equation (27) and its companion formula for $\frac{\partial W}{\partial M_B}$, and then simplifying and solving for M_A and M_B:

$$M_A = -l\,\frac{\displaystyle\int_0^l \frac{M_S(l-x)\,dx}{I_x}\int_0^l \frac{x^2\,dx}{I_x} - \int_0^l \frac{M_S\,x\,dx}{I_x}\int_0^l \frac{x(l-x)\,dx}{I_x}}{\displaystyle\int_0^l \frac{x^2\,dx}{I_x}\int_0^l \frac{(l-x)^2\,dx}{I_x} - \left[\int_0^l \frac{x(l-x)\,dx}{I_x}\right]^2} \qquad (31)$$

and,

$$M_B = -l\,\frac{\displaystyle\int_0^l \frac{M_S\,x\,dx}{I_x}\int_0^l \frac{(l-x)^2\,dx}{I_x} - \int_0^l \frac{M_S(l-x)\,dx}{I_x}\int_0^l \frac{x(l-x)\,dx}{I_x}}{\displaystyle\int_0^l \frac{x^2\,dx}{I_x}\int_0^l \frac{(l-x)^2\,dx}{I_x} - \left[\int_0^l \frac{x(l-x)\,dx}{I_x}\right]^2} \qquad (32)$$

Denote the integrals in Equations (31) and (32) as follows:

$$\int_0^l \frac{x(l-x)\,dx}{I_x} = \frac{l^3 F_1}{I_A} \qquad (33)$$

$$\int_0^l \frac{x^2\,dx}{I_x} = \frac{l^3 F_2}{I_A} \qquad (34)$$

and,

$$\int_0^l \frac{(l-x)^2\,dx}{I_x} = \frac{l^3 F_3}{I_A} \qquad (35)$$

If P is a concentrated load located at any point on the A-section of a member of double taper,

$$\int_0^l \frac{M_S\,x\,dx}{I_x} = \frac{P\,l^3 F_4}{I_A} \qquad (36)$$

and,

$$\int_0^l \frac{M_S\,(l-x)\,dx}{I_x} = \frac{P\,l^3 F_5}{I_A} \qquad (37)$$

Then,

$$M_A = -P\,l\,\frac{F_5 F_2 - F_4 F_1}{F_2 F_3 - F_1^2} \qquad (38)$$

and,

$$M_B = -P\,l\,\frac{F_4 F_3 - F_5 F_1}{F_2 F_3 - F_1^2} \qquad (39)$$

If the load, P, is on the B-section of a member of double taper,

$$\int_0^l \frac{M_S\,x\,dx}{I_x} = \frac{P\,l^3 F_6}{I_A} \qquad (40)$$

and,

$$\int_0^l \frac{M_S\,(l-x)\,dx}{I_x} = \frac{P\,l^3 F_7}{I_A} \qquad (41)$$

Then,

$$M_A = -P\,l\,\frac{F_7 F_2 - F_6 F_1}{F_2 F_3 - F_1^2} \qquad (42)$$

and,

$$M_B = -P\,l\,\frac{F_6 F_3 - F_7 F_1}{F_2 F_3 - F_1^2} \qquad (43)$$

If a member supports a uniformly distributed load, w, per unit length:

$$\int_0^l \frac{M_S\,x\,dx}{I_x} = \frac{w\,l^4 F_8}{I_A} \qquad (44)$$

and,

$$\int_0^l \frac{M_S\,(l-x)\,dx}{I_x} = \frac{w\,l^4 F_9}{I_A} \qquad (45)$$

Then,

$$M_A = - w\, l^2 \frac{F_9 F_2 - F_8 F_1}{F_2 F_3 - F_1^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (46)$$

and,

$$M_B = - w\, l^2 \frac{F_8 F_3 - F_9 F_1}{F_2 F_3 - F_1^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (47)$$

Carry-Over Factor

According to Professor Cross the carry-over factor is defined[4] as follows:

"If one end of a member which is on unyielding supports at both ends is rotated while the other end is held fixed the ratio of the moment at the fixed end to the moment producing rotation at the rotating end is herein called the 'carry-over factor'."

Since there are no loads on the member except the end moments, Equation (25) becomes,

$$M = M_a \left(\frac{l - x}{l} \right) + M_b \frac{x}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots (48)$$

If End B is fixed, M_b in Equation (48) becomes M_B. If C_{AB} is the carry-over factor from End A to End B, the foregoing definition may be expressed algebraically, as follows:

$$C_{AB} = \frac{M_B}{M_a} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (49)$$

The strain energy for the member (see Equation (26)) is:

$$W = M_a^2 \int_0^l \frac{(l - x)^2\, dx}{2\, l^2\, E\, I_x} + M_a\, M_B \int_0^l \frac{x\,(l - x)\, dx}{l^2\, E\, I_x} + M_B^2 \int_0^l \frac{x^2\, dx}{2\, l^2\, E\, I_x} \quad \ldots (50)$$

For fixation at End B:

$$\frac{\partial W}{\partial M_B} = M_a \int_0^l \frac{x\,(l - x)\, dx}{l^2\, E\, I_x} + M_B \int_0^l \frac{x^2\, dx}{l^2\, E\, I_x} = 0 \quad \ldots\ldots (51)$$

Therefore,

$$C_{AB} = \frac{M_B}{M_a} = - \frac{\displaystyle\int_0^l \frac{x\,(l - x)\, dx}{I_x}}{\displaystyle\int_0^l \frac{x^2\, dx}{I_x}} = - \frac{F_1}{F_2} \quad \ldots\ldots\ldots (52)$$

Similarly, for the other end,

$$C_{BA} = - \frac{F_1}{F_3} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (53)$$

Stiffness

Professor Cross defines[4] "stiffness" of a member as follows:

" 'Stiffness', as herein used, is the moment at one end of a member (which is on unyielding supports at both ends) necessary to produce unit rotation of that end when the other end is fixed."

[4] "Analysis of Continuous Frames by Distributing Fixed-End Moments", by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 2.

According to this definition the stiffness of a member would be $\frac{M_a}{\theta_A}$. For uniform members Professor Cross does not use this value, however, but uses instead $\frac{I}{l}$, which is proportional to it, the relation between the two values being,

$$\frac{I}{l} = \frac{M_a}{4\,E\,\theta_A} \qquad \text{(54)}$$

It is immaterial, of course, whether one uses $\frac{I}{l}$, or $\frac{M_a}{\theta_A}\left(\text{which is } \frac{4\,E\,I}{l}\right)$ as long as one uses the same form for all the members of the structure. Since for uniform members, $\frac{I}{l}$ is a most convenient form, and is in common use, and since uniform and tapered members may be combined in the same structure, the stiffness of a member as used herein is in a form that corresponds to $\frac{I}{l}$, for uniform members. Therefore, the stiffness, S_A, of End A may be expressed by the formula:

$$S_A = \frac{M_a}{4\,E\,\theta_A} \qquad \text{(55)}$$

The slope deflection, θ_A, can be found by equating the external to the internal work; thus:

$$\frac{M_a\,\theta_A}{2} = \int_0^l \frac{M^2\,dx}{2\,E\,I_x} = M_a^2 \int_0^l \frac{(l-x)^2\,dx}{2\,l^2\,E\,I_x} + M_a\,M_B \int_0^l \frac{x\,(l-x)\,dx}{l^2\,E\,I_x} + M_B^2 \int_0^l \frac{x^2\,dx}{2\,l^2\,E\,I_x} \qquad \text{(56)}$$

$$\theta_A = \frac{M_a \int_0^l \frac{(l-x)^2\,dx}{I_x} + 2\,M_B \int_0^l \frac{x\,(l-x)\,dx}{I_x} + \frac{M_B^2}{M_a} \int_0^l \frac{x^2\,dx}{I_x}}{E\,l^2} \qquad \text{(57)}$$

and,

$$\theta_A = \frac{\left(M_a\,F_3 + 2\,M_B\,F_1 + \frac{M_B^2}{M_a}\,F_2\right) l}{E\,I_A} \qquad \text{(58)}$$

From Equation (52),

$$\frac{M_B}{M_a} = -\frac{F_1}{F_2} \qquad \text{(59)}$$

Then,

$$\theta_A = \frac{(M_a\,F_3 + M_B\,F_1)\,l}{E\,I_A} \qquad \text{(60)}$$

and (see Equation (55)):

$$S_A = \frac{M_a\,I_A\,E}{4\,E\,(M_a\,F_3 + M_B\,F_1)\,l} = \frac{F_2\,I_A}{4\,(F_2\,F_3 - F_1^2)\,l} \qquad \text{(61)}$$

Similarly, for the other end,

$$S_B = \frac{F_2 I_A}{4\,(F_2 F_3 - F_1^2)\,l} \quad \text{.....................(62)}$$

Equations (38), (39), (42), (43), (46), (47), (52), (53), (61), and (62) are general expressions for the fixed-end moments, carry-over factors, and stiffness for members of any kind in terms of the integrals expressed by the symbols, F_1, F_2, etc. For uniform members these F-terms can be evaluated directly. For tapered members they can be found by performing the integrations indicated, using substitute I-curves.

A summary of the formulas used in this method giving values for the F-terms is given subsequently in Cases 1 to 5. In each example, the quantities, F_1, F_2, and F_3, are functions of the properties of the member and are independent of the loading. The stiffness and carry-over factors, which also depend on properties of a member only, are given in terms of F_1, F_2, and F_3. The expression, $F_2F_3 - F_1^2$, occurs repeatedly as the denominator in formulas for stiffness and for values of the fixed-end moments. The F-terms with subscripts greater than 3 are functions of the loading as well as of the properties of the member.

Evaluation of F-Terms

Case 1.—Unsymmetrical Member of Double Taper.—This is the most general case (see Fig. 6). First, the values of A, B, n, m, C_{AB}, C_{BA}, S_A, and S_B, are determined by Equations (7), (8), (10), (11), (52), (53), (61), and (62), respectively, in which:

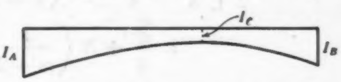

FIG. 6.—CASE 1, UNSYMMETRICAL MEMBER (DOUBLE TAPER.)

$$F_1 = r^2\left[\frac{1}{2} - \frac{r}{3} + A\left(\frac{1}{n+2} - \frac{r}{n+3}\right)\right]$$

$$+ s^2\,\frac{I_A}{I_B}\left[\frac{1}{2} - \frac{s}{3} + B\left(\frac{1}{m+2} - \frac{s}{m+3}\right)\right] \quad \text{.........(63)}$$

$$F_2 = r^3\left[\frac{1}{3} + \frac{A}{n+3}\right] + s\,\frac{I_A}{I_B}\left[1 - s + \frac{s^2}{3}\right.$$

$$\left. + B\left(\frac{1}{m+1} - \frac{2s}{m+2} + \frac{s^2}{m+3}\right)\right] \quad \text{..............(64)}$$

and,

$$F_3 = r\left[1 - r + \frac{r^2}{3} + A\left(\frac{1}{n+1} - \frac{2r}{n+2} + \frac{r^2}{n+3}\right)\right]$$

$$+ s^3\,\frac{I_A}{I_B}\left[\frac{1}{3} + \frac{B}{m+3}\right] \quad \text{.....................(65)}$$

When a load, P, is placed on the left section, a distance, $k\,l$, from the origin, ($k \leqq r$), the moments are determined by Equations (38) and (39), in which:

$$F_4 = k\,F_1 - \frac{k^3}{6} - A\,\frac{k^{n+3}}{r^n\,(n+2)\,(n+3)} \quad \text{.............(66)}$$

and,

$$F_5 = k\,F_2 - \frac{3\,k^2 - k^3}{6} - A\,\frac{k^{n+2}\,(n+3-kn-k)}{r^n\,(n+1)\,(n+2)\,(n+3)} \quad \text{......(67)}$$

When the load is on the right section, ($k \geqq r$), the moments are determined by Equations (42) and (43), in which,

$$F_6 = (1-k)\,F_2 - \frac{I_A\,(2-3\,k+k^3)}{6\,I_B} - B\,\frac{I_A\,(1-k)^{m+2}\,(2+k\,m+k)}{I_B\,s^m\,(m+1)\,(m+2)\,(m+3)} \quad \text{..(68)}$$

and,

$$F_7 = (1-k)\,F_1 - \frac{I_A\,(1-k)^3}{6\,I_B} - B\,\frac{I_A\,(1-k)^{m+3}}{I_B\,s^m\,(m+2)\,(m+3)} \quad \text{....(69)}$$

In Equations (66) to (69) the values of F_1, F_2, and F_3 are those of Equations (63), (64), and (65), respectively.

The moments for a uniform load over this entire beam are determined by Equations (46) and (47), in which:

$$F_8 = \frac{r^3}{2}\left[\frac{1}{3} - \frac{r}{4} + A\left(\frac{1}{n+3} - \frac{r}{n+4}\right)\right] + \frac{s^2}{2}\,\frac{I_A}{I_B}\left[\frac{1}{2} - \frac{2\,s}{3} + \frac{s^2}{4} + B\left(\frac{1}{m+2} - \frac{2\,s}{m+3} + \frac{s^2}{m+4}\right)\right] \quad \text{............(70)}$$

and,

$$F_9 = \frac{r^2}{2}\left[\frac{1}{2} - \frac{2\,r}{3} + \frac{r^2}{4} + A\left(\frac{1}{n+2} - \frac{2\,r}{n+3} + \frac{r^2}{n+4}\right)\right] + \frac{s^3\,I_A}{2\,I_B}\left[\frac{1}{3} - \frac{s}{4} + B\left(\frac{1}{m+3} - \frac{s}{m+4}\right)\right] \quad \text{..........(71)}$$

Case 2.—Symmetrical Member of Double Taper.—The formulas applying to the symmetrical member of double taper (see Fig. 7) are obtained by making the two ends alike in the formulas of Case 1; thus: $I_A = I_B$; $r = s = 0.5$; and $A = B$.

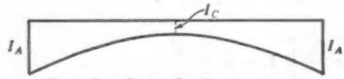

FIG. 7.—CASE 2, SYMMETRICAL MEMBER (DOUBLE TAPER.)

As before, the values of A, n, $C_{AB} = C_{BA}$, and $S_A = S_B$ are determined by Equations (7), (8), (52), and (61), respectively, in which,

$$F_1 = \frac{1}{6} + A\,\frac{n+4}{4\,(n+2)\,(n+3)} \quad \text{................(72)}$$

$$F_2 = \frac{1}{3} + A\,\frac{(n+1)\,(n+4)+4}{4\,(n+1)\,(n+2)\,(n+3)} \quad \text{...........(73)}$$

and,

$$F_3 = F_2 \quad \text{..........................(74)}$$

In applying Equation (61) to this case it is to be noted that since $F_3 = F_2$ in a symmetrical member, the denominator for the stiffness and fixed-end moments becomes $F_2^2 - F_1^2$.

When the load is on the left section, ($k \leqq \frac{1}{2}$), the moments are determined by Equations (38) and (39) in which,

$$F_4 = k\,F_1 - \frac{k^3}{6} - A\,\frac{2^n\,k^{n+3}}{(n+2)\,(n+3)} \qquad (75)$$

and,

$$F_5 = k\,F_2 - \frac{3\,k^2 - k^3}{6} - A\,\frac{2^n\,k^{n+2}\,(n + 3 - k\,n - k)}{(n+1)\,(n+2)\,(n+3)} \qquad (76)$$

When the load is on the right section, ($k \geqq \frac{1}{2}$), the moments are determined by Equations (42) and (43), in which:

$$F_6 = (1-k)\,F_2 - \frac{2 - 3\,k + k^3}{6} - A\,\frac{2^n\,(1-k)^{n+2}\,(2 + k\,n + k)}{(n+1)\,(n+2)\,(n+3)} \qquad (77)$$

and,

$$F_7 = (1-k)\,F_1 - \frac{(1-k)^3}{6} - A\,\frac{2^n\,(1-k)^{n+3}}{(n+2)\,(n+3)} \qquad (78)$$

In Equations (75) to (78) the values of F_1 and F_2 are those of Equations (72), and (73), respectively.

When the loading is symmetrical a further simplification occurs in the fixed-end moments due to the fact that $F_4 = F_5$. Thus, for a concentrated load at the center of a symmetrical beam, Equation (38) becomes,

$$M_A = M_B = -\,P\,l\,\frac{F_{10}}{F_2 + F_1} \qquad (79)$$

in which,

$$F_{10} = \frac{1}{16} + \frac{A}{8\,(n+2)} \qquad (80)$$

Similarly, for a uniformly distributed load, $F_9 = F_8$, Equation (46) becomes,

$$M_A = M_B = -\,w\,l^2\,\frac{F_8}{F_2 + F_1} \qquad (81)$$

in which,

$$F_8 = \frac{1}{24} + A\,\frac{n+4}{16\,(n+2)\,(n+3)} \qquad (82)$$

Case 3.—Unsymmetrical Member of Single Taper.—For this case (see Fig. 8), $r = 1$ and $s = 0$. Making the necessary substitutions in Equations (7), (8), (52), (53), (61), and (62), the values of A, n, C_{AB}, C_{BA}, S_A and S_B, are determined as in Case 1, with:

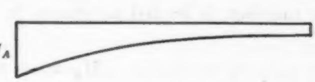

FIG. 8.—CASE 3, TAPERED MEMBER (SINGLE TAPER.)

$$F_1 = \frac{1}{6} + \frac{A}{(n+2)\,(n+3)} \qquad (83)$$

$$F_2 = \frac{1}{3} + \frac{A}{n+3} \dots\dots\dots\dots\dots\dots\dots\dots (84)$$

and,

$$F_3 = \frac{1}{3} + \frac{2A}{(n+1)(n+2)(n+3)} \dots\dots\dots\dots\dots\dots (85)$$

The moments with a concentrated load at any distance, $k\,l$, from the left end are determined by Equations (38) and (39), with:

$$F_4 = k\,F_1 - \frac{k^3}{6} - A\,\frac{k^{n+3}}{(n+2)(n+3)} \dots\dots\dots\dots\dots (86)$$

and,

$$F_5 = k\,F_3 - \frac{3\,k^2 - k^3}{6} - A\,\frac{k^{n+2}\,(n+3-k\,n-k)}{(n+1)\,(n+2)\,(n+3)} \dots\dots (87)$$

In Equations (86) and (87) the values of F_1, F_2, and F_3 are those of Equations (83), (84), and (85), respectively.

The moments for a uniform load over the entire beam, are determined by Equations (46) and (47), in which:

$$F_8 = \frac{1}{24} + \frac{A}{2\,(n+3)\,(n+4)} \dots\dots\dots\dots\dots\dots (88)$$

and,

$$F_9 = \frac{1}{24} + \frac{A}{(n+2)\,(n+3)\,(n+4)} \dots\dots\dots\dots\dots (89)$$

Since members of this kind are sometimes required to withstand earth pressure, formulas are necessary for triangular loading. For example, when

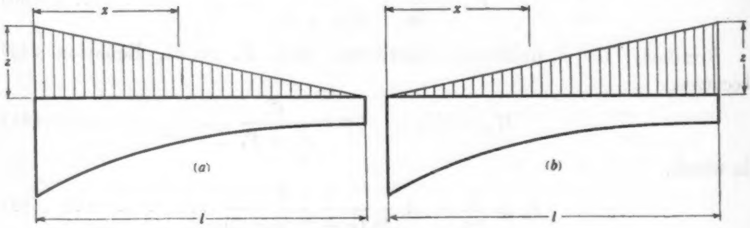

FIG. 9.—TRIANGULAR LOADINGS.

the member is loaded as shown in Fig. 9(a), Equation (31) becomes,

$$M_A = -\,z\,l^2\,\frac{F_{12}\,F_2 - F_{11}\,F_1}{F_2\,F_3 - F_1^2} \dots\dots\dots\dots\dots\dots (90)$$

and Equation (32) becomes,

$$M_B = -\,z\,l^2\,\frac{F_{11}\,F_3 - F_{12}\,F_1}{F_2\,F_3 - F_1^2} \dots\dots\dots\dots\dots\dots (91)$$

in which,

$$F_{11} = \frac{7}{360} + \frac{A\,(n+7)}{6\,(n+3)\,(n+4)\,(n+5)} \qquad \text{(92)}$$

and,

$$F_{12} = \frac{1}{45} + \frac{A\,(n+8)}{3\,(n+2)\,(n+3)\,(n+4)\,(n+5)} \qquad \text{(93)}$$

When the member is loaded as shown in Fig. 9(*b*), Equations (31) and (32) become,

$$M_A = -\,z\,l^2\,\frac{F_{14}\,F_2 - F_{13}\,F_1}{F_2\,F_3 - F_1^2} \qquad \text{(94)}$$

and,

$$M_B = -\,z\,l^2\,\frac{F_{13}\,F_3 - F_{14}\,F_1}{F_2\,F_3 - F_1^2} \qquad \text{(95)}$$

in which,

$$F_{13} = \frac{1}{45} + \frac{A}{3\,(n+3)\,(n+5)} \qquad \text{(96)}$$

and,

$$F_{14} = \frac{7}{360} + \frac{A\,(2\,n+7)}{3\,(n+2)\,(n+3)\,(n+4)\,(n+5)} \qquad \text{(97)}$$

By adding the moments due to uniform and triangular loadings, moments for a trapezoidal loading diagram can be obtained.

Case 4.—"Stepped" Member, without Taper.—The stepped member (see Fig. 10) finds application in the columns of mill buildings, for example. In this case, A and B are equal to zero and C_{AB}, C_{BA}, S_A, and S_B are determined by Equations (52), (53), (61), and (62), in which:

FIG. 10.—CASE 4, STEPPED MEMBER.

$$F_1 = r^2\left(\frac{1}{2} - \frac{r}{3}\right) + s^2\,\frac{I_A}{I_B}\left(\frac{1}{2} - \frac{s}{3}\right) \qquad \text{(98)}$$

$$F_2 = \frac{r^3}{3} + \frac{s\,I_A}{I_B}\left(1 - s + \frac{s^2}{3}\right) \qquad \text{(99)}$$

and,

$$F_3 = r\left(1 - r + \frac{r^2}{3}\right) + \frac{s^3\,I_A}{3\,I_B} \qquad \text{(100)}$$

When the concentrated load is to the left of the step the moments are determined by Equations (38) and (39), substituting values of F_4 and F_5 from Equations (66) and (67), in which the taper modulus, A, is equal to zero.

When the concentrated load is to the right of the step, the moments are determined by Equations (42) and (43), except that the taper modulus, B, in Equations (68) and (69) is zero.

The moments for a uniform load over the entire beam are determined by Equations (46) and (47) in which:

$$F_8 = \frac{r^3}{2}\left(\frac{1}{3} - \frac{r}{4}\right) + \frac{s^2 I_A}{2 I_B}\left(\frac{1}{2} - \frac{2s}{3} + \frac{s^2}{4}\right) \quad \ldots\ldots\ldots (101)$$

and,

$$F_9 = \frac{r^2}{2}\left(\frac{1}{2} - \frac{2r}{3} + \frac{r^2}{4}\right) + \frac{s^3 I_A}{2 I_B}\left(\frac{1}{3} - \frac{s}{4}\right) \quad \ldots\ldots\ldots (102)$$

Case 5.—Member with Uniform Depth and Cross-Section.—For the simplest type of member, with a uniform depth and cross-section (see Fig. 11), in which $r = 1$ and $s = 0$, the formulas are derived directly from the equations of Case 4; that is, $F_1 = \frac{1}{6}$; $F_2 = F_3 = \frac{1}{3}$; $C_{AB} = C_{BA} = -\frac{1}{2}$; and $S_A = S_B = \frac{I}{l}$. With a concentrated load, the moments are determined by Equations (38) and (39), in which:

FIG. 11.—CASE 5, UNIFORM MEMBER.

$$F_4 = \frac{k - k^3}{6} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (103)$$

and,

$$F_5 = \frac{2k - 3k^2 + k^3}{6} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (104)$$

or simply:

$$M_A = -P\,l\,k\,(1 - k)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (105)$$

and,

$$M_B = -P\,l\,k^2\,(1 - k) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (106)$$

When the concentrated load is at the center of the beam, $F_{10} = \frac{1}{16}$ and Equation (79) becomes:

$$M_A = M_B = -P\,l\,\frac{F_{10}}{F_2 + F_1} = -\frac{P\,l}{8} \quad \ldots\ldots\ldots\ldots (107)$$

For a uniformly distributed load, $F_8 = F_9 = \frac{1}{24}$, and Equation (81) becomes:

$$M_A = M_B = -w\,l^2\,\frac{F_8}{F_2 + F_1} = -\frac{w\,l^2}{12} \quad \ldots\ldots\ldots\ldots (108)$$

For a triangular loading, such as that in Fig. 9(*a*), $M_A = -\frac{z\,l^2}{20}$; and $M_B = -\frac{z\,l^2}{30}$. The moments may also be determined by Equations (90) and (91), recalling that $F_2 = F_3$;. $F_{11} = \frac{7}{360}$; and $F_{12} = \frac{1}{45}$. Thus, by

breaking down from Case 1 to Case 5 the familiar values for uniform beams are obtained.

Variation of the Cross Method

Professor Cross gives one variation in his method well worth mention. When one end of a member is free to rotate, no moment need be carried over to it, but a modified stiffness should be used for the other end. This modified stiffness for tapered members is found as follows: Assuming End B as free to rotate, make M_B zero in Equation (58); thus,

$$\theta_A = \frac{M_A F_3 l}{E I_A} \quad \text{.......................(109)}$$

Then, Equation (55) becomes:

$$S'_A = \frac{M_A}{4 E \theta_A} = \frac{I_A}{4 l F_3} \quad \text{...................(110)}$$

Similarly, if End A is hinged:

$$S'_B = \frac{I_A}{4 l F_3} \quad \text{.......................(111)}$$

Working Lines

In applying the Cross method to framed structures composed of tapered members it is important to fix the working lines correctly. It has been found that where the curvature of a member is not too great, the working line can be taken as a straight line near the neutral axis of the minimum section. The reason for this location becomes obvious when one considers that the work terms are maximum where the moment of inertia is small, and that the working line should be located to be correct for the region contributing the greatest amount to the internal work. As an illustration Fig. 12 shows the working line for a part of a framed structure. Such lines are to be used only for the determination of the statically unknown quantities. In determining the maximum fiber stresses, the statically unknown factors having been found, the working lines, of course, should be the neutral surfaces of the members.

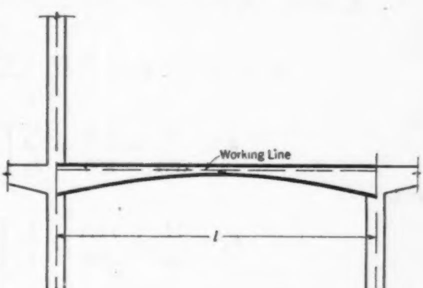

Fig. 12.

Approximate Solution

Since structures composed of tapered members are usually statically indeterminate the procedure is first to assume a trial design, analyze the stresses, modify the design, re-analyze the stresses, etc. It is very convenient in work of this nature to have an approximate solution that can be applied quickly.

Values of 2 for the shape exponent, n, have been noted frequently where the taper modulus is positive. If this value is used the work is considerably shortened, often with little sacrifice of accuracy. It has also been found in members of double taper that the I-curve is quite flat for a considerable distance near the central part of the member. There would then be small loss in accuracy by making r and s equal to one-half.

As an illustration of this procedure formulas for the F-terms of Cases 1 to 3, with the aforementioned approximations, are as follows:

In Case 1 (Equations (63) to (71)):

$$F_1 = \frac{1}{12} + \frac{3A}{80} + \frac{I_A}{I_B}\left[\frac{1}{12} + \frac{3B}{80}\right] \qquad (112)$$

$$F_2 = \frac{1}{24} + \frac{A}{40} + \frac{I_A}{I_B}\left[\frac{7}{24} + \frac{B}{15}\right] \qquad (113)$$

$$F_3 = \frac{7}{24} + \frac{A}{15} + \frac{I_A}{I_B}\left[\frac{1}{24} + \frac{B}{40}\right] \qquad (114)$$

$$F_4 = k F_1 - \frac{k^3}{6} - \frac{A k^5}{5} \qquad (115)$$

$$F_5 = k F_3 - \frac{3k^2 - k^3}{6} - A\,\frac{k^4(5 - 3k)}{15} \qquad (116)$$

$$F_6 = (1 - k) F_2 - \frac{I_A(2 - 3k + k^3)}{6 I_B} - B\,\frac{I_A(1 - k)^4(2 + 3k)}{15 I_B} \qquad (117)$$

$$F_7 = (1 - k) F_1 - \frac{I_A(1 - k)^3}{6 I_B} - B\,\frac{I_A(1 - k)^5}{5 I_B} \qquad (118)$$

$$F_8 = \frac{5}{384} + \frac{7A}{960} + \frac{I_A}{I_B}\left[\frac{11}{384} + \frac{11B}{960}\right] \qquad (119)$$

and,

$$F_9 = \frac{11}{384} + \frac{11A}{960} + \frac{I_A}{I_B}\left[\frac{5}{384} + \frac{7B}{960}\right] \qquad (120)$$

In Case 2 (Equations (72) to (82)):

$$F_1 = \frac{1}{6} + \frac{3A}{40} \qquad (121)$$

$$F_2 = \frac{1}{3} + \frac{11A}{120} = F_3 \qquad (122)$$

$$F_4 = k F_1 - \frac{k^3}{6} - \frac{A k^5}{5} \qquad (123)$$

$$F_5 = k F_2 - \frac{3k^2 - k^3}{6} - A\,\frac{k^4(5 - 3k)}{15} \qquad (124)$$

$$F_6 = (1 - k)\,F_3 - \frac{2 - 3\,k + k^3}{6} - A\,\frac{(1 - k)^4\,(2 + 3\,k)}{15} \quad \ldots\ldots(125)$$

$$F_7 = (1 - k)\,F_1 - \frac{(1 - k)^3}{6} - A\,\frac{(1 - k)^5}{5} \quad \ldots\ldots(126)$$

$$F_{10} = \frac{1}{16} + \frac{A}{32} \quad \ldots\ldots(127)$$

and,

$$F_8 = \frac{1}{24} + \frac{3\,A}{160} = F_9 \quad \ldots\ldots(128)$$

In Case 3 (Equations (83) to (97)):

$$F_1 = \frac{1}{6} + \frac{A}{20} \quad \ldots\ldots(129)$$

$$F_2 = \frac{1}{3} + \frac{A}{5} \quad \ldots\ldots(130)$$

$$F_3 = \frac{1}{3} + \frac{A}{30} \quad \ldots\ldots(131)$$

$$F_4 = k\,F_1 - \frac{k^3}{6} - A\,\frac{k^5}{20} \quad \ldots\ldots(132)$$

$$F_5 = k\,F_3 - \frac{3\,k^2 - k^3}{6} - A\,\frac{k^4\,(5 - 3\,k)}{60} \quad \ldots\ldots(133)$$

$$F_8 = \frac{1}{24} + \frac{A}{60} \quad \ldots\ldots(134)$$

$$F_9 = \frac{1}{24} + \frac{A}{120} \quad \ldots\ldots(135)$$

$$F_{11} = \frac{7}{360} + \frac{A}{140} \quad \ldots\ldots(136)$$

$$F_{12} = \frac{1}{45} + \frac{A}{252} \quad \ldots\ldots(137)$$

$$F_{13} = \frac{1}{45} + \frac{A}{105} \quad \ldots\ldots(138)$$

and,

$$F_{14} = \frac{7}{360} + \frac{11\,A}{2520} \quad \ldots\ldots(139)$$

Conclusion

It is intended that this analysis be taken broadly as suggesting a general method of treating tapered members. Although the material presented gives the application to certain types of analysis and to some special kinds of

members, it can be elaborated and extended to apply to many other kinds of analysis and other forms of members. It is hoped that the method of substitute I-curves will thus aid in the development of classes of structures which have been hampered in the past by mathematical difficulties.

APPENDIX

NOTATION

a_0, a_1, a_2, etc. = constants in the equation of a simple-beam moment diagram;
e = proportion of ordinate to span;
f = proportion of ordinate to span;
k = proportion of the ordinate of a concentrated load to the span;
l = length, or span, of a structural member;
m = a shape exponent;
n = a shape exponent;
r = proportion of length of section of a member to span;
s = proportion of length of section of a member to span;
v = a horizontal distance measured from the right end of a member;
w = load per unit distance;
x = horizontal distance measured from the left end of a member;
y = deflection; y_A = deflection of one end of a member from its original position;
z = maximum intensity of a uniformly varying load;
A = taper modulus;
B = taper modulus;
C_{AB} = carry-over factor from End A to End B, etc.;
E = modulus of elasticity;
F_1, F_2, F_3, etc. = constants in the Cross method of distributing fixed-end moments;
H = an unknown force in the method of least work;
I = rectangular moment of inertia; I_x = moment of inertia at any point; I_0, I_A, etc. = moment of inertia where $x = 0$, at Point A, etc.;
M = bending moment; M_R = bending moment at any point due to end restraint; M_S = moment at any point in a member, assuming the ends to be simply supported; M_a = restraining moment at End A, etc.; M_A = fixed-end moment at End A, etc.;
P = concentrated load;
S_A = stiffness of a member in the Cross method at End A, etc.;
S'_A = modified stiffness at End A of a member when End B is free to rotate, etc.;
W = work, or energy; strain energy;
θ = slope deflection; θ_A = slope deflection at Point A, etc.

DISCUSSION

FRED L. PLUMMER,[5] M. AM. SOC. C. E. (by letter).—In an effective manner the authors illustrate a valuable, although not new, method of expressing mathematically the approximate variation in moment of inertia of structural members of variable cross-section. The form of the empirical equation is such that the integrations required for the solution of most problems involving deflections or redundant forces in structures consisting of members subjected to bending moments, can be performed very easily. In 1925, the writer developed a modified form of the slope deflection method which could be used for members of variable cross-section (printed in blue-print form only). Formulas corresponding to Equation (31) to Equation (47) were developed. In applying these formulas to specific types of members the true variation in moment of inertia was used in many cases, even though the resulting integrations were quite difficult. In a few cases a variation identical with that proposed by the authors was used.

Unfortunately, many engineers in design offices are unwilling or unable to carry through the very simple integrations which are required when the method suggested by the authors is followed. Formulas or tabulated coefficients must be made available before such engineers, many of whom have had little or no training in the analysis of continuous structures, can be expected to use such structures and to design them easily and competently. These men will welcome the formulas developed by the authors. Extensive tables of coefficients have been prepared and published by L. T. Evans[6], Assoc. M. Am. Soc. C. E., E. B. Russell[7], T. F. Hickerson[8], M. Am. Soc. C. E., and others. The mere availability of tables and formulas giving coefficients for tapered members, however, will not produce well designed structures. Such aids are only tools to help eliminate some of the analysis routine. The values depend upon definite assumptions[9] which must be recognized and given consideration when the designing engineer attempts to predict how a given structure will act and what stresses will probably exist when such action takes place.

A number of tables containing constants for use in designing tapered beams[10] has been produced by A. Strassner. These values were revised by Walter Ruppel, Assoc. M. Am. Soc. C. E., and printed in a form suitable for use in connection with the conjugate and fixed-point methods of analysis.[11] The same values are equally important in connection with other methods since they represent some of the general integrals set up by the authors. Six sets

[11] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 167 *et seq.*

of values are given by the tables for various types of members and kinds of loads. The tables cover several forms of members and types of loading. Equations (52), (53), (61), (62), (110), and (111) of the paper may be extended, as follows, respectively:

$$C_{AB} = -\frac{F_1}{F_2} = \frac{-v}{1-v} \quad \text{.....................(140)}$$

$$C_{BA} = -\frac{F_1}{F_3} = \frac{-u}{1-u} \quad \text{.....................(141)}$$

$$S_A = \frac{I_A}{4\,L}\,\frac{F_2}{(F_2\,F_3 - F^2_1)} = \frac{I}{4\,L}\,\frac{1-v}{p\,(1-u-v)} \quad \text{..........(142)}$$

$$S_B = \frac{I_A}{4\,L}\,\frac{F_3}{(F_2\,F_3 - F^2_1)} = \frac{I}{4\,L}\,\frac{1-u}{q\,(1-u-v)} \quad \text{.......(143)}$$

$$S'_A = \frac{I_A}{4\,L\,F_3} = \frac{I}{4\,L\,p\,(1-u)} \quad \text{................(144)}$$

and,

$$S'_B = \frac{I_A}{4\,L\,F_2} = \frac{I}{4\,L\,q\,(1-v)} \quad \text{................(145)}$$

In Equations (140) to (145), I is the minimum value for the members and is not necessarily equal to I_A, the moment of inertia at the left end of the member. Furthermore (differing from the notation of the paper),

$$u = \frac{\dfrac{1}{L}\displaystyle\int_0^L \frac{(L-x)\,x\,dx}{Z}}{\displaystyle\int_0^L \frac{(L-x)\,dx}{Z}}$$

and,

$$v = \frac{\dfrac{1}{L}\displaystyle\int_0^L \frac{(L-x)\,x\,dx}{Z}}{\displaystyle\int_0^L \frac{x\,dx}{Z}}$$

in which Z is the ratio of the moment of inertia of the cross-section to the least value of the moment of inertia for the member.

The writer has reproduced and demonstrated the use of these same constants in connection with the slope deflection, moment distribution, and other methods.[13] While these tables cover a wide range of conditions, the original tables by Strassner are even more extensive and include all forms that are commonly used in engineering structures.

[13] "Statically Indeterminate Structures", 1934, Edwards Bros., Inc.

Any engineer who attempts to develop additional tables, however, will find that the method suggested by the authors will very materially facilitate his work and, at the same time, result in no appreciable loss of accuracy.

LEROY W. CLARK,[13] M. AM. SOC. C. E. (by letter).—The method of analyzing tapered members presented by the authors is interesting and ingenious, but the writer doubts whether it will be generally adopted. To test its usefulness he assigned to a group of graduate students some problems using haunched beams, and found that except in a few cases they could obtain correct results in less time by using the column analogy[14], while the substitute I-curve gave results which were very unreliable.

For beams with moderate haunches the results agree very well with correct values. For the beam, as shown in Fig. 13(a), using the authors' suggested

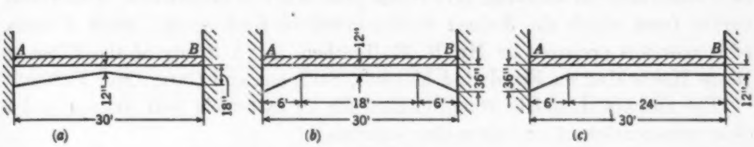

FIG. 13.—EXAMPLES OF TAPERED MEMBERS.

approximate value of 2 for the shape modulus, n gives results not exceeding 8% in error. With n based on I at a distance of 7.5 ft from End A, the errors do not exceed $2\frac{1}{2}$ per cent.

For beams with deep short haunches the method is not so satisfactory. Computations were made for the beam shown in Fig. 13(b). The shape exponent was taken first as 2, and then calculated for the moments of inertia at distances of 1, 2, 3, 4, and 5 ft from End A. The percentage of error in each

TABLE 1.—PERCENTAGE OF ERROR, WEISKOPF-PICKWORTH ANALYSIS

Values of n	Bending moment, M.	Stiffness factor, S.	Carry-over factor, C.
2	4.8	146	9.3
Values of n corresponding to the moment of inertia at:			
$x = 1$ ft.	2.4	85	4.9
$x = 2$ ft.	2.6	90	5.3
$x = 3$ ft.	2.2	81	4.5
$x = 4$ ft.	0.7	55	1.9
$x = 5$ ft.	—3.5	7	—5.3

case is shown in Table 1. If n is computed for the moment of inertia at a distance of 6 ft, the results are the same as those for a prismatic beam of uniform depth of 1 ft.

In the case of an unsymmetrical beam of the dimensions shown in Fig. 13(c), an attempt to solve the problem by using one section for the entire beam and a value of $n = 2$, gave absurd results, as might have been expected.

[13] Prof. of Mechanics, Rensselaer Polytechnic Inst.; Cons. Engr., Troy, N. Y.

[14] *Bulletin 215*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.

With this solution, using a value of n based on the moment of inertia at $x = 3$ ft, the stiffness factors at Ends A and B were 110% and 25% in error, respectively. Using two I-curves reduced the maximum error to about 4%, but the labor involved is at least as great as in the column analogy. It is evident that the greatest errors always occur in the stiffness factor, S.

In practically all the problems solved the results were considerably in error, and the errors varied widely, depending upon the point through which the substitute I-curve is made to pass. This is a matter of judgment, and a designer with limited experience would have no criterion by which to judge the correctness of his work, whereas he could have absolute confidence in the results of the column analogy. Although an experienced designer could doubtless use the substitute I-curve satisfactorily, it is doubtful whether he would save much time in so doing, and in all probability he would have constructed curves from which the desired results could be read easily. Such a series of curves was prepared by Mr. R. H. Trathen, in "A Study of the Effect of Beam Haunching on Fixed End Moment, Stiffness, and Carry-Over Factor."[15]

The authors should be complimented for an extremely well written, and a clear presentation of an interesting solution.

E. G. PAULET,[16] Assoc. M. Am. Soc. C. E. (by letter).—The formula for the variation of moment of inertia introduced by Professor Max Ritter and presented by Walter Ruppel, Assoc. M. Am. Soc. C. E.[17], is directly reducible to Equation (1) suggested by the authors. When the shape exponent is made equal to 1, a special case of Professor Ritter's formula results.[18] The writer

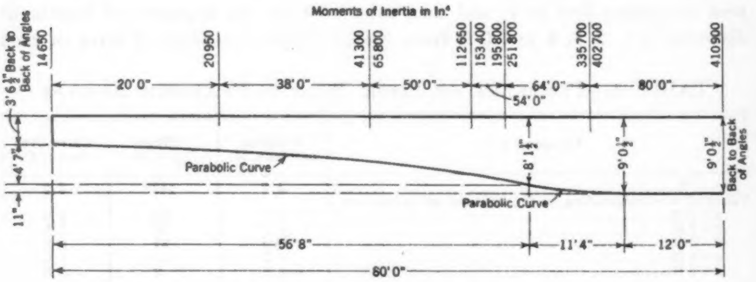

FIG. 14.—CHARACTERISTICS OF ONE ARM OF A SWING SPAN.

has used the formula for this special case in the analysis of tapered members encountered in structures, such as swing and bascule girder bridges, and rigid-frame bridges.

[17] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 159; also, "Analysis of Continuous Frames", by E. B. Russell, Second Edition, p. 23, San Francisco, Calif., 1934.

[18] *Bulletin No. 66*, Ohio State Univ., Columbus, Ohio.

In Fig. 14 is shown one arm of an actual girder swing span with equal arms, the bottom chord of which is on a tangent and two reverse curves, the ratio of the curves being one-fifth, although one-fourth is also employed. Using the authors' notation and letting Fig. 15 represent the tapered member with its elastic behavior similar to that of the swing span arm, the ordinates of the influence line for the center reaction are given by the following equations:

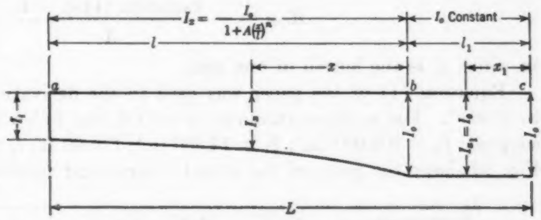

FIG. 15.—TAPERED MEMBER USED FOR ANALYSIS OF SWING SPAN.

$$y_{(x=0\ to\ l)} = \frac{3}{\left[L^3 + 3\,A\,l^3\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3}\right)\right]}\left\{\frac{L^2\,l}{2} + l^3\left[-\frac{1}{6} + A\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3}\right)\right] + \frac{x\,(l^2 - L^2)}{2} + x^2\left[-\frac{l}{2} + \frac{x}{6} - \frac{A\,x^n}{l^{n-1}}\left(\frac{1}{n+1} - \frac{1}{n+2}\right) - \frac{A\,x^{n+1}}{l^n}\left(-\frac{1}{n+2} + \frac{1}{n+3}\right)\right]\right\} \quad ..(146)$$

and,

$$y_{(x_1=0\ to\ l_1)} = 1.0 - \frac{x_1^2\,(3\,L - x_1)}{2\left[L^3 + 3\,A\,l^3\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3}\right)\right]} \quad ..(147)$$

From Equations (146) and (147), the positive center reaction due to a uniform load, $w = 1.0$ per unit length, covering both arms, is:

$$R_{center} = \frac{6\,l^3}{\left[L^3 + 3\,A\,l^3\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3}\right)\right]}\left\{\frac{L^3}{4} + l^2\left[-\frac{1}{24} + A\,l^2\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3} - \frac{\left(\frac{1}{n+1} - \frac{1}{n+2}\right)}{n+3} - \frac{\left(-\frac{1}{n+2} + \frac{1}{n+3}\right)}{n+4}\right)\right]\right\}$$
$$+\left[2 - \frac{l_1^2\,(4\,L - l_1)}{4\left[L^3 + 3\,A\,l^3\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3}\right)\right]}\right]l_1 \quad .....(148)$$

and the negative end reaction due to a uniform load, $w = 1.0$ per unit length, covering one arm, is:

$$R_{\text{end}} = -\frac{\text{Equation (148)} - L}{4} \quad \text{.................(149)}$$

in which L is the length of one arm.

Equation (1) of the paper was used in the derivation of Equations (146) to (149)[19]. For a shape exponent, $n = 1.0$, the following design values were adopted: $I_0 = 403\,000$ in.^{4}; $I_l = 14\,650$ in.^{4}; $l = 60$ ft; $l_1 = 20$ ft; and $A = 26.5$. Fig. 16 shows the paths of the actual I-curve and substitute I-curve. A value

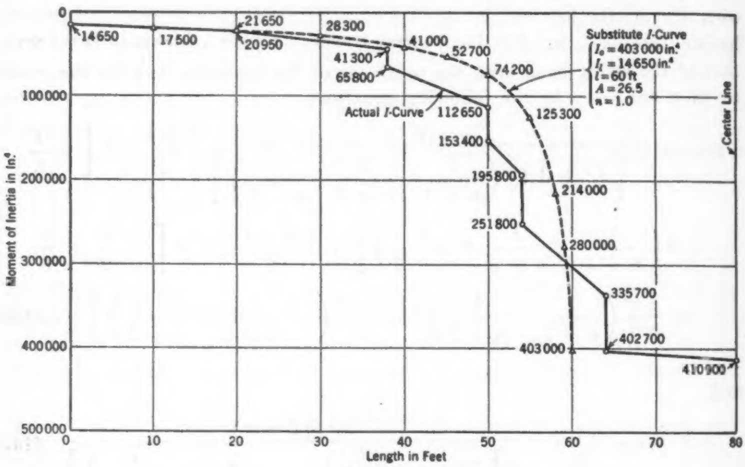

FIG. 16.

of $l = 64$ ft for the length of the tapered member would be preferable, provided a suitable shape exponent, n, were determined. However, since Equations (146) to (149) had first been derived with a value of $n = 1.0$, and the substitute I-curve with such a value would rise quickly as shown in Fig. 16, a length, $l = 60$ ft, for the tapered member was chosen as a rational value.

After substitution of the design values in Equations (148) and (149), the center reaction is found to be $1.471\,w\,L$, and the negative end reaction, $-0.1178\,w\,L$. By the moment-area method, the center reaction is $1.472\,w\,L$, and the negative end reaction is $-0.1179\,w\,L$. Therefore, when a shape exponent, $n = 1.0$, is used, and judgment is exercised in the selection of a rational value for l, similar cases may be thusly approached and results obtained satisfactory for all practical purposes. However, since the shape exponent, n, appears in Equations (146) to (149), its rational value could well be substituted in these equations. The most probable value of n, obtained by the least square method, is 1.64, and the arithmetic mean value is 1.55 ($l = 64$ ft being used). Obviously, such values for n can be obtained only

[19] The complete discussion, with supporting derivation, has been filed for reference in Engineering Societies Library, New York, N. Y.

when the sections at various points along the tapered member are already known. Consequently, a value of n that is suitable for the majority of cases would be desirable. The authors mention a value of 2 for n. If $n = 2$, then $l = 64$ ft, $l_1 = 16$ ft, $L = 80$ ft, and $A = 26.5$, are substituted in Equations (148) and (149), the center reaction is found to be 1.451 $w\,L$ and the negative end reaction is $-$ 0.1129 $w\,L$. These values of reactions compare very favorably with those found by the moment-area method, and a shape exponent, $n = 2$, would be a satisfactory value for this class of structures.

A comparison of the values for the center reaction and the negative end reaction obtained by considering I to be variable, with those obtained when I is considered constant, shows that the center and end reactions of the former case are, respectively, 18% and 88% greater than in the latter case. For uplift, the consideration of the tapered member analysis is important. This analysis yields final design moments which are greater than those obtained by the analysis when I is considered constant, the excess varying from 9% at the quarter-point from the end to 4% at the center support.

The deflection at each end of the tapered arms of a swing span with equal arms due to a concentrated load, P, applied at each end is:

$$y = \frac{P}{E I_o}\left[\frac{L^3}{3} + A\,l^3\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3}\right)\right] \quad\ldots\ldots(150)$$

Let $P = 15\,000$ lb; $E = 30\,000\,000$ lb per sq in.; $I_o = 403\,000$ in.^{4}; $L = 80$ ft; $l = 64$ ft; and $A = 26.5$. Substituting these values in Equation (150), the end deflection, y, is found to be 1.03 in. when $n = 1.64$, 1.09 in. when $n = 1.55$, and 1.62 in. when $n = 1.0$. By the moment-area method, $y = 1.11$ in.

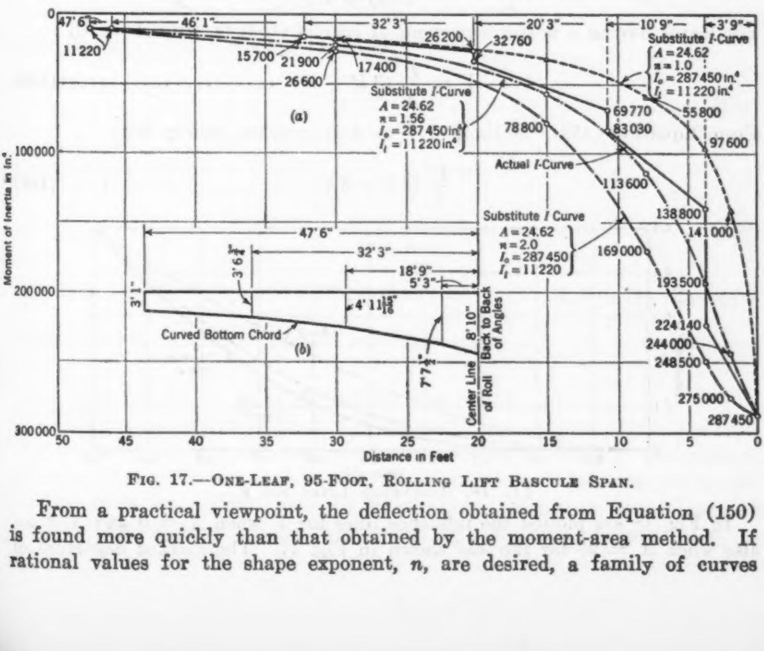

FIG. 17.—ONE-LEAF, 95-FOOT, ROLLING LIFT BASCULE SPAN.

From a practical viewpoint, the deflection obtained from Equation (150) is found more quickly than that obtained by the moment-area method. If rational values for the shape exponent, n, are desired, a family of curves

similar to Fig. 2 may be prepared and used in conjunction with a diagram of the actual I-curve of the member drawn to the same scale as the n-curves. By properly placing the n-curves over the actual I-curve, as shown in Fig. 1, a satisfactory value for the shape exponent, n, may be chosen.

In Fig. 17 are given the general dimensions and moments of inertia at various sections of one leaf of a double-leaf, rolling, lift, bascule girder bridge. The taper modulus, A, is 24.62. The most probable value of the shape exponent, n, is 1.56, and the arithmetic mean value is 1.42. The graph of the three substitute I-curves having shape exponents, 1.0, 1.56, and 2.0, shows the relative departure of these curves from the actual I-curve.

The shear, V, carried by the center lock of a double-leaf bascule bridge, the main girders of which are tapered and loaded with a concentrated load, P, distant $k\,l$ from the center line of trunnion or roll (the leaves being assumed cantilevered from the trunnion or roll, and $I_x = \dfrac{I_0}{1 + A\left(\dfrac{x}{l}\right)^n}$) is:

$$V = P\left[\frac{k^2}{2} - \frac{k^3}{6} + A\,k^{n+3}\left(-\frac{1}{n+2} + \frac{1}{n+3}\right) + A\,k^{n+2}\left(\frac{1}{n+1} - \frac{1}{n+2}\right)\right] \div 2\left[\frac{1}{3} + A\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3}\right)\right] \quad \text{........(151)}$$

and adopting a shape exponent of $n = 2.0$,

$$V = P\left[\frac{2\,(15\,k^2 - 5\,k^3) + 5\,A\,k^4 - 3\,A\,k^5}{40 + 4\,A}\right] \quad \text{...........(152)}$$

For leaves having a uniform moment of inertia (that is, with $A = 0$),

$$V = \frac{P}{4}\,(3\,k^2 - k^3) \quad \text{.....................(153)}$$

From Equation (152), the limit of V as A approaches infinity is:

$$\frac{P}{4}\,(5\,k^4 - 3\,k^5) \quad \text{.......................(154)}$$

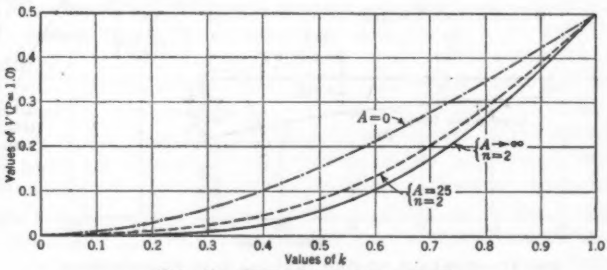

FIG. 18.—INFLUENCE LINES FOR V.

In Fig. 18 are plotted the influence lines for V when $A = 0$ and $A \rightarrow \infty$, also when $A = 25$ for the leaf shown in Fig. 17. The marked departure of

the curves for $A = 0$ and $A \rightarrow \infty$ near the center of the leaf where it is a maximum at $k = 0.624$, indicates whether the leaf should be analyzed as a member of constant moment of inertia or as a tapered member. The choice is a matter of individual preference. Considering the uncertainty of endfixity of the leaves at the trunnion, or the center line of the roll, and the value of the positive taper modulus, A, as being in general above 20, the writer has adopted the following equation for the influence line for V,

$$V = \frac{P\,k^2}{8}\,(3 - k + 5\,k^2 - 3\,k^3) \text{ ....(155)}$$

The influence line given by Equation (155) is for $A = 10$, and plots midway between the curves for $A = 0$ and $A \rightarrow \infty$.

The shear, V, carried by the center lock, due to a uniform load, w, per unit length, extending throughout the length, l, of one leaf is: For a tapered member:

$$V = \frac{w\,l\left[\frac{1}{4} + A\left(\frac{1}{n+1} - \frac{3}{n+2} + \frac{3}{n+3} - \frac{1}{n+4}\right)\right]}{4\left[\frac{1}{3} + A\left(\frac{1}{n+1} - \frac{2}{n+2} + \frac{1}{n+3}\right)\right]} \text{ ...(156)}$$

and for a member of uniform moment of inertia,

$$V = \frac{3\,w\,l}{16} \text{ ....(157)}$$

From Equation (157), when $n = 2$ and $A = 10$,

$$V = \frac{5\,w\,l}{32} \text{ ....(158)}$$

Furthermore, when $n = 2$ and $A \rightarrow \infty$, the limit of,

$$V = \frac{w\,l}{8} \text{ ....(159)}$$

It may be seen from Equations (157), (158), and (159), that as the value of A increases, the value of V rapidly converges toward $\frac{w\,l}{8}$. For a concentrated load, P, on one leaf, a rapid convergence also exists.

With the aid of Equation (1), of the paper, an analysis of various types of structures having tapered members will show directly the relative behavior of their component parts. The derivation of formulas for sought values, while not difficult, may be lengthy and tedious at times; however, for the simpler types of structures which are of frequent application, an

analytical treatment should certainly receive consideration. The authors[20] have already contributed much information in this direction.

In his analysis of symmetrical parabolic arches, F. Guerrini[21] uses a function for the substitute I-curve similar to the authors' Equation (4), and which is:

$$I_x \cos \theta_x = \frac{I_0}{1 - 0.5\left(\frac{x}{l}\right)^2} \quad \text{.................. (160)}$$

in which θ_x is the angle that the tangent to the parabolic axis of the arch makes with the horizontal at any point distant x from the crown, and l is the half-span length, I_0 and I_x being, respectively, the moments of inertia of the arch at the crown and at any point distant x from the crown.

Professor J. Rieger[22] has analyzed members of variable moment of inertia involving straight haunches. His analysis is exact but usually leads into complicated expressions unless certain approximations are adopted. He has also considered such approximations and has compared the results with those obtained by exact analysis. Tapered members with straight haunches may be analyzed with Equation (1) when a suitable shape exponent, n, is used. For positive taper modulus, $A = 4$ to $A = 10$, a value of 2 for n would be satisfactory for all practical purposes. For straight haunches, with positive taper modulus, $A = 0$ to $A = 20$, the curve of arithmetic mean values for n is approximately given by, $n = \sqrt{\frac{A + 0.14}{3.5}} + 0.8$, and the curve of most probable values for n is approximately given by, $n = 0.63\sqrt{\frac{A + 0.14}{3.5}} + 0.874$. The variable error occurring when these approximate equations are used does not exceed 6 per cent.

The method of substitute I-curves is convenient for the direct analysis of structures having tapered members. When more than three statically indeterminate quantities are sought and, therefore, a direct solution becomes involved if not impracticable, recourse to a method such as the slope-deflection method or the Cross method of distributing fixed-end moments, is convenient. With the authors' method of substitute I-curves all the necessary coefficients entering into the slope-deflection and Cross methods may be computed and put in tabular[23] or graphical[18] form.

Although Equation (1) is Professor Ritter's general formula re-stated in a different form, its convenient presentation, its interpretation, and its applications, undoubtedly demonstrate the convenient adaptability and far-reaching possibilities of the method of substitute I-curves.

J. CHARLES RATHBUN,[34] M. AM. SOC. C. E. (by letter).—As a study of one variation of the beam theory, this paper is of undoubted value. The authors have developed, rather completely, the theory as applied to a beam with moments of inertia that vary according to a given mathematical formula that contains three arbitrary constants. As the paper is well written, it should help very much in clarifying the beam theory.

From an engineering standpoint the writer feels that the value of this work depends upon its superiority over other methods both as to ease of application and of understanding. Whether the method can stand this test is open to question. Using this paper as a guide the analysis of a few beams would involve considerable study on the part of the engineer. Some labor could be saved in the authors' methods if one were to develop a series of tables or diagrams covering the various changes in the formula for taper as the assumed constants change. This would only be economical if the engineer were required to deal with a very large number of tapered beams to which this formula applies. The writer feels that such an addition should not be made as the merit of the paper lies in its theoretical rather than its practical interest.

The most obvious variation of the method used by the authors is to assume that the $\frac{1}{I}$ - curve varies as a parabola, or that,

$$\frac{1}{I} = p_2 x^2 + p_1 x + p_0 \qquad (161)$$

in which p_2, p_1, and p_0 are constants so chosen that the curve will pass through predetermined points. By assuming more terms, the curve of Equation (161) may be made to pass through four or more points. Loads are usually concentrated, uniform, or, in a few cases, uniformly varying. These loads lead to moment curves with equations of the form:

$$M = a_3 x^3 + a_2 x^2 + a_1 x + a_0 \qquad (162)$$

in which, again, a_3, a_2, a_1, and a_0 are constants. It follows at once that the $\frac{M}{I}$ - curve is of this same form. Equation (162) is a form that is readily integrable as the only integral form used is $\int x^n \, dx = \frac{x^{n+1}}{n+1}$. This statement is true also of the expression in Equations (12), (13), (14), and (15), of the paper, and the expressions used in the Cross method. These parabolic curves can be made to fit the $\frac{M}{I}$ - curve more closely than those of the authors as the irregularities of the curves (as in Fig. 1) need not be ironed out. If Equation (161) is substituted in Equation (52), the carry-over factor, C_{AB}, is obtained.

[34] Associate Prof., Civ. Eng., Coll. of the City of New York, New York, N. Y.

As examples of the method of using Equations (161) and (162), consider the five cases cited by the authors, E being considered equal to unity.

Case 1.—Assume Equation (161) as the formula of the $\frac{1}{I}$-curve, and define i_A as $\frac{1}{I}$ at the point, A. When $x = 0$, $\frac{1}{I_A} = i_A$; when $x = l$, $\frac{1}{I_B} = i_B$; and, when $x = \frac{l}{2}$, $\frac{1}{I_C} = i_C$, the origin being taken at the left end. Consequently, $i_A = p_0$; $i_B = p_2 l^2 + p_1 l + p_0$; and, $i_C = \frac{p_2 l^2}{4} + p_1 \frac{l}{2} + p_0$. From these equations it follows that, $p_0 = i_A$; $p_1 = \frac{4\,i_C - i_B - 3\,i_A}{l}$; and $p_2 = \frac{2\,(i_A - i_B - 2\,i_C)}{l^2}$.

The $\frac{M}{I}$-curve becomes, for a uniform load: $\frac{M}{I} = \left(\frac{w\,l\,x - w\,x^2}{2}\right)(p_2 x^2 + p_1 x + p_0)$; and, by double integration:

$$y = \frac{w\,l}{2}\left(p_0 \frac{x^3}{6} + p_1 \frac{x^4}{12} + p_2 \frac{x^5}{20}\right) - \frac{w}{2}\left(p_0 \frac{x^4}{12} + p_1 \frac{x^5}{20} + p_2 \frac{x^6}{30}\right) + C\,x \quad \text{..(163)}$$

The constant, C, is obtained by placing $y = 0$ and $x = l$.

Case 2.—In this example, i_A may equal i_B as suggested by the authors, where $p_0 = i_A$; $p_1 = \frac{4\,i_C - 4\,i_A}{l}$; and $p_2 = \frac{4\,i_A - 4\,i_C}{l^2} = \frac{-p_1}{l}$. On the other hand, one may shift the origin to the center taking advantage of the symmetry of the equations. Then the $\frac{M}{I}$-curve becomes $\left(\frac{w\,l^2}{8} - \frac{w\,x^2}{2}\right)(i_C + p x^2)$; and, by double integration:

$$y = \frac{w\,l^2}{16}\,i_C x^2 + \frac{w(i_A - 2\,i_C)}{24}\,x^4 - \frac{w\,(i_A - i_C)}{15\,l^2}\,x^6 + C\,x \quad \text{.....(164)}$$

and the constant can be obtained by letting $x = \frac{l}{2}$ and $y = 0$.

Case 3.—This is the same as Case 2, or Case 1, depending upon the shape of the curve—that is, depending on whether or not it has zero slope at Point C.

Case 4.—In this case the authors make the approximation of substituting a continuous curve for a discontinuous one, as shown in Fig. 1. The I-curve is not continuous. In Fig. 19, the writer has developed numerical examples for both a concentrated and a uniform load in order to show that the conventional method presents no difficulties; nor does it involve excessive labor. For example, referring to Fig. 19(a), $18\,C = \frac{18 \times 6}{3} + 18 \times 6 + \frac{36 \times 6}{2} - \frac{9 \times 6}{3} + 45 \times 6 + \frac{36 \times 6}{2} - \frac{18 \times 6}{3}$; and $C = 32$. Furthermore, at the third-points, the ordinates to the deflection curve are: $\frac{6^3}{6} - 32 \times 6 = -156$; and $-156 + 3 \times 6^2 - \frac{6^3}{6} - 14 \times 6 = -150$.

Referring to Fig. 19(*b*), $18\ C = \dfrac{324 \times 12}{3} - \dfrac{144 \times 12}{4} + 180 \times 6 + \dfrac{216 \times 6}{2} - \dfrac{54 \times 6}{3} - \dfrac{36 \times 6}{4} = 2\,430$. $C = 135$. Furthermore, at the third-point indicated, the ordinate to the deflection curve is: $\dfrac{9 \times 12^3}{12} - \dfrac{3 \times 12^4}{144} - 135 \times 12 = -756$.

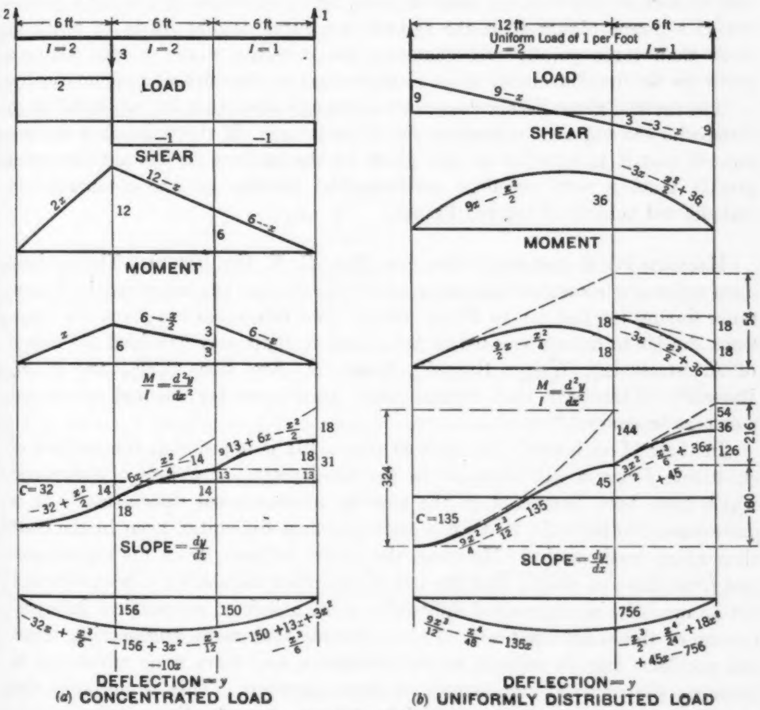

FIG. 19.—ALTERNATE SOLUTION, CASE 4.

This method has the advantage that it is theoretically exact. All the computations are given here or in the illustration. With more complicated numbers the use of the slide-rule will reduce the work to approximately that of the examples.

The equations are written on the curves for those who prefer the multiple-integration method and the areas are divided for those who prefer to integrate by computing areas. With the curves the origin is taken at the left of the section for which the curve is written. When this system is followed the constant of integration is obtained by placing x equal to the section length in

the section to the left of the one being integrated. For the constant of the slope curve in the extreme left section, C, the area under the entire curve, considering the temporary axes as at the beginning of the left end of the curve, is computed. This area is divided by the length of the beam.

Case 5.—This problem is only the simple beam theory as given in texts on the subject.

It is the writer's opinion that the substitution of a parabolic curve for the reciprocal inertia curve is simpler to understand, is as readily applied, and is more elastic than the method given by the authors. By using a parabola of a power higher than the second, the curve can be made to check at more than three points. By changing the equation where sudden changes occur in the inertia curve, these changes can be considered mathematically.

The method given herein does not involve any ideas that are not familiar to those who are engaged in work on the beam theory. If the writer has demonstrated that it is superior to that given by the authors he has not detracted greatly from a very excellent mathematical treatise on the comparatively complicated subject of tapered beams.

Halvard W. Birkeland,[25] Jun. Am. Soc. C. E. (by letter).—The authors have written a commendable paper on a subject that has increased in importance during the last ten to fifteen years. Two references are given for equations similar to those presented in the paper; to these may be added the names of A. Strassner[26], Walter Ruppel[27], Assoc. M. Am. Soc. C. E., and E. B. Russell[28]. There are also several other references for tapered structural members in general.[29]

In their "Conclusion", the authors state: "It is hoped that the method of substitute I-curves will thus aid in the development of classes of structures which have been hampered in the past by mathematical difficulties." It is quite true, and pathetic, that some engineers have difficulties even in the most elementary mathematics. However, the writer believes, from his experiences and from those of others, that the use of haunched members has been retarded not so much by mathematical difficulties as by a lack of geometrical interpretations of the beam constants. It is fortunate that many engineering terms and problems may be reduced to their elements, and there is no advantage in ignoring the physical significance of those elements. This is not only the writer's observation. The same opinion was expressed editorially[30] in 1935,

[30] *Engineering News-Record*, October 17, 1935, p. 551.

although it was written in connection with a rather general article on structural analysis:

"Just as every complex operation is made up of simple elements, so all phases of engineering consist of elementary facts and relations. Much of the engineer's skill lies in his grasp of these elements and his ability to recognize them in the particular problem with which he may be dealing. Nowhere is this truer than in the field of structures. Here the engineer's success at all times depends on how intimately he understands elementary physical facts and behavior."

With the preceding in mind, the physical meanings of the F-term will be presented. In this discussion the following fundamental F-terms will be considered: F_1, F_2, F_3, F_4, and F_5. An inspection of Equations (36), (37), (40), and (41) shows that $F_6 \equiv F_4$ and $F_7 \equiv F_5$ so far as any general discussion is concerned, and all other F-terms may be obtained by the proper integrations of F_4 and F_5. To illustrate the last statement, Equation (88) may be obtained from Equation (86) thus:

$$F_8 = \int_{k=0}^{k=1.0} F_4 \, dk \ldots\ldots\ldots\ldots\ldots\ldots\ldots(165)$$

Before giving the geometrical interpretations, it is necessary to introduce a fictitious beam, the "unit beam", so called for reasons which will be apparent later.

Definitions of the Actual Beam and the Unit Beam.—An actual beam is a beam or a member as it is in a structure, with all its actual dimensions, regardless of end restraints and loads. An example of an actual beam is shown in Fig. 20(*a*). Each actual beam has a unit beam which corresponds to it.

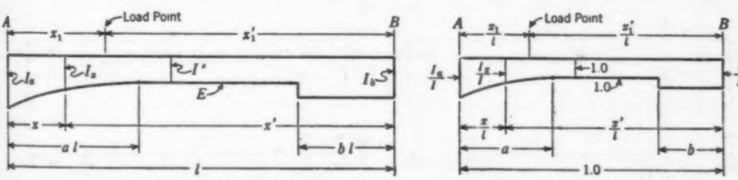

FIG. 20.

All dimensions of this unit beam are proportional to those of the actual beam: Longitudinal dimensions are reduced by the factor, l, usually the span length; the modulus of elasticity at every point is reduced by the factor, E, usually the modulus of elasticity of the material; and the moment of inertia at every point is reduced by the factor, I, usually the moment of inertia at the minimum section of the beam. An example of a unit beam is shown in Fig. 20(*b*). The beam in Fig. 20 is chosen as an illustration because it embodies dissymmetry, and constant section as well as gradual and abrupt changes in section, and will signify a beam with any arbitrary variation in moment of inertia.

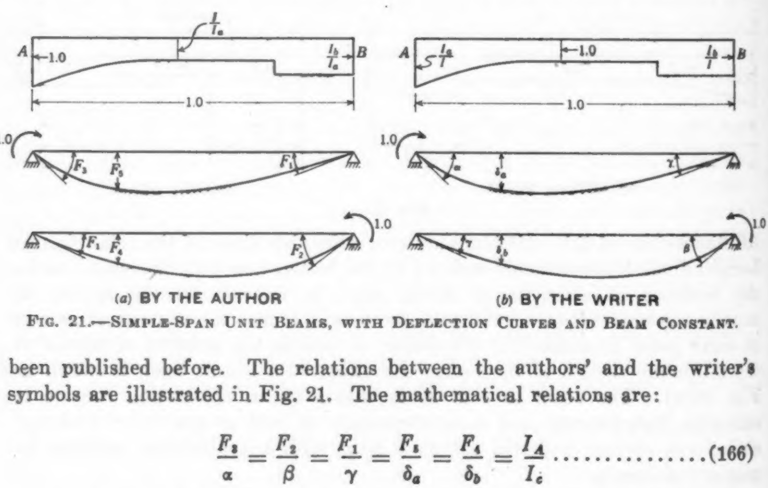
The unit beam was defined by deriving it from the actual beam. Imagine the procedure reversed, and it is seen that one unit beam may be

the source of any number of actual beams. Another unit beam may be the source of another group of actual beams. Unit beams, therefore, may be said to be a criterion of actual beams.

Credit for originating the unit beam concept should go to Mr. Ruppel, who states:[31] "When values for special loadings or beams are determined, it is suggested that they be computed for, or reduced to, coefficients for a unit load on the span of unity with I and E equal to unity."

Geometrical Interpretations of F-Terms.—Consider a simple-span unit beam in which the reduction factors are the span length, the modulus of elasticity of the material, and the moment of inertia at End A, as shown in Fig. 21(a). Then F_3 = the rotation at A due to a unit moment at A; F_2 = the rotation at B due to a unit moment at B; F_1 = the rotation at B due to a unit moment at A, or the rotation at A due to a unit moment at B; F_5 = the rotation at A due to a unit load at the load point, or the deflection at the load point due to a unit moment at A; and F_4 = the rotation at B due to a unit load at the load point, or the deflection at the load point due to a unit moment at B. The double definitions of F_1, F_5, and F_4 are due to Maxwell's law of reciprocal displacements.

The foregoing study of the physical meanings of the F-terms suggests that better symbols might have been chosen. The writer, therefore, proposes the following substitutions: α for F_3; β for F_2; γ for F_1; δ_a for F_5; and δ_b for F_4. The writer also proposes that the reduction factor for moment of inertia be I_c, the minimum moment of inertia of the member. This latter suggestion will make many of the authors' equations more symmetrical, and will simplify the relations between their paper and most of the material that has



(a) BY THE AUTHOR (b) BY THE WRITER

* Only for symmetrical beams.
† Symbols similar to those of Cross and Morgan have been assigned by the writer.

There are several books, booklets, and articles which have tabulations of beam constants for variously haunched beams, and these constants are usually directly applicable only to the particular method with which they are presented. Because one set of tables may cover loads or haunches not included in other tables, it may be useful to have conversion formulas so that any one set of tables may be used for all methods. The writer has used such formulas since 1933 and has made them more complete from time to time. An extract is presented in Table 2, with the F-terms of the authors and the simple-span unit beam of the writer included. The table is arranged so that all terms in one column are equal. If the equations are solved for the constants used by the many other writers on the subject, the complete set of conversion formulas may be obtained.

Concerning the substitute I-curves in general, the writer advances the suggestion that there is little need for such substitutions, but what is needed is more accurate and more complete tables (not curves) of beam constants, similar to those presented by Strassner, Ruppel, and Russell.

C. W. Dunham,[32] M. Am. Soc. C. E. (by letter).—The method of analysis set forth in this paper should be useful as a means of checking design calculations for certain special structures after the sections and stresses have been determined by other simple and approximate methods. However, there is one point or feature which is touched upon almost too lightly; namely, the "working lines."

One of the most common uses of the tapered section is in rigid frames and the location of the working lines may cause considerable variation in the results of the analysis. It may be advantageous for the authors to give more emphasis to this matter and to include in their method the necessary data to serve as a guide of sufficient accuracy so that the possible error which may be introduced, due to incorrect working lines, shall not exceed that which would result from the use of more simple methods of analysis.

In one rather extreme case of rigid frames, the stresses resulting from the use of a working line through the center of gravity of the center section varied more than 10% from those computed by using a working line through the center of gravity of the haunch. Of course, this error works in opposite directions as far as the stresses at the crown and haunch are concerned, but, in any event, it is too large to neglect.

Although the rigid frame is only one of the types of structures in which the tapered member is used, it is an important type. Such frames often have a definite camber or curve in the top chord. This adds a thrust in the frame, because of the tendency toward a partial arch action which is not included in the formulas given in the paper, but which should not be omitted in the calculations. Furthermore, assuming a portal-like member supported by columns in a building, as suggested by Fig. 12, the location of the working line in the tapered section may greatly affect the moments in the columns themselves.

[32] Asst. Engr., Design Div., Port of New York Authority, New York, N. Y.

FANG-YIN TSAI,[33] ASSOC. M. AM. SOC. C. E. (by letter).—The outstanding feature of the method described in this paper is the substitution of an approximate I-curve for the actual one so that the various constants can be expressed by formulas derived by direct integration. Several sets of such formulas, most of which are rather lengthy and involve fractional exponents, are presented for the computation of the various constants involved in the moment distribution method proposed by Hardy Cross, M. Am. Soc. C. E. To those who prefer to solve the problem by formulas, this paper may be of value.

In the aforementioned formulas, the authors have introduced the various constants, F_1, F_2, F_3, etc., without assigning to them any physical meaning. Elsewhere[34], the writer has stated that,

> "* * * to analyze, by any method, a continuous structure with a moment of inertia varying in any manner, five independent constants or coefficients must be known (three beam coefficients and two load coefficients) for every span of the structure considered as a simply supported beam; and these five coefficients may be expressed in various ways to suit any particular method of analysis."

It may be of interest to compare the authors' F-constants with those of the other systems, and, before doing so, a brief explanation of the latter with regard to their characteristics and adaptability to certain methods of analysis will be necessary. Among the various prevailing systems of expressing these beam and load constants, the following are the most outstanding: (1) The method of angle changes; (2) the method of moment areas; (3) application of Ruppel's constants; (4) application of Strassner's constants; and (5) application of constants in the Cross method.

(1).—Angle Changes.—The system of expressing the constants in terms of angle changes was first introduced apparently, by German authors and was used by Ernst Suter[35] and A. Strassner[36] in developing their methods of analysis. Considering the beam, LR, in Fig. 22, as simply supported and subjected to any loading, the following angle changes occur: α^0 = angle change due to the given loading (see Fig. 22(*b*)); α = angle change due to a moment of unity applied at the same end as α^0 (see Fig. 22(*c*) and Fig. 22(*d*)); and β = angle change at either end of a beam due to a moment of unity applied at the other end (see Fig. 22(*c*) and Fig. 22(*d*)). The subscripts, L and R, denote left end and right end, respectively.

(2).—Moment Areas.—Again, considering Beam LR (Fig. 22) as simply supported and subjected to any loading[34]: A_0 = area of the $\frac{M}{I}$-diagram due to loading; g = abscissa ratio of the centroid of A_0 from End L; A = area of the $\frac{M}{I}$-diagram due to a moment of unity applied at the designated end (the

end indicated by the subscripts, L or R); and u and v = abscissa ratios, of the centroid of A_L and A_R from Ends L and R, respectively.

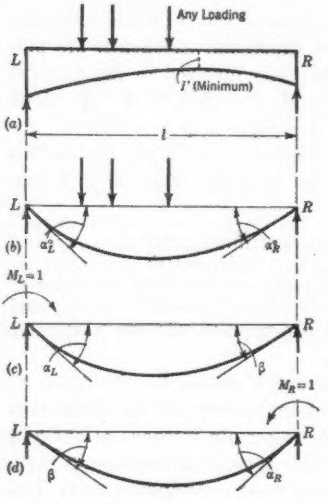

FIG. 22.

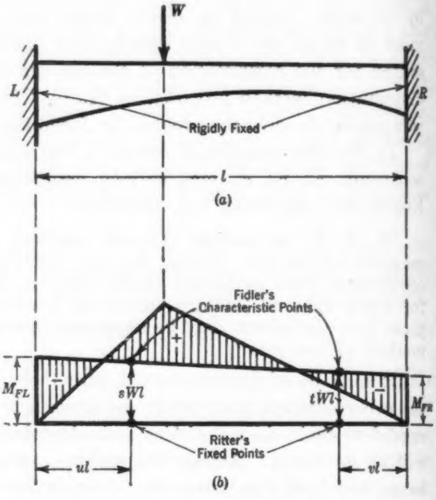

FIG. 23.

Of the six constants, only five are independent, since it can be shown easily that, according to Maxwell's principle of reciprocal deflections (angular), the following relation is always valid:

$$A_L u = A_R v \qquad (167)$$

(3).—Constants in Ruppel's Tables[37].—The tables introduced by Walter Ruppel, Assoc. M. Am. Soc. C. E., were converted and also extended from Strassner's tables[36] for use in the graphical method of fixed points or conjugate points developed by T. C. Fidler[38], A. Ostenfeld[39], and L. H. Nishkian and D. B. Steinman[40], Members, Am. Soc. C. E. In these tables are found the beam constants or coefficients, p, q, u, and v, and the load coefficients, s and t. The constants, u and v, are identical with those of the moment areas previously mentioned. The physical meaning of the constants, u, v, s, and t, is shown in Fig. 23. Again, only five of the six constants are independent, since the following relationship is always valid:

$$p\,u = q\,v \qquad (168)$$

[37] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 167–187.
[38] *Minutes of Proceedings*, Inst. C. E., London, Vol. 74 (1883), p. 196.
[39] "Teknisk Statik" (in Danish), Vol. II, Copenhagen, 1925, pp. 83–142.
[40] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), pp. 1–48.

(4).—Constants in Strassner's Tables[38].—The beam constants[41], ϕ_{aL}, ϕ_{aR}, and ϕ_β, and the load constants, ϕ_s and ϕ_t, are presented in Strassner's tables. An important feature of this system is that, for a uniform load over the full length of a symmetrical double-tapered member of any shape, the load constants, ϕ_s and ϕ_t, are always equal to unity. Hence, for the given case, no tables are needed for those two constants.

(5).—Constants in Cross' Method of Moment Distribution.—In applying the method of moment distribution developed by Professor Cross[42], the following constants for every span of a continuous structure must be first determined: C_{LR} = the factor required to carry over the moment at End L, to End R. (C_{RL} = the factor required to carry over the moment at End R, to End L. The sign for C_{LR} and C_{RL} will be considered here as positive); S_L = the stiffness factor when a moment is applied at End L with End R fixed. (S_R refers to the moment applied at End R with End L fixed. This stiffness factor is in accordance with Professor Cross' definition[43]. That given by the authors' in Equation (61) or Equation (62) is equal to $\frac{S}{4E}$, which corresponds to $\frac{I}{l}$ for beams of constant moment of inertia. Similarly, the modified stiffness factor given by the authors' in Equation (110) or Equation (111) is equal to $\frac{S'}{4E}$, which corresponds to $\frac{3I}{4l}$ for beams of constant moment of inertia); and M_{FL} = the fixed-end moment at End L, due to loading, with both ends fixed. Again, only five of the six constants are independent since the following relation is always valid:

$$C_{LR}\,S_L = C_{RL}\,S_R \qquad (169)$$

In addition, the following modified constants are worthy of note: S'_L = the stiffness factor when the moment is applied at End L with the other end simply supported; and M'_{FL} = the fixed-end moment at End L due to the given loading, with the other end simply supported. The following relations can be found easily:

$$S'_L = S_L\,(1 - C_{LR}\,C_{RL}) \qquad (170)$$

$$S'_R = S_R\,(1 - C_{LR}\,C_{RL}) \qquad (171)$$

$$M'_{FL} = M_{FL} + C_{RL}\,M_{FR} \qquad (172)$$

$$M'_{FR} = M_{FR} + C_{LR}\,M_{FL} \qquad (173)$$

and,

$$C_{LR}\,S'_L = C_{RL}\,S'_R \qquad (174)$$

[41] There are no such notations in Strassner's tables ("Neuere Methoden zur Statik der Rahmenträgwerke und der Elastischen Bogenträger", Vol. 1, pp. 101–112), and they are introduced by the writer, indicating that they are the functions of a_L, a_R, β, s, and t. Similar tables are also found in "Die Methode der Festpunkte", by Ernst Suter, pp. 413–419.

* Signs for the various quantities in the table are disregarded; 1 kip = 1 000 lb.

Comments.—The relation between all the constants of the aforementioned five systems are presented in Table 3[44], in which all the quantities on the same horizontal line are equal to one another and the additional notation is defined as follows: I' = minimum moment of inertia of the tapered member, in feet^4; E = modulus of elasticity, in kips per square foot; l = span length, in feet; W = total load on the span, in kips (in applying Strassner's and Ruppel's tables, the load constants for each load must be computed separately and used with the proper summation if there are several loads on the span); and K = a factor to be used in connection with Strassner's tables only. $K = 1$ for concentrated load and $K = 4$ for uniform load over the full span length. By means of this conversion table (Table 3), the constants of any other system may be computed easily when those of any one system are known.

Of the five systems of expressing the constants, each has its own especial adaptability to a particular method of analysis. That the angle changes and Strassner's constants are especially adapted to Suter's and Strassner's methods and that Ruppel's constants are especially computed for the graphical method of fixed or conjugate points have already been indicated. Elsewhere[45] the writer has used the angle changes in developing the general form of the three-moment equation, resulting in an exceedingly simple formula as follows (see Fig. 24):

$$\beta_1 M_A + (\alpha_{R1} + \alpha_{L2}) M_B + \beta_2 M_C = -\alpha^\circ_{R1} - \alpha^\circ_{L2} \quad \ldots\ldots(175)$$

The same constants have also been used by the writer in developing the generalized graphical analysis of restrained and continuous beams[46] and the slope-deflection equations[47], as follows:

$$M_{LR} = \frac{1}{\alpha_L \alpha_R - \beta^2} \left[\alpha_R \theta_L + \beta\theta_R - (\alpha_R + \beta) \frac{d}{l} \mp (\alpha_R \alpha^\circ_L - \beta\alpha^\circ_R)\right] . (176)$$

and,

$$M_{RL} = \frac{1}{\alpha_L \alpha_R - \beta^2} \left[\alpha_L \theta_R + \beta\theta_L - (\alpha_L + \beta) \frac{d}{l} \pm (\alpha_L \alpha^\circ_R - \beta\alpha^\circ_L)\right] . (177)$$

The constants of moment areas have been used by A. W. Earl[48], M. Am. Soc. C. E., in writing the slope-deflection equations; by Thomas F. Hickerson[49], M. Am. Soc. C. E., in developing his method of analysis; and by Ralph W.

used by E. B. Russell[51] in his method of restraining stiffness, and may be also used in writing the slope-deflection equations, as follows:

$$M_{LR} = S_L \left[\theta_L + C_{LR}\,\theta_R - (1 + C_{LR})\frac{d}{l}\right] \mp M_{FL} \ldots\ldots (178)$$

and,

$$M_{RL} = S_R \left[\theta_R + C_{RL}\,\theta_L - (1 + C_{RL})\frac{d}{l}\right] \pm M_{FR} \ldots\ldots (179)$$

The comparison of the authors' F-constants with those of the five systems previously mentioned are presented in Table 4, in which the value of A is computed by the authors' Equation (7). This factor, $A + 1$, is introduced because, for reference of computation, the writer and others have all used the minimum moment of inertia, I', or I_C, whereas the authors have used the maximum moment of inertia, I_A, which is equal to $I_C\,(A + 1)$, or $I'\,(A + 1)$. Tables 3 and 4 not only facilitate the application of the authors' formulas to any method of analysis, but also furnish a comprehensive view of the relation between all the constants of the various systems.

Of the aforementioned systems, that of angle changes is perhaps the most fundamental and elegant inasmuch as such changes not only possess a definite physical meaning, but they also represent, directly, the predominant deformations of continuous structures, on the basis of which most of the methods of analysis are developed. Moreover, their use in certain methods, gives exceed-

F_2	$\frac{EI'(A+1)}{l}\,\alpha_R$	$\frac{I'(A+1)}{l}\,A_R\,(1-v)$	$q\,(1-v)\,(A+1)$	$\frac{A+1}{3}\,\phi\,\alpha_R$	$\frac{EI'(A+1)}{l}\,\frac{1}{S_R(1-C_{LR}\,C_{RL})}$
F_3	$\frac{EI'(A+1)}{l}\,\alpha_L$	$\frac{I'(A+1)}{l}\,A_L\,(1-u)$	$p\,(1-u)\,(A+1)$	$\frac{A+1}{3}\,\phi\,\alpha_L$	$\frac{EI'(A+1)}{l}\,\frac{1}{S_L(1-C_{LR}\,C_{RL})}$
$F_4, F_6, F_8, F_{11}, F_{13}$	$\frac{EI'(A+1)}{Wl^2}\,\alpha^\circ{}_R$	$\frac{I'(A+1)}{Wl^2}\,A_0\,g$	$tq\,(A+1)$	$\frac{A+1}{K\,6}\,\phi_\beta\,\phi_t$	$\frac{EI'(A+1)}{Wl^2}\,\frac{M_{FR}+C_{LR}\,M_{FL}}{S_R(1-C_{LR}\,C_{RL})}$
$F_5, F_7, F_9, F_{12}, F_{14}$	$\frac{EI'(A+1)}{Wl^2}\,\alpha^\circ{}_L$	$\frac{I'(A+1)}{Wl^2}\,A_0\,(1-g)$	$sp\,(A+1)$	$\frac{A+1}{K\,6}\,\phi_\beta\,\phi_s$	$\frac{EI'(A+1)}{Wl^2}\,\frac{M_{FL}+C_{RL}\,M_{FR}}{S_L(1-C_{LR}\,C_{RL})}$

ingly simple results, as in the case of the theorem of three moments presented by Equation (175). From Table 4, it is seen that the authors' F-constants are similar and proportional to those angle changes, and the former may be considered as the coefficients for the latter. Angle changes are, perhaps, most easily computed by the method of moment areas, applied either graphically, as shown by Ernst Suter[52], or by numerical summation, as shown by G. E. Large[53], Assoc. M. Am. Soc. C. E.

The authors' method is inherently approximate, since it requires the replacement of the actual I-curve by a substitute I-curve, and the latter can rarely fit the former exactly, especially when the actual I-curve is very irregular, or has some abrupt changes, as illustrated by the authors' Fig. 1. Although close approximation is not objectionable in the analysis of continuous structures (particularly in the case of reinforced concrete, in view of the many other uncertain and even untrue assumptions involved), the application of the authors' formulas for computing the F-constants requires much more labor than the moment-area method. It is regrettable that they have not given a numerical example to indicate how approximate the results of their method are and how much labor their computations require. For this purpose, the writer has solved the numerical example given by Professor Large[53] (Mr. Tsun-Kuai Liu has computed the various constants). Using the results of Professor Large's computations, the following constants of the moment-area method are derived (see Fig. 25): $A_0 = 89.15 \times 3 = 267.45$ kip-ft^{-2}; $A_L = 9.12 \times \dfrac{3}{10} = 2.736$ ft^{-3}; $v = 1 - \dfrac{19.62}{30} = 0.346$; $g = \dfrac{18.03}{30} = 0.601$; and $u = \dfrac{13.92}{30} = 0.464$. (The reason for using the multiplier, 3, in the computation for A_L is explained by Professor Large. The denominator, 10, is necessary since Professor Large used an end moment of 10 instead of unity, which is the value used by the writer in defining A_L and A_R). By Equation (167), $A_R = \dfrac{2.736 \times 0.464}{0.346} = 3.669$ ft^{-3}; or, using Professor Large's results, $A_R = 12.27 \times \dfrac{3}{10} = 3.681$ ft^{-3}. Both values of A_R are in close agreement. However, in order to check all the results exactly, the value, 3.669, will be used for A_R in all the computations. For the purpose of illustrating and comparing all the beam and load constants of the various systems, they have been computed for the same example in accordance with Table 3 and are arranged for comparison in Table 5. All the results in this table are cross-checked by computing them with 6-place logarithm tables to a precision of at least four significant figures, which, of course, is rarely necessary in ordinary practice.

FIG. 25.

Using the authors' method and referring to Fig. 25(*b*): By Equation (7),

$$A = \frac{28 - 2.6}{2.6} = 9.77\text{; by Equation (8), } n = \frac{\log \dfrac{28 - 6}{9.77 \times 6}}{\log \dfrac{0.3}{0.6}} = 1.41\text{; by}$$

Equation (10), $B = \dfrac{11.5 \times 2.6}{2.6} = 3.42$; and, by Equation (11),

$$m = \frac{\log \dfrac{11.5 - 3.6}{3.42 \times 3.6}}{\log \dfrac{0.2}{0.4}} = 0.64.$$

With the foregoing four constants known, the authors' *F*-constants and Professor Cross' constants are computed by their "exact" and approximate formulas. The same constants are also computed from Professor Large's results in accordance with Tables 3 and 4. All the values are arranged in Table 6, in which the percentages of the errors in the values of the authors' formulas in comparison with those by the moment-area method are also shown. Since the results of Professor Large's computations are sufficiently accurate (he has checked them, at least partly, by models), the authors' "exact" formulas yield errors as great as 12% and their approximate formulas yield errors as great as 50% even for this quite ordinary case. As far as the writer's experience is concerned, the application of the authors' lengthy formulas involving fractional exponents requires considerably more time and is also more susceptible to errors than the moment-area method applied either graphically or by numerical summation. In view of the foregoing comparison, it is very doubtful whether the authors' method will replace the moment-area method and find favor among practising engineers. In fact, since the design of continuous structures usually requires a long cut-and-try process (as stated by the authors under the heading "Approximate Solution"), it seems

to the writer that there is absolutely no reason why, ordinarily, a designer should not design his tapered members in accordance with those prevailing types (straight, parabolic, and sharply curved tapers), for which many sets of very comprehensive tables and charts are now available, in order to save the enormous amount of labor which would be required if he chooses to do otherwise.

TABLE 6.—COMPARISON OF THE VALUES OF CONSTANTS COMPUTED BY MOMENT AREAS AND BY THE AUTHORS' METHOD ($A = 9.77$; $B = 3.42$; $n = 1.41$; and $m = 0.64$.)

Description	Moment-area method	THE AUTHORS' METHOD					
		"Exact"	Equation No.	Percentage error	Approximate	Equation No.	Percentage error
The Author's Constants:							
F_1	1.185	1.162	(63)	− 1.2	0.965	(112)	−18.6
F_2	2.240	2.355	(64)	+ 5.1	1.552	(113)	−30.7
F_3	1.369	1.358	(65)	− 0.8	1.253	(114)	− 8.3
F_6	0.500	0.483	(68)	− 3.4	0.348	(117)	−30.4
F_7	0.332	0.318	(69)	− 4.2	0.275	(118)	−17.2
The Cross' Constants:							
C_{LR}, or C_{AB}	0.5291	0.4935	(52)	− 6.7	0.6219	(52)	+17.5
C_{RL}, or C_{BA}	0.8657	0.8554	(53)	− 1.2	0.7702	(53)	−11.0
$\frac{S_L}{4E}$, or S_A, in feet³	0.3145	0.2972	(61)	− 5.5	0.3576	(61)	+13.7
$\frac{S_R}{4E}$, or S_B, in feet³	0.1922	0.1715	(62)	−10.8	0.2888	(62)	+50.2
M_{FL}, or M_A, in kip-feet	27.26	30.49	(42)	+11.8	26.80	(42)	− 1.7
M_{FR}, or M_B, in kip-feet	52.55	46.53	(43)	−11.5	50.56	(43)	− 1.9

From Fig. 25(b) it is seen that the authors' substitute I-curve falls short quite considerably in comparison with the actual I-curve at Section 9. Since a change in the I-value near the end of a member usually has a greater effect on the various functions than a change near the center, the large errors in the fixed-end moments computed by the authors' "exact" formulas may be attributed to this cause. The errors might possibly diminish somewhat if the substitute I-curve for the left half of the beam had been made to pass through the actual I-curve at Section 9 (in which case, $f = 0.1$; $I_f = 6.5$; and $m = 1.075$) instead of Section 8. However, if this is done, the substitute I-values to the right of Section 9 would be much too large, and the fitting of the substitute I-curve would also require a few trials. For this reason, the writer has tried to find some other equation for the substitute I-curve which will fit the actual I-curve better than that of the authors', and obtained the following results (see Fig. 25(c)):

$$I_a = I_c + (I_A - I_c)\left[\lambda\left(\frac{a}{r}\right)^2 + (1 - \lambda)\left(\frac{a}{r}\right)^3\right] \quad \ldots\ldots(180)$$

$$\lambda = \frac{\dfrac{I_e - I_C}{I_A - I_C}\left(\dfrac{r}{e}\right)^3 - 1}{\dfrac{r}{e} - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots(181)$$

$$I_b = I_C + (I_B - I_C)\left[\mu\left(\frac{b}{s}\right)^2 + (1-\mu)\left(\frac{b}{s}\right)^3\right] \ldots\ldots (182)$$

and,

$$\mu = \frac{\dfrac{I_f - I_C}{I_B - I_C}\left(\dfrac{s}{f}\right)^3 - 1}{\dfrac{s}{f} - 1} \ldots\ldots\ldots\ldots (183)$$

Equations (180) to (183) correspond, respectively, to the author's Equations (6), (8), (9), and (11), with the difference that the variable abscissa ratios, a and b, are measured from the ordinate of I_C to the left and right, respectively, and that the values of λ and μ may be either positive or negative within certain limits. Applying Equations (181) and (183) to the foregoing example:

$$\lambda = \frac{\dfrac{6 - 2.6}{28 - 2.6}\left(\dfrac{0.6}{0.3}\right)^3 - 1}{\dfrac{0.6}{0.3} - 1} = +\ 0.071$$

and,

$$\mu = \frac{\dfrac{3.6 - 2.6}{11.5 - 2.6}\left(\dfrac{0.4}{0.2}\right)^3 - 1}{\dfrac{0.4}{0.2} - 1} = -\ 0.101.$$

The writer's substitute I-curve, together with the actual I-curve, is plotted in Fig. 25(c), from which it is seen that the fit is much better than that shown in Fig. 25(b), particularly at the left half where the curves almost coincide. The writer hopes that the authors will investigate the possibility of using the foregoing equations in their method.

The position of the working line shown in the authors' Fig. 12 is very reasonable and is in agreement with that used by German writers[35, 36]. However, a study should also be made of the condition at the intersections of beams and columns, which affects greatly their I-values and, consequently, the moments[54]. As indicated in Fig. 12, the authors have assumed the condition of Fig. 26(b) for considering the I-values of beams, which is also in agreement with German writers[35, 36]; but the condition shown in Fig. 26(c) is also very reasonable and may represent the actual condition more or less, particularly when the width of columns is considerable. For considering the I-values of columns, the conditions shown in Fig. 26(d) and Fig. 26(e) have usually been assumed, in which case the following angle changes may be easily derived when the cross-section of the columns is constant:

$$\alpha_B = \frac{(h')^3}{3\,E\,I\,h^2} \ldots\ldots\ldots\ldots (184)$$

[54] "Analysis of Continuous Frames by the Method of Restraining Stiffness", by E. B. Russell, San Francisco, Second Edition, 1904, p. 45.

$$\alpha_L = \frac{h^3 - (h'')^3}{3\,E\,I\,h^2} \qquad (185)$$

and,

$$\beta = \frac{(h')^2\,(h + 2\,h'')}{3\,E\,I\,h^2} \qquad (186)$$

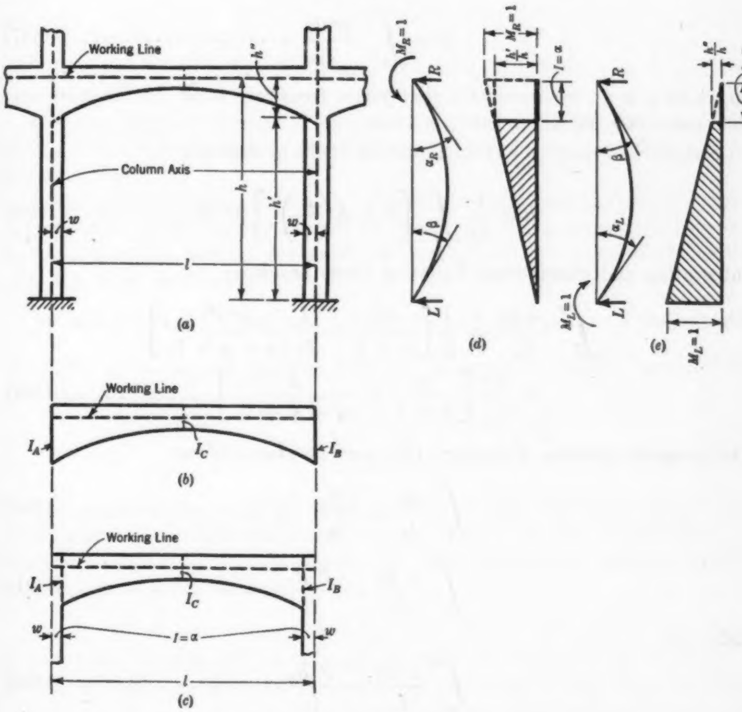

Fig. 26.

With the foregoing value known, Professor Cross' stiffness and carry-over factors may readily be computed. To make sure of the assumed conditions regarding the I-values and the working lines, experimental investigations with models in this direction will be of great value.

Its title indicates that the paper should cover a much wider scope than it actually does, inasmuch as the term, "structural members", as commonly understood, includes such members under the action of flexure, compression, tension, or torsion, or any combination of them. Actually, the paper treats such members under the action of flexure only, and, therefore, it would be more appropriate and also more precise if the word, "structural", in the title were changed to read "flexural."

A. A. EREMIN,[55] ASSOC. M. AM. SOC. C. E. (by letter).—An interesting method of computing the elastic coefficients of tapered members is presented in this paper. With the equations developed by the authors, a complete analytical analysis of perfectly rigid frames can be made.

The computations of the coefficients, F, may be simplified, as follows: A general integral expression of the elastic coefficients of tapered members is:

$$R = \int_0^l \frac{x^p\,dx}{I_x} \qquad (187)$$

In which p is an exponent of x that varies from zero to 5. In the most common cases (see Equation (24)), $p = 5$.

Substitute Equation (1) in Equation (187) as follows:

$$R = \frac{1}{I_0} \int_0^l \left[1 + A\left(\frac{x}{l}\right)^n\right] x^p\,dx \qquad (188)$$

Integrating and simplifying, Equation (188) becomes:

$$\int_0^l \frac{x^p\,dx}{I_x} = \frac{1}{I_0}\left[\frac{x^{p+1}}{p+1} + \frac{A}{l^n}\,\frac{x^{n+p+1}}{(n+p+1)}\right]$$
$$= \frac{l^{p+1}}{I_0}\left[\frac{1}{p+1} + \frac{A}{(n+p+1)}\right] \qquad (189)$$

The integrals entering Equation (189) may be expressed as:

$$\int_0^l \frac{dx}{I_x} = \frac{l\,R_0}{I_0} \qquad (190)$$

$$\int_0^l \frac{x\,dx}{I_x} = \frac{l^2\,R_1}{I_0} \qquad (191)$$

and,

$$\int_0^l \frac{x^2\,dx}{I_x} = \frac{l^3\,R_2}{I_0} \qquad (192)$$

From Equation (189), the values of R are:

$$R_0 = 1 + \frac{A}{n+1} \qquad (193)$$

$$R_1 = \frac{1}{2} + \frac{A}{n+2} \qquad (194)$$

and,

$$R_2 = \frac{1}{3} + \frac{A}{n+3} \qquad (195)$$

---

[55] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

Therefore, from Equations (33), (34), (35), (190), (191), and (192):

$$\int_0^l \frac{x(l-x)\,dx}{I_x} = \frac{l^3}{I_A}(R_1 - R_2) \qquad (196)$$

$$\int_0^l \frac{x^2\,dx}{I_x} = \frac{l^3}{I_A} R_2 \qquad (197)$$

and,

$$\int_0^l \frac{(l-x)^2\,dx}{I_x} = \frac{l^3}{I_A}(R_0 - 2R_1 + R_2) \qquad (198)$$

Equation (189) is especially convenient in computing the loading coefficients, with bending moments in which the power of x is the highest, as in Equation (24).

Computation of the coefficients for tapered members may be further simplified by means of Strassner's tables[56], in which the elastic properties of members with variable sections are expressed by formulas for moment of inertia similar to those in this paper.

Assume that $N = \frac{I_0}{I_e}$; and that $t = \frac{x}{l}$. Then Equation (1) for the moment of inertia of a tapered member becomes the same as that introduced by Professor Strassner[56],

$$I_x = \frac{I_0}{1-(1-N)\,t^n} \qquad (199)$$

The formulas developed by Messrs. Weiskopf and Pickworth suggest the construction of various tables and curves to simplify the computation of stresses in statically indeterminate frames. The authors have made a valuable contribution to the profession.

Austin H. Reeves,[57] Assoc. M. Am. Soc. C. E. (by letter).—The great worth of this paper is proved more conclusively with each increment of study. Having designed many types of structural frameworks containing members of variable moment of inertia by both conjugate points (fixed points) and the method of fixed-end moment distribution, it was with a critical (if not, antagonistic) state of mind that the writer approached the paper. This condition was caused by a casual glance disclosing plenty of calculus.

However, a start was made by checking about twenty of the equations against several designs which the writer knew to be correct. The accuracy of the results of the analytical treatment was thus established. Nevertheless, a further and much more exhaustive study was made, which produced an ever-increasing respect for the authors' treatment of the subject. For example, the writer solved the problem shown in Fig. 27, a beam with a lateral width of 12 in. Within 5 min it was determined that n should be less than 1.3.

[56] "Der Durchlaufende Rahmen", by A. Strassner.

[57] Newark, N. J.

Within an additional 5 min it was decided that an accurate enough value of n would be 1.1; that is, since $e\ l$ = 4.9 ft; I_e = 4 411 in.^{4}; I_A = 46 656 in.^{4}; and I_C = 1 728 in.^{4}, A is found by Equation (7) to be 26. Then, it is a matter of simple substitution in Equation (8) to determine that n = 1.1.

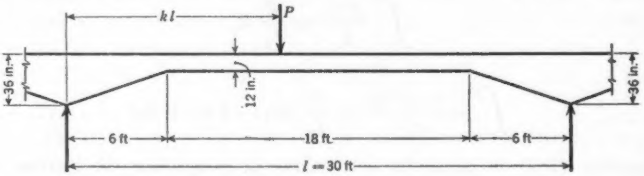

FIG. 27.

It is impossible to have more than one correct value for n. A correct substitute I-curve cannot run through any arbitrarily selected point because it must satisfy the following two conditions[58]:

(a) The area of the actual I-curve must be maintained in selecting a substitute curve; and,

(b) The distance from the left support to the center of gravity of this area must be the same for the substitute I-curve as for the actual curve because it controls the size of the carry-over factor, whereas the area controls the rigidity and is also a factor in determining the amount of the fixed-end moments.

It is incorrect to run a substitute I-curve, successively, through a number of points selected arbitrarily by measurements from the left support. Of course, such procedure would give to n a different value for each point selected.

The paper is so excellent that the writer hesitates to make suggestions. However, emphasis should be laid upon the fact that $e\ l$ and I_e should be selected correctly first (using Conditions (a) and (b) as criteria), and then the correct value of n can be computed by Equation (8) of the paper.

In conclusion, the writer wishes to express his admiration for the thorough manner in which so complicated a subject has been presented. The paper should be used extensively in the future as its full import becomes appreciated.

A. W. FISCHER,[59] ESQ. (by letter).—A very thorough mathematical treatment for solving the values of M_A, C_{AB}, and S_A, is presented in this paper. The results are reliable when the substitute I-curve practically coincides with the actual I-curve. By solving for the shape exponent, n, at several points along the tapered member a value can be selected such that the substitute I-curve will fit the actual I-curve very well. Members of uniform depth, with straight-line haunches at either end, or at both ends, should be divided into sections so as to fit the substitute I-curve more closely to the actual I-curve. The taper modulus, A, can be determined readily, but the accu-

[58] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 90.

[59] Care, Pennsylvania Sugar Co., Philadelphia, Pa.

rate determination of n is another problem. Since an average can be selected, however, so that the substitute I-curve will give reliable results, it seems that the authors have added a very important item in the theory pertaining to this subject.

For the solution of general tapered members used in ordinary practice it seems that the values of the constants, M_A, C_{AB}, and S_A, can be taken directly from charts[60] in just a fraction of the time required to calculate the constants using the authors' method; and especially is this true for straight haunched beams in which the haunch does not extend to the center of the span.

As an example, consider the symmetrical rigid-frame concrete bridge[61], shown in Fig. 28. If a width of 12 ft is used, $I = d^3$, in feet. Substituting in Equation (7): $A = \dfrac{76.77 - 5.359}{5.359} = 13.33$ = taper modulus for the horizontal member.

At a point 12 ft from the left support for the horizontal member the depth = 2.65 ft, from which $I_e = 18.61$, and substituting in Equation (8), $n = \log \dfrac{76.77 - 18.61}{13.33 \times 18.61} \div \log \dfrac{12}{30} = 1.583$ = the shape exponent for the horizontal member. In solving the value of n at other points, it seems that the

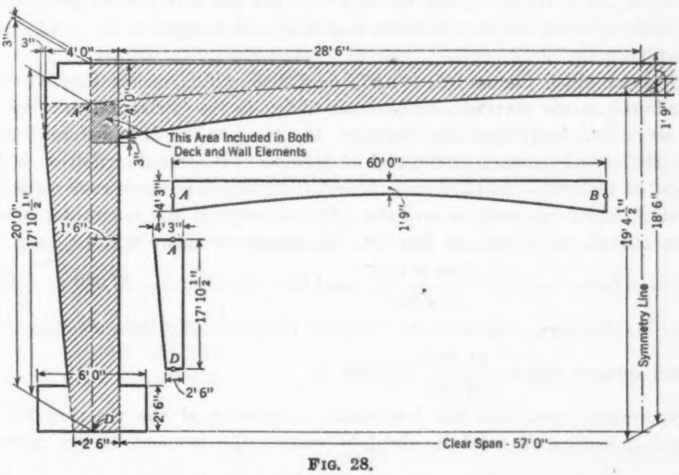

FIG. 28.

value, 1.583, is somewhat too great, and a value of 1.55 is selected so that the substitute I-curve will fit quite well with the actual I-curve for the horizontal member.

Case 2 will apply for the horizontal member and, from Equation (72), $F_1 = 1.3117$; from Equation (73), with $n = 1.55$, $F_2 = 1.8023$; and, from Equation (74), $F_3 = F_2$.

[60] See "Design of Continuous Frames Having Variable Moments of Inertia", *Civil Engineering*, October, 1932, pp. 647–648.

[61] "Analysis of Rigid Frame Concrete Bridges", Portland Cement Assoc., Third Edition, 1935.

For a uniformly distributed load of $w = 90$ lb per lin ft, on a span of $l = 60$ ft, with $n = 1.55$, Equation (82) yields $F_8 = 0.32797$, and, from Equation (81), $M_A = M_B = -34\,120$ ft-lb.

For a concentrated load of 2 500 lb at the center of the span, Equation (80) gives $F_{10} = 0.5319$, and, from Equation (79), with $P = 2\,500$ lb, $M_A = M_B = -25\,620$ ft-lb. Therefore, the total, live load, fixed-end moment $= -34\,120 - 25\,620 = -59\,740$ ft-lb. From Equation (52), $C_{AB} = -\frac{F_1}{F_2} = -0.7278$; and, from Equation (61), with $I_A = 76.77$, $S_A = 0.3775$.

For the vertical member, from Equation (7), $A = 3.912$. At a point 6 ft from the top of the member the thickness $= 3.66$ ft, and $I_e = 49.03$. Substituting in Equation (8), with $e = 6$ and $r = 17.88$, $n = 1.771$. In solving for the value of n at other points, it seems that 1.771 is slightly too small; therefore, a value of 1.8 will be used. The vertical member comes under Case 3, and, from Equation (85), $F_2 = 0.4865$.

Variation of the Cross Method When One End Is Hinged.—From Equation (110), $S'_A = 2.206$. As the horizontal member is symmetrical and $M_A = M_B$, a modified S_A can be used[62] so that one distribution is all that is required. Calling the new stiffness factor, S''_A, it is equal to $S_A \times (1 + C_{AB}) = 0.1028$.

The combined factors, $S'_A + S''_A = 2.3088$, which means that 95.55% is distributed to the vertical member and 4.45% to the horizontal member. As the total, live load, fixed-end moment, $M_A = -59\,740$ ft-lb before distribution, the actual moment at the end of Member AB after distribution will be, $-59\,740\,(1.0000 - 0.0455) = -57\,080$ ft-lb, which is the corner moment at Point A when the deck is straight. On account of the horizontal member being curved, as shown in Fig. 28, the corner moment will be less. The reduction factor[63] will be $\frac{17.88 + 0.75}{19.38}$, and this value times $-57\,080 = -54\,870$ ft-lb. As the corner moment is $-54\,870$, the horizontal thrust acting at the hinged support will be $\frac{54\,870}{17.88} = 3\,069$ lb.

Assuming, now, that the horizontal component of the reaction for the foregoing loading is 3 069 lb, then, by statics, the moment at the crown is,

$$
\begin{aligned}
&+ 90 \times 30 \times 0.5 \times 30 = +\ 40\,500 \\
&+ 0.5 \times 2\,500 \quad \times \quad 30 = +\ 37\,500 \\
&- 3\,069 \times 19.375 \qquad\quad = -\ 59\,450 \\
\hline
&\text{Total}\ldots\ldots\ldots\ldots\ldots = +\ 18\,550 \text{ ft-lb}
\end{aligned}
$$

[62] "Continuous Frames of Reinforced Concrete", by Hardy Cross and N. D. Morgan, Members, Am. Soc. C. E., N. Y., John Wiley & Sons, 1932, Fig. 88, p. 119.

[63] "Analysis of Rigid Frame Concrete Bridges", Portland Cement Assoc., Third Edition, 1935, p. 17.

Using a method advanced by the Portland Cement Association[64], the total positive live load moment at the crown, assuming a simply supported deck, is found to be 78 000 ft-lb. Then the difference between this moment and the negative corner moment created by the same loading is 78 000 − 57 080 = + 20 920 ft-lb, which is the moment at the crown of the frame with a straight deck. The reduction factor[63] will be, $\frac{17.88 + 0.5 \times 1.50}{17.88 + 1.50} = \frac{18.63}{19.38}$, and this value times 20 920 = 20 120 ft-lb.

The foregoing example was also solved by the writer using the "method of elastic weights", and the corner moments by that method were found to be − 55 100 ft-lb, and the crown moments, + 18 310 ft-lb. As the results by the authors' method check very closely with the method of elastic weights it shows that the former is sufficiently accurate for practical purposes.

The authors' method for the analysis of tapered members will give the desired results; but for the analysis of such a structure as the rigid-frame bridge, hinged at the supports, there are other analytical methods that are shorter, and if a systematic arrangement of tables is used the writer is of the opinion that the method of elastic weights will give the desired results in the shortest time.

By means of the method of elastic weights, the depth of the frame can vary along its length in any proportion, the axis can be of any shape, the end-posts need not be vertical, and, if the division points are taken sufficiently close, the results will agree very well with any of the analytical methods.

The one great disadvantage of the authors' method for the analysis of the rigid-frame bridge is that it is based on a straight-line axis for the horizontal member, and as practically all horizontal members have a curved axis a correction must be made by introducing a reduction factor which is only approximate. Another disadvantage is that, when the load is not symmetrical, there will be side-sway, and a correction must be made for that also.

Even if the method is not generally adopted, the authors should be commended for introducing a mathematical treatment which, some day, may be further elaborated, and eventually an average value of n can be selected more readily, so that the substituted I-curve will give as close results as the actual I-curve.

L. Legens,[65] Esq. (by letter).—A method of analyzing structures, composed of members of non-uniform cross-section, is discussed in this paper, and the authors have indicated its application to some classical methods of analysis. The hope is expressed in conclusion that the resulting method of substitute I-curves may aid in the development of classes of structures which have been hampered in the past by mathematical difficulties of design. The use of this method, in general, is most advantageous and becomes necessary for the calculation of many basically and indeterminate systems.

[64] "Analysis of Rigid Frame Concrete Bridges", Portland Cement Assoc., Third Edition, 1935, p. 24.

[65] Engr., Alsace-Lorraine R. R., Strasbourg, France.

For the arch fixed at the two ends, in the past, it was generally agreed, for the purpose of computation, that the reduced moment of inertia, $I' = I \cos \phi$, should be constant and equal to the moment of inertia, I_c, at the crown (see Fig. 29). Müller-Breslau[66] was one of the first to state that this assumption was not admissible, and to suggest that the arch should be computed as a tapered beam.

Assuming a parabolic arch barrel and selecting a Cartesian system of co-ordinates with the origin in O (Fig. 29), he determined the three statically indeterminate reactions, X_a, X_b, and X_c, for a concentrated load, P_m, with the general equations of elasticity.

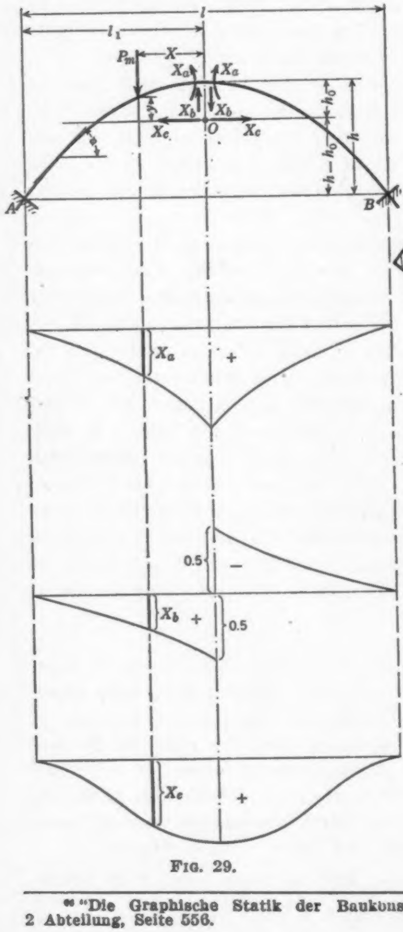

Fig. 29.

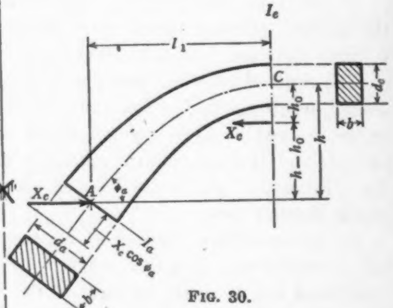

Fig. 30.

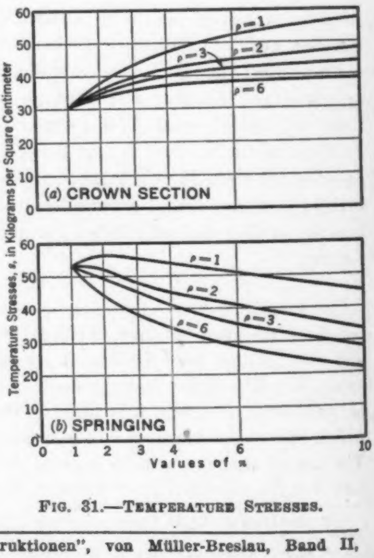

Fig. 31.—Temperature Stresses.

[66] "Die Graphische Statik der Baukonstruktionen", von Müller-Breslau, Band II, 2 Abteilung, Seite 556.

Expressing the reduced moment of inertia, I'_n, of the end cross-sections by:

$$I'_n = \frac{1}{\alpha} I_c \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (200)$$

he chose for the function of the I'-curve, the formula,

$$\frac{I_c}{I'} = 1 - (1 - \alpha) \left(\frac{x}{l_1}\right)^n \quad \ldots\ldots\ldots\ldots\ldots\ldots (201)$$

which is similar to Equation (1) of the paper, except that the center of ordinates for Equation (201) is at the mid-points, whereas in the paper (Equation (1)) it is at the ends. For $\alpha = 1$, Equation (201) will reduce to $I' = I \cos \phi = I_c$, an expression which was recognized by early mathematicians; and, for the distance, h_0 (see Fig. 30), Müller-Breslau derives the expression:

$$h_0 = \left(\frac{h(\rho + 1)}{3(\rho + \alpha)}\right)\left(\frac{\rho + 3\alpha}{\rho + 3}\right) \quad \ldots\ldots\ldots\ldots\ldots (202)$$

in which values of ρ, corresponding to n, are shown in Fig. 31.

Fig. 29 presents the influence lines for the reactions, X_a, X_b, and X_c. These values have been calculated by Müller-Breslau for various ratios, $\frac{x}{l_1}$, as shown in Table 7. The difference between the values resulting from

TABLE 7.—Computation of Reactions for Various Positions of Load

$\frac{x}{l_1}$	Values of X_a			Values of X_b			Values of X_c		
	$\alpha = 0.25$		$\alpha = 1.00$	$\alpha = 0.25$		$\alpha = 1.00$	$\alpha = 0.25$		$\alpha = 1.00$
	$\rho = 1$	$\rho = 2$		$\rho = 1$	$\rho = 2$		$\rho = 1$	$\rho = 2$	
0.0	6.0000	6.2500	7.5000	0.5000	0.5000	0.5000	0.9973	0.9950	0.9290
0.2	3.4560	3.6480	4.8000	0.3328	0.3331	0.3520	0.8941	0.8981	0.8562

* Values of h_0, in meters.

the Müller-Breslau "shape exponents", $\rho = 1$ and $\rho = 2$, is not very great; but there is considerable variation between the different values, X_a, X_b, and X_c, for $\alpha = 0.25$ or for $\alpha = 1.00$. For practical purposes, $\alpha = 0.25$ will be a good average value and it is not permissible to assume that $\alpha = 1$ (that is, to neglect the super-modulus).

It is well known that for flat arches $\left(\frac{h}{l} \leq \frac{1}{10}\right)$, the influence of temperature is very considerable and in every case is more important than that of loads.

Referring to the general equations of elasticity, let δ = deformation; then: $\delta_{at} = 0$; $\delta_{bt} = 0$; $\delta_{ct} = 2\,\epsilon\,t\,l_1 = \epsilon\,t\,l = \Delta\,l$; $X_a = \frac{\delta_{at}}{\delta_{aa}} = 0$; $X_b = \frac{\delta_{bt}}{\delta_{bb}} = 0$; $X_c = \frac{\delta_{ct}}{\delta_{cc}}$; and,

$$X_c = \frac{\Delta\,l\,E\,I_c}{h\,l\left(\frac{1}{5}\,h\,\frac{\rho + 5\,\alpha}{\rho + 5} - \frac{1}{3}\,h_0\,\frac{\rho + 3\,\alpha}{\rho + 3}\right)} \quad \text{..........(203)}$$

The writer prefers to use the reciprocal values introduced by Müller-Breslau. Therefore, according to Equations (200) and (201), $n = \frac{1}{\alpha}$; $I'_n = n\,I_0$; and,

$$\frac{I_c}{I'} = 1 - \frac{n-1}{n}\left(\frac{x}{l_1}\right)^{\rho} \quad \text{..................(204)}$$

Equation (203) becomes:

$$X_c = \frac{E\,I_c}{h^2}\,\frac{\Delta\,l}{l}\,\frac{1}{\frac{1}{5}\,\frac{n\,\rho + 5}{n\,(\rho + 5)} - \frac{1}{9}\,\frac{n\,(\rho + 1)}{n\,\rho + 1}\left[\frac{n\,\rho + 3}{n\,(\rho + 3)}\right]^2} \quad \text{....(205)}$$

Referring to Fig. 30 the unit stress, s, is obtained for the crown section, C, by the equation:

$$s = \frac{X_c}{A_c} \pm \frac{X_c\,h_0}{I_c}\,\frac{d_c}{2} \quad \text{..................(206)}$$

in which A_c and I_c are the area and the moment of inertia and are equal, respectively, to: $A_c = b\,d_c$; and $I_c = \frac{b\,d^3_c}{12}$. When the signs, $\pm$ or $\mp$, appear, the positive refers to the intrados and the negative refers to the extrados. Finally, according to Equations (202), (205), and (206), for h_0, X_c, A_c, and I_c:

$$s = \frac{E\,\frac{\Delta\,l}{l}\left(\frac{d_c}{h}\right)^2\frac{1}{12}\left[1 \pm \frac{2\,h}{d_c}\,\frac{\rho + 1}{\rho + 3}\,\frac{n\,\rho + 3}{n\,\rho + 1}\right]}{\frac{1}{5}\,\frac{n\,\rho + 5}{n\,(\rho + 5)} - \frac{1}{9}\,\frac{n\,(\rho + 1)}{n\,\rho + 1}\left[\frac{n\,\rho + 3}{n\,(\rho + 3)}\right]^2} \quad \text{........(207)}$$

For Sections A at the springing (see Fig. 30), the unit stress, s, will be:

$$s = \frac{X_c \cos\phi_a}{A_a} \mp \frac{X_c\,(h - h_0)}{I_n}\,\frac{d_a}{2} \quad \text{..............(208)}$$

in which $I_n = \frac{b\,d^3_a}{12}$; and, $A_a = b\,d_a$. Furthermore,

$$I'_a = I_a \cos\phi_a = n\,I_c = \frac{n\,b\,d^3_c}{12} \quad \text{..............(209)}$$

$$\frac{I_a}{I_c} = \frac{n}{\cos\phi_a}\,\frac{d^3_a}{d^3_c} \quad\text{.........................(210)}$$

$$\cos\phi_a = \frac{1}{\sqrt{1+\left(\frac{4\,h}{l}\right)^2}} \quad\text{..................(211)}$$

and,

$$h - h_o = \frac{2}{3}\,h\,\frac{\rho\,n\,(\rho+4)+3}{\rho\,[\,n\,(\rho+3)+1]+3} \quad\text{...........(212)}$$

from which Equation (208) becomes:

$$s = \frac{X_c\cos\phi_a}{b\,d_a}\left[1 \mp \frac{h-h_o}{b\,d^3_a} \times \frac{12\,b\,d_a}{\cos\phi_a} \times \frac{d_a}{2}\right]$$

$$= \frac{X_c\cos\phi_a}{b\,d_a}\left[1 \mp \frac{6\,(h-h_o)}{d_a\cos\phi_a}\right] \quad\text{................(213)}$$

and,

$$s = \frac{E\,\frac{\Delta\,l}{l}\,\frac{\cos\phi_a}{12}\left(\frac{d_c}{h}\right)^2\left[1 \mp \frac{4\,h}{d_a}\,\frac{1}{\cos\phi_a}\,\frac{\rho\,n\,(\rho+4)+3}{\rho\,[\,n\,(\rho+3)+1]+3}\right]}{\frac{1}{5}\,\frac{n\,\rho+5}{n\,(\rho+5)} - \frac{1}{9}\,\frac{n\,(\rho+1)}{n\,\rho+1}\left[\frac{n\,\rho+3}{n\,(\rho+3)}\right]^2} \quad\text{.(214)}$$

in which,

$$\frac{d_a}{d_c} = \frac{\sqrt[3]{n}}{\sqrt[3]{\cos\phi_a}} \quad\text{......................(215)}$$

and,

$$d_a\cos\phi_a = d_c\,\sqrt[3]{n}\,\sqrt[3]{\cos^2\phi_a} \quad\text{.................(216)}$$

It follows that:

$$s = \frac{E\frac{\Delta l}{l}\,\frac{\cos\,\phi_a}{12}\left(\frac{d_c}{h}\right)^2\frac{\sqrt[3]{\cos\,\phi_a}}{\sqrt[3]{n}}\left[1 \mp \frac{4\,h}{d_c}\,\frac{1}{\sqrt[3]{n}}\,\frac{1}{\sqrt[3]{\cos^2\phi_a}}\,\frac{\rho\,n\,(\rho+4)+3}{\rho\,[n\,(\rho+3)+1]+3}\right]}{\frac{1}{5}\,\frac{n\,\rho+5}{n\,(\rho+5)} - \frac{1}{9}\,\frac{n\,(\rho+1)}{n\,(\rho+1)}\left[\frac{n\,\rho+3}{n\,(\rho+3)}\right]^2} \quad\text{........(217)}$$

For flat arches one may assume that $\sqrt[3]{\cos\,\phi_a}$ varies as 1 and $\sqrt[3]{\cos^2\,\phi_a}$ varies as 1, in which case, Equation (217) becomes:

$$s \backsim \frac{E\frac{\Delta l}{l}\left(\frac{d_c}{h}\right)^3\frac{1}{12\,\sqrt[3]{n}}\,\frac{1}{\sqrt{1+4\left(\frac{h}{l}\right)^2}}\left[1 \mp \frac{4\,h}{d_c}\,\frac{1}{\sqrt[3]{n}}\,\frac{\rho\,n\,(\rho+4)+3}{\rho\,[n\,(\rho+3)+1]+3}\right]}{\frac{1}{5}\,\frac{n\,\rho+5}{n\,(\rho+5)} - \frac{1}{9}\,\frac{n\,(\rho+1)}{n\,\rho+1}\left[\frac{n\,\rho+3}{n\,(\rho+3)}\right]^2}$$

Finally, for the crown section:

$$s = E \frac{\Delta l}{l} \left(\frac{d_c}{h}\right) \frac{1}{6} h_3(\rho, n) \left[\frac{1}{2}\left(\frac{d_c}{h}\right) \mp h_4(\rho, n)\right] \quad \ldots\ldots\ldots (218)$$

and, for the section at the springing:

$$s \backsim E \frac{\Delta l}{l} \left(\frac{d_c}{h}\right) \frac{1}{3} \frac{1}{\sqrt{1+\left(\frac{4h}{l}\right)^2}} h_1(\rho, n) \left[\frac{1}{4}\left(\frac{d_c}{h}\right) \pm h_2(\rho, n)\right] \quad \ldots (219)$$

in which:

$$h_1(\rho, n) = \frac{1}{\frac{1}{5}\frac{n\rho+5}{n(\rho+5)} - \frac{1}{9}\frac{n(\rho+1)}{n\rho+1}\left[\frac{n\rho+3}{n(\rho+3)}\right]^2} \frac{1}{\sqrt[3]{n}} \quad \ldots (220)$$

$$h_2(\rho, n) = \frac{\rho n(\rho+4)+3}{\rho[n(\rho+3)+1]+3} \frac{1}{\sqrt[3]{n}} \quad \ldots\ldots\ldots\ldots (221)$$

$$h_3(\rho, n) = \frac{1}{\frac{1}{5}\frac{n\rho+5}{n(\rho+5)} - \frac{1}{9}\frac{n(\rho+1)}{n\rho+1}\left[\frac{n\rho+3}{n(\rho+3)}\right]^2} = \sqrt[3]{n}\, h_1(\rho, n) \quad \ldots\ldots\ldots\ldots (222)$$

and,

$$h_4(\rho, n) = \frac{\rho+1}{\rho+3} \frac{n\rho+3}{n\rho+1} \quad \ldots\ldots\ldots\ldots (223)$$

Values of h are listed in Table 8. The maximum stresses are found for the intrados at the crown and for the extrados at both springing lines.

TABLE 8.—VALUES OF $h(\rho, n)$ IN EQUATIONS (220) TO (223), INCLUSIVE

Values of n	For Values of ρ Equal to:				For Values of ρ Equal to:			
	1	2	3	6	1	2	3	6
	(a) Values of h_1 (Equation (220))				(c) Values of h_3 (Equation (222))			
1	11.25	11.25	11.25	11.25	11.25	11.25	11.25	11.25
2	13.50	12.55	12.01	11.11	17.01	15.81	15.14	14.00
3	14.68	13.00	12.08	10.65	21.18	18.75	17.42	15.36
4	15.38	13.11	11.92	10.19	24.41	20.82	18.93	16.18

10	16.20	12.27	10.52	8.33	34.90	26.43	22.66	17.95
	(b) Values of h_2 (Equation (221))				(d) Values of h_4 (Equation (223))			
1	1.00	1.00	1.00	1.00	1.00	1.00	1.00	1.00
2	0.86	0.86	0.85	0.83	0.83	0.84	0.86	0.90
3	0.78	0.77	0.77	0.74	0.75	0.77	0.80	0.86
4	0.72	0.71	0.70	0.68	0.70	0.73	0.77	0.84
6	0.65	0.64	0.62	0.61	0.64	0.69	0.74	0.82
10	0.56	0.54	0.53	0.51	0.59	0.66	0.71	0.80

The writer has computed these stresses for a concrete arch bridge, 74 m (242.8 ft) long and 6.75 m (22.1 ft) high for super-moduli of $n = 1, 2, 3, 4, 6,$ and 10, and the shape exponents, $\rho = 1, 2, 3,$ and 6. They are shown in Fig. 31. With increasing values of n and ρ the stresses decrease at the springing, increase at the crown, and are almost equal at both sections for $n = 5$ and $\rho = 2$ which are good average values as determined for a considerable number of actual bridges.

For practical purposes it may be sufficient to compute the influence of temperature by the old formulas (assuming $n = 1$), the actual stresses being always less than those calculated.

In conclusion, the writer wishes to express his appreciation of the clear method described in this paper. It permits a rapid analysis of structures with variable moments of inertia. Although Müller-Breslau anticipated the method proposed by the authors, he did not apply it in such a general manner. Of course, the equations presented by the writer could be easily transformed to make them agree with the equation for the moment of inertia of tapered members presented by Messrs. Weiskopf and Pickworth.

WALTER H. WEISKOPF,[67] AND JOHN W. PICKWORTH,[67] MEMBERS, AM. SOC. C. E. (by letter).—The broad approach to the subject adopted by discussers of this paper is gratifying. It is a strong human trait to be distrustful of new methods and engineers are undoubtedly unfamiliar with the general application of substitute I-curves. The many suggestions and examples of use, as well as the fund of data that has been so generously contributed, are greatly appreciated, constituting as they do a tribute to the progressive spirit of the profession.

The frank statement that this method employs a substitute I-curve might lead some students of the subject to feel that for this reason the analysis is inherently inaccurate and to be distrusted. It should be realized that for all tapered members, except a few very simple forms, there is no exact treatment. Whether the designer realizes it or not, all methods are approximations or, in a sense, use substitute I-curves.

In the commonly used methods the integrations are performed by dividing the member into sections along its length. The value of $\frac{1}{I}$, or $\frac{M}{I}$, at the mid-point of each of these sections is assumed to apply to its entire length. In reality, this substitutes a series of steps, not only for the I-curves, but for the moment diagram as well. The latter inaccuracy is one which the writers' method does not introduce. The accuracy of the common method depends on the number of sections or steps employed. Usually, these sections are from 3 to 6 ft long, and the results are sufficiently accurate for ordinary engineering purposes, but such approximations are no more trustworthy than the use of a smooth curve which follows the general course of the I-diagram.

[67] Cons. Engr. (Weiskopf & Pickworth), New York, N. Y.

Messrs. Large and Morris[53] have improved on the "stepped" substitute I-curve by introducing a series of inclined straight lines or chords. The area under the curve is thus divided into a series of trapezoids instead of rectangles. This method still involves a substitute I-curve, although an excellent one.

The accuracy of the method of substitute I-curves depends on the skill employed in fitting the curve. As Professor Clark discovered in turning his students loose on it, the method is not a fool-proof one that can be used safely by any beginner, but should be applied intelligently.

Mr. Reeves mentions two conditions that should be satisfied by the substitute curve: The area and the center of gravity of the area under the I-curve should be maintained. An additional thought should be borne in mind, namely, that where an exact fit is impossible it is more important to have a close fit at parts of the member where the moment of inertia is small rather than where it is large. This follows from the fact that the contribution of the work terms is large where the value of I is small, and *vice versa.*

Professor Plummer gives the relations between the terms F_1, F_2, and F_3 and the constants used in the conjugate and fixed-point methods of analysis. The following relations can be added to those which he gives:

$$u = \frac{F_1}{F_1 + F_3} \qquad (224)$$

and,

$$v = \frac{F_1}{F_1 + F_2} \qquad (225)$$

Professor Clark finds results obtained by means of the substitute I-curves satisfactory where he used the formulas for two-section members on a member which has two sections (Fig. 13(a)). In Fig. 13(b), however, he tried the formulas for two-section members on what is very obviously one with three distinct parts, a long uniform center section with sharp haunches at the two ends. It would have been more in the spirit of the writers' work to treat the center section as uniform and fit a substitute I-curve to each of the haunches. This can be done either by integrating with numerical values for an individual member, or by integrating to derive formulas. For such a member the formulas are no more complicated than those of Case 1 and are much more accurate.

Even if it is stretching the mathematics considerably to apply two-section formulas to a three-section member, the results are quite accurate if judgment is exercised. As mentioned previously, it is more important to have the two I-curves fit where the member is small than where it is large. This explains why Professor Clark obtained best results using a shape exponent which made the curves coincide where $x = 5$, and is obvious to one skilled in the method. Trying the other values ($x = 1$, $x = 2$, $x = 3$, etc.) was misleading. On the other hand Mr. Reeves treating the same member (Fig. 27) immediately selected a value of 4.9 for $e\,l$.

Professor Clark tried to test the speed of the method of substitute I-curves by having some of his students work the same problem, by using it, and by using the column analogy. The column analogy is a general method of analyzing statically indeterminate structures. The substitute I-curve affords a means of integrating the functions of x divided by I, which can be used in any method of analysis, the column analogy as well as any other. The two are not comparable. What Professor Clark means, of course, is that he compared the speed in obtaining results using formulas derived by the least work theory and substitute I-curves for the integrations, with the column analogy and a step-by-step summation for the integrations. Such a comparison in any case is not very clear, but considering that the students were presumably familiar with the step-by-step summation and totally unfamiliar with the method of substitute I-curves, it is of no value.

Mr. Paulet has contributed several illuminating examples of the use of the method. His thorough grasp of the fundamentals enables him to make variations in the application which add to the flexibility. For instance, his arbitrary assumption of the length in order to maintain a simple shape exponent is an ingenious hint that should prove useful to the skillful designer. Another excellent suggestion by Mr. Paulet to those who desire a visual guide in the selection of the shape exponent is to prepare a family of curves similar to Figs. 2 and 3 for ready use.

Professor Rathbun suggests another substitute curve, based on the assumption that the reciprocal of I varies as a parabola, and he further suggests that by increasing the power of x and the number of terms, the I-curves can be made to coincide at three, four, or more points. This is a possibility, of course, and there may be designers who prefer this curve. A disadvantage, however, is that the constants which Professor Rathbun designates p_1, p_2, etc., are expressed by formulas and have lost all obvious relationship to the form of the member. The constants, A (taper modulus) and n (shape exponent), in the writers' curve (Equation (1)), have a clear and obvious significance.

Professor Rathbun is incorrect in stating that the writers make the approximation of substituting a continuous curve for the two sections of the "stepped" member, Case 4. This case is treated by making the two parts of the member uniform, but not the same ($A = 0$, $B = 0$, I_A does not equal I_B). Since the terms, A, B, n, and m disappear, the formulas foı Case 4 are not approximate as Professor Rathbun states, but are exact.

Mr. Birkeland stresses the importance of an understanding of the physical significance of the mathematical terms employed by the engineer. He presents a geometrical interpretation of the F-terms by means of angular changes in the unit beam due to various unit moments and loads, which is undoubtedly clarifying to those accustomed to study the behavior of structures in terms of slope changes and deflections.

Correctly, he points out that all F-terms beyond F_5 can be obtained from F_4 and F_5, but such formulas as his Equation (165), should be used with care. In members of more than one section the integrations must be performed separately for each section.

Mr. Birkeland suggests using I_C instead of I_A as a reduction factor to obtain the F-terms. This is entirely a matter of personal preference. The writers intended to present a general method which an individual engineer can use to best advantage by adaptation to his own particular taste. If a designer prefers using I_C to I_A, and has sufficient mastery of the method to make this modification throughout, there can be no objections.

Mr. Dunham very properly emphasizes the importance of fixing the working lines correctly. The suggestions embodied in Fig. 12, and in Professor Tsai's Fig. 26 should be followed. Another method, brought out by Mr. Fischer in connection with the curved girder of a rigid frame, is to use a working line through the center of gravity of the ends of the member and later apply a correction.

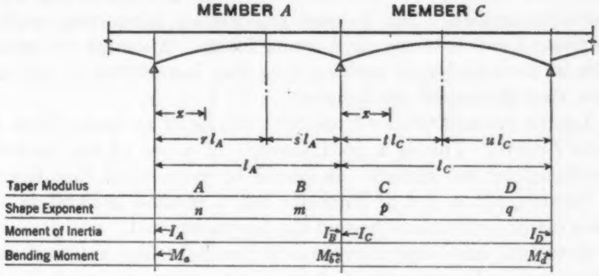
Professor Tsai presents an extensive discussion of the various methods of analyzing structures composed of tapered members, and very complete tables showing the equivalents of the constants of the various systems. These are valuable records compiled in a scholarly manner. He is to be complimented on his presentation of the generalized equation of three moments. The method so often used in the past for want of a better one, assuming that a tapered continuous beam is uniform for the purpose of computing the reactions, is frequently grossly inaccurate. There has been a real need for this equation, but to the best of the writers' knowledge it has never appeared in any text. The writers had, independently, derived a generalized three-moment equation for tapered members using F-terms (see Fig. 32).

Professor Tsai tried the method of substitute I-curves on the member shown in Fig. 25[53] for a concentrated load at Point $k = 0.7$ and found that the resulting fixed-end moments differed about 12% from those obtained by step-by-step summation. A better test for accuracy is the area under the influence line, or what amounts to the same thing, the fixed-end moment for uniform load. This will more nearly approach the actual loading on the member.

For a uniform load the difference between the step-by-step value and that obtained using Professor Tsai's substitute I-curve is 6 per cent. Professor Tsai's shape exponent ($m = 0.64$), however, is poor. He seems to have sensed this for he states that better values might have been obtained using $f = 0.1$. Using a value of $m = 1$ the difference for the concentrated load is 5% instead of 12%, and for the uniform load, 2% instead of 6 per cent. If he had continued his comparative studies in order to develop influence lines by both methods, he would have appreciated the savings in time and labor which accrue once F_1, F_2, and F_3 are found.

Apparently, Professor Tsai does not fully appreciate the inaccuracy of the step-by-step summation. For M_A on this same member he obtains 27.26 ft-kips, whereas Professor Large obtained 27.95, a difference of $2\frac{1}{2}\%$; yet Professor Tsai uses his step-by-step summation as a standard of comparison for the substitute I-curve. The writers obtained a value of $M_A = 28$ ft-kips using $m = 1$. Professor Tsai refers to the writers' "exact" formulas. These

formulas are not exact, and in no place are they so designated. An exception to this generality is Case 4, the "stepped" member (and, of course, Case 5), the formulas for which are exact.



$$\frac{M_a l_A F_{1A}}{I_A} + M_{bc}\left(\frac{l_A F_{2A}}{I_A} + \frac{l_C F_{3C}}{I_C}\right) + \frac{M_d l_C F_{1C}}{I_C} = \begin{cases} -\dfrac{Pl_A^2F_{4A}}{I_A} & k < r \\[2ex] -\dfrac{Pl_A^2F_{6A}}{I_A} & k > r \\[2ex] -\dfrac{Pl_C^2F_{5C}}{I_C} & k < t \\[2ex] -\dfrac{Pl_C^2F_{7C}}{I_C} & k > t \\[2ex] -\dfrac{w_A l_A^3 F_{8A}}{I_A} - \dfrac{w_C l_C^3 F_{9C}}{I_C} & \end{cases}$$

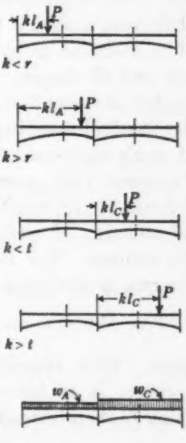


FIG. 32.—THREE-MOMENT EQUATION FOR TAPERED MEMBERS

Professor Tsai suggests another substitute I-curve in the form, $I_x = a + bx^2 + cx^3$; but in order to integrate functions of x divided by I, the value of I must be expressed in some reciprocal relation to x. The writers do not understand how Professor Tsai's curve makes it possible to perform these integrations; nor does he furnish any light in this direction.

Professor Tsai mentions the condition at the intersections of members. When members are shallow this presents no difficulties, but when they are deep and the working points are well within the adjacent members, the point is well worth considering. The most rational treatment of this condition is to assign a value of infinity to the moment of inertia for the length between the edge of an adjacent member and the working point. Thus, the columns in Fig. 26(a) would have an infinite moment of inertia for h'', the upper part of the length, h. This can easily be taken care of in the writers' formulas by

considering the column as a two-section "stepped" member (Case 4) with I_B equal to infinity. The resulting formulas, of course, are quite simple.

Mr. Eremin gives a simple method of computing the F-terms which is convenient for members of one section. It is not applicable, however, to multi-section members. Mr. Fischer presents an interesting application of the substitute I-curves to the rigid frame bridge. Although the writers differ with him in the selection of working lines they have found by various checks, as he has, that the results are accurate.

Mr. Legens presents Müller-Breslau's analysis of an arch, which utilizes a substitute I-curve. This is a good example of a use of the method beyond any mentioned by the writers. It should be emphasized that their purpose was to furnish, not a list of formulas but a method, general in its scope. which has many applications beyond the few mentioned.

For those who have repetitive cases to handle, tables are most useful and as has been pointed out by more than one discusser, the method will be an aid to those computing and checking such tables. The writers do not agree that design should be restricted in any way by the scope of existing tables. It is desirable to have available a method (or rather, methods) for analyzing any and all shapes.

Mr. Birkeland and Professor Tsai refer to the importance of understanding the physical meaning of the F-terms. They interpret these constants in terms of angle changes. Three discussers, Professor Plummer, Mr. Birkeland, and Professor Tsai present conversion tables which show the equivalents of the F-terms to the constants of other methods. The writers agree that the physical meaning of such constants is important to a thorough understanding of the subject. The following analytical interpretation of the meaning of the F-terms is preferred by the writers.

The F-terms are ratios, the integrals being divided by $\frac{l^3}{I_A}$ to obtain them. This simplifies numerical computation. For theoretical purposes, however, it is better to denote each integral as it stands by a symbol. Using G then instead of F:

$$G_1 = \frac{l^3 F_1}{I_A} = \int \frac{x(l-x)\,dx}{I_x} \qquad (226)$$

$$G_2 = \frac{l^3 F_2}{I_A} = \int \frac{x^2\,dx}{I_x} \qquad (227)$$

and,

$$G_3 = \frac{l^3 F_3}{I_A} = \int \frac{(l-x)^2\,dx}{I_x} \qquad (228)$$

It is apparent from Equations (226), (227), and (228), that G_2 is the moment of inertia of the reciprocal I-diagram about an axis at the left end of the member, and G_3 is the moment of inertia of the reciprocal I-diagram about an axis at the right end; G_1 is a fourth dimensional quantity for which there seems to be no name in engineering nomenclature. It is the summation of the product of each elementary strip of the area under the reciprocal I-curve

times, first, its distance from the left end, and then its distance from the right end. It is like a product of inertia, except that the two axes are parallel instead of at right angles to each other. It will, therefore, be termed the "parallel product of inertia."

Other properties of the reciprocal I-diagram can be expressed in terms of the constants, G_1, G_2, and G_3, thus:

$$A_0 = \int \frac{dx}{I_x} = \frac{2\,G_1 + G_2 + G_3}{l^2} \quad \ldots\ldots\ldots\ldots\ldots (229)$$

$$\int \frac{x\,dx}{I_x} = \frac{G_1 + G_2}{l} \quad \ldots\ldots\ldots\ldots\ldots (230)$$

$$\int \frac{(l-x)\,dx}{I_x} = \frac{G_1 + G_3}{l} \quad \ldots\ldots\ldots\ldots\ldots (231)$$

$$x_0 = l\,\frac{G_1 + G_2}{2\,G_1 + G_2 + G_3} \quad \ldots\ldots\ldots\ldots\ldots (232)$$

and,

$$v_0 = l\,\frac{G_1 + G_3}{2\,G_1 + G_2 + G_3} = l - x_0 \quad \ldots\ldots\ldots\ldots\ldots (233)$$

Equation (229) is the area under the reciprocal I-curve; Equations (230) and (231) are the statical moments of the area under the reciprocal I-curve about the left end and the right end, respectively; and x_0 and v_0, respectively (Equations (232) and (233)), are the distances to the center of gravity from the left and right ends of the member.

The moment of inertia of the reciprocal I-curve about its center of gravity axis is found to be:

$$G_0 = \frac{G_2\,G_3 - G_1^2}{2\,G_1 + G_2 + G_3} \quad \ldots\ldots\ldots\ldots\ldots (234)$$

It is interesting to note the appearance of the expression, $G_2G_3 - G_1^2$, analogous to $F_2F_3 - F_1^2$ which appeared in the denominator of the equations for fixed-end moments and for stiffness.

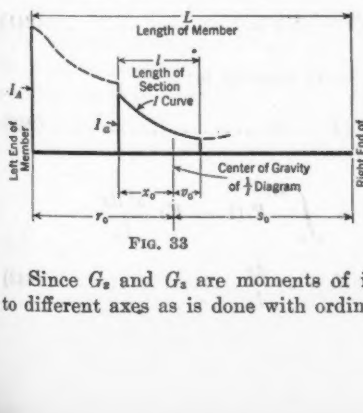

FIG. 33

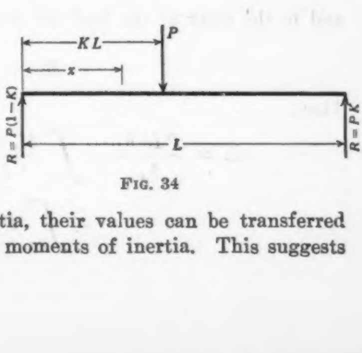

FIG. 34

Since G_2 and G_3 are moments of inertia, their values can be transferred to different axes as is done with ordinary moments of inertia. This suggests

that in a complicated member composed of several sections the values of G_2 and G_3 can be summed up as the area of each section, the location of its center of gravity, and its G_0 are known.

Fig. 33 represents the I-curve for a section of a member. In general, small letters will be used to represent properties of the section about axes of the section, and capital letters to represent properties of the member about its axes. The values of g_1, g_2, and g_3 for this section about its own ends can be found by the formulas of Case 3, the section of single taper, multiplying the F-terms by $\frac{l^3}{I_a}$. Then, from Equations (229) to (234),

$$a_0 = \frac{2\,g_1 + g_2 + g_3}{l^2} \qquad (235)$$

$$x_0 = l\,\frac{g_1 + g_2}{2\,g_1 + g_2 + g_3} \qquad (236)$$

and,

$$g_0 = \frac{g_2\,g_3 - g_1^2}{2\,g_1 + g_2 + g_3} \qquad (237)$$

Knowing x_0, values of r_0 and s_0 can be found. Then for the entire member,

$$G_2 = \Sigma\,(g_0 + a_0\,r_0^2) \qquad (238)$$

and,

$$G_3 = \Sigma\,(g_0 + a_0\,s_0^2) \qquad (239)$$

An expression analogous to these for G_1 is:

$$G_1 = \Sigma\,(-\,g_0 + a_0\,r_0\,s_0) \qquad (240)$$

Thus the properties of a member can be found simply no matter into how many sections it is divided. For a concentrated load, P (see Fig. 34), the terms, G_4 and G_5, analogous to F_4 and F_5, can similarly be found. To the left of the load the simple beam moment is:

$$M_s = P\,(1 - K)\,x \qquad (241)$$

and to the right of the load the simple beam moment is:

$$M_s = PK\,(L - x) \qquad (242)$$

Then,

$$G_4 = \frac{P\,L^3\,F_4}{I_A} = \int_0^L \frac{M_s\,x\,dx}{I_x} = \int_0^{KL} P\,(1 - K)\,\frac{x^2\,dx}{I_x} + \int_{KL}^{L} P\,K\,x\,(L - x)\,\frac{dx}{I_x} \qquad (243)$$

By Equations (238), (239), and (240):

$$G_4 = P\,(1 - K) \sum_{0}^{KL} (g_o + a_o\, r_o^2) + P\,K \sum_{KL}^{L} (-\,g_o + a_o\, r_o\, s_o) \ldots (244)$$

In a similar manner,

$$G_5 = \frac{P\,L^3\,F_5}{I_A} = P\,(1 - K) \sum_{0}^{KL} (-\,g_o + a_o\, r_o\, s_o)$$

$$+\;P\;K \sum_{KL}^{L} (g_o + a_o\, s_o^2) \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (245)$$

Thus, all the elastic properties can be obtained for a member of any number of sections (see Table 9).

TABLE 9.—PROPERTIES OF RECIPROCAL *I*-DIAGRAM FOR A SECTION OF A MEMBER

INTEGRAL	DEFINITION	FORMULA
$\int \frac{dx}{I_s}$	AREA under $\frac{1}{I}$ -curve	$\frac{2\,g_1 + g_2 + g_3}{l^2}$
$\int \frac{x\,dx}{I_s}$	STATICAL MOMENT about left end of section	$\frac{g_1 + g_2}{l}$
$\int \frac{(l-x)\,dx}{I_s}$	STATICAL MOMENT about right end of section	$\frac{g_1 + g_3}{l}$
$\int \frac{x\,(l-x)\,dx}{I_s}$	PARALLEL PRODUCT OF INERTIA	$g_1 = \frac{l^3\,F_1}{I_a}$
$\int \frac{x^2\,dx}{I_s}$	MOMENT OF INERTIA about left end of section	$g_2 = \frac{l^3\,F_2}{I_a}$
$\int \frac{(l-x)^2\,dx}{I_s}$	MOMENT OF INERTIA about right end of section	$g_3 = \frac{l^3\,F_3}{I_a}$
	Distance from left end of section to center of gravity	$l\,\frac{g_1 + g_2}{2\,g_1 + g_2 + g_3} = x_o$
	Distance from right end of section to center of gravity	$l\,\frac{g_1 + g_3}{2\,g_1 + g_2 + g_3} = v_o$
	MOMENT OF INERTIA about axis through center of gravity	$\frac{g_2\,g_3 - g_1^2}{2\,g_1 + g_2 + g_3} = g_o$

This theory of combining sections of a member has been found particularly convenient where a part of the member is uniform, since for this section the g-terms are very simple. From the formulas given in Case 5, the uniform member, there is obtained:

$$g_1 = \frac{l^3}{6\,I_a} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (246)$$

$$g_2 = g_3 = \frac{l^3}{3\,I_a} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (247)$$

and,

$$g_0 = \frac{l^3}{12\,I_a} \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (248)$$

Equations (247) and (248) are obviously the moments of inertia of a rectangle of length, l, and width, $\frac{1}{I_m}$, about axes at its edge and center of gravity.

In the member given by Professor Clark shown in Fig. 13(*b*) (a uniform center section with a straight haunch at each end) this method was found more convenient than the three section formulas. It was also found possible to integrate the section with the straight haunch using the actual *I*-curve, $I_x = (a + bx)^3$, to find g_1, g_2, and g_3. The foregoing relations thus make an exact solution possible for a member of any number of sections where the moment of inertia varies as the cube of the depth and the edges of each section are straight.

It has even been found possible to perform the integrations and thus obtain an exact solution where the contours of portions of a member are conic sections and I varies as the cube of the depth, $I_x = (\, a + bx + cx^2)^3$, but this solution is too long for use in design work.

It is apparent that all the relations of the properties of the reciprocal *I*-curve given in Equations (226) to (248) are mathematical theorems that do not depend on, and are not limited by, substitute *I*-curves. In the original paper it was brought out that the substitute *I*-curve furnishes a way of integrating the functions of x divided by I which can be used in any method of analysis. Conversely, it is possible to use these theorems without employing substitute *I*-curves. Thus, if one chose, one could find the values of g_1, g_2, and g_3 of the sections of a member by the step-by-step summation or by the Large-Morris approximation, and then, by means of the relations of Equations (235) to (245), find all the elastic properties of the member.

It has been found that many different kinds of members can be treated more conveniently by summing the properties of individual sections than by endeavoring to consider the member as a whole in the beginning. Examples of such members are:

Example (*a*).—A member framing into two deep members of such proportions that an infinite moment of inertia should be used at both ends. There would be three or more sections to such a member. The numerical work, however, is greatly reduced by the fact that for the end sections, in which I equals infinity, the g-terms are zero.

Example (*b*).—Steel members in which cover-plates discontinue at frequent intervals. In some cases it is accurate enough to use a smooth substitute *I*-curve for the entire length. In others, any number of sections can be employed so that the results can be obtained with any desired degree of accuracy. This is an example of the flexibility of the general method.

The writers recognize fully the thought and careful work which has gone into the preparation of the many discussions of this paper. They wish to thank all the contributors most sincerely, and express appreciation of the manner in which they have amplified a subject that was treated, with some difficulty, within the confines of limited space.

INFLUENCE OF DIVERSION ON THE MISSISSIPPI AND ATCHAFALAYA RIVERS

By E. F. Salisbury,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Leo M. Odom, E. W. Lane, and E. F. Salisbury.

Synopsis

The effect of an outlet, operative at all stages, from the Mississippi River into the Atchafalaya River, is discussed in this paper. This continuous diversion decreases the volume of the Mississippi and increases that of the Atchafalaya. The result of this diversion is set forth and provides a means of proving or of disproving some of the present hydraulic theories and opinions.

For present purposes, a like volume of water (bank-full stage) through the various years, and the passage of this like volume of water past the gauge station as registered by the gauge height are analyzed at points on both rivers.

On the Mississippi River, gauge stations are analyzed where they are not affected, as well as where they are affected, by continuous diversion, in order to obtain comparative data and to place before the mind of the reader some of the ordinary causes that influence the variation in gauge height for the same volume of discharge. This analysis shows: (1) That at points not affected by diversion operative at all stages, the same volume of water is now passing at the same elevation as in earlier years; (2) that the Mississippi River has conformed itself to the hydraulic theory and increased its slope as the volume has been diminished by diversion; and, likewise (3), the Atchafalaya River has conformed itself to the hydraulic theory and flattened its slope as its volume has been increased through diversion.

Note.—Published in November, 1935, *Proceedings*.

Introduction

At only one point in the entire reach of the Mississippi River is its water diverted at practically all stages, namely, at Red River Landing (Angola, La.), about 190 miles up stream from New Orleans, where it is diverted into the Atchafalaya River. The result of this diversion is clearly reflected in the available data and should prove or disprove present theories and opinions.

In his study of sediment-bearing streams, Guglielmini, an Italian engineer of the Seventeenth Century, advanced the hydraulic theory[2] that: (1) The greater the quantity of water a stream carries, the less will be its fall; (2) the greater the force of a stream, the less will be the slope of its bed; and (3), the slope of the bottom in rivers will diminish in the same proportion in which the body of water is increased, and *vice versa*.

Commenting on this theory, Humphreys and Abbot state[2]:

> "* * *. These rules have their explanation in the facts, that the beds of rivers, of the character above mentioned, are capable of resisting, unchanged, only a certain velocity of current; and, on the other hand, that the sedimentary matter, contained in the river-water requires a certain degree of velocity to keep it in suspension. From the counteracting tendencies of the above two causes, a mean becomes established at which the current ceases to deposit its sediment, and the bottom ceases to be abraded; in other words, the bottom becomes permanent. But if, from any cause, such as throwing off a portion of the water through a waste-weir, the velocity of the current is diminished, it is no longer able to maintain its sediment in suspension, but will continue to deposit in its bed until, through the elevation of the bed, its velocity again becomes, what it was before it was disturbed, sufficient to maintain its sediment in permanent suspension."

While he was a member of the Mississippi River Commission, the late James B. Eads, F. Am. Soc. C. E., clearly and ably expounded this same theory. In a letter to the Mississippi River Commission[3] dated April 12, 1882, he stated emphatically that, in flood time, the current cannot be checked in the slightest degree without causing a deposition of some part of the sediment. In this connection he named three controlling factors that are involved in every problem presented by the characteristic phenomenon of the Mississippi River: (1) The force of the current; (2) the frictional resistance of the river bed; and (3) the intimate relation between the quantity of sediment carried in the water, and the velocity of the current. If the current is increased or decreased from any cause (such as the friction between the water and the bed of the stream) the quantity of sediment carried in suspension is likewise increased or decreased. If the volume is diminished, the ratio of friction to volume will be increased; and, conversely, if the volume is increased the ratio of frictional resistance will be decreased.

Diagrammatically, Mr. Eads demonstrated the rapidity with which frictional resistance increases if the sedimentary river is divided into two or more channels. Unless the two new channels have steeper slopes it is impossible

[2] "Report on the Physics and Hydraulics of the Mississippi River", by A. A. Humphreys and H. L. Abbot, 1861 (reprinted 1876), *Professional Papers No. 4*, Corps of Topographical Engrs., U. S. A., p. 415.

[3] Annual Rept. of the Chf. of Engrs., U. S. Army, to the Secretary of War, for the Year, 1882, Pt. III, Appendix RR, p. 2769 *et seq.*

for the water to flow as fast as it would in the original, single channel. Quoting from the letter:

"There are no truths more capable of complete demonstration or more generally recognized by hydraulic engineers than these and the effects already treated by the Atchafalaya bear ample testimony to the soundness of the deductions thus advanced. For instance, the volume in the main river below the Atchafalaya outlet is decreased by the volume carried off through the Atchafalaya. Therefore, in proportion as the lower Mississippi has lost this volume the slope of the river or its flood line should be steepened. The volume has been steadily increased in the Atchafalaya and as a natural result of such increase its slope has diminished."

If the foregoing theory is correct, the action of the Mississippi River at the point of almost constant diversion is a logical place to test its accuracy. Opposite Red River Landing the Red and Atchafalaya Rivers are virtually parallel to the Mississippi River (see Fig. 1), with a connection between the two called "Old River." This junction has been ably compared to the capital letter, H. The right-hand side of the letter is the Mississippi River; the other side above the cross-bar, the Red River, and below the cross-bar, the Atchafalaya; the cross-bar connection, seven miles in length, is Old River. The direction of flow in Old River is dependent on stages prevailing on the Mississippi and Red Rivers, the flow being most frequently from the Mississippi River through Old River into the Atchafalaya. This condition can occur at all stages of the Mississippi. The volume of water diverted from the Mississippi into the Atchafalaya decreases the volume of water in the Mississippi River below Old River. Therefore, if the hydraulic theory is correct, the slope of the Mississippi River below Old River should be increased. Furthermore, as the volume in the Atchafalaya is increased by waters from the Mississippi, the slope of the Atchafalaya River should be diminished.

In testing the correctness of this hydraulic theory, it is necessary to follow a like volume of water through the various years and the passage of this like volume of water by the gauge stations as registered by the gauge heights. In selecting this like volume of water it should be close to the bank-full stage of the river. This selection will give a desirable wide range of gauge readings for consideration not only in the different years, but during the same year. Furthermore (and this is very important), it represents the flow at bank-full stage, the form of the river which all the forces acting on it during the year are striving to create. The usual mistake made by river experts is to confine their discussions to flood stages, ignoring the forces acting during low water. A flood acts but a comparatively short time and during the remainder of the 365 days the river modifies the results which then occur.

It is apparent from the discharge observations recorded by the Mississippi River Commission that the above requirements are fulfilled by a volume of 1 100 000 to 1 200 000 cu ft per sec for the Mississippi River, and 300 000 cu ft per sec for the Atchafalaya River. In preparing the study for each gauge station, all gauges published by the Mississippi River Commission and measured with meters were used, falling within 25 000 cu ft per sec above or below the selected volume for the stations on the Mississippi River and 15 000 cu ft per sec above or below the selected volume for the Atchafalaya

River. The gauge for these volumes was adjusted to give a gauge for the selected volume. Readings measured with rods and floats were not used. All recorded readings were checked as to influence by crevasses and levee changes. These volumes are close to bank-full stage and no effect from crevasses was found. At only one point was the gauge station affected by levee changes and the results are discussed subsequently. That crevasses and levee confinement have not had any measurable effect on the carrying capacity of the main river is substantiated by reports of the Army Engineers.[4] During the period of this analysis only two cut-offs occurred; one at Mile 680 (Waterproof), in 1884; the other at Mile 638 (Yucatan), in 1928. These cut-offs are approximately 100 miles away from the nearest gauge station used in this paper and are so distant that they would not have any measurable effect.

To analyze the gauge and discharge record at any station it is necessary to understand that a silt-bearing river is somewhat human in its ability to do more work at one time than another. It will discharge a given volume of water at different gauge heights, depending upon its physical condition and the movement of water. This phenomenon of the river's capacity, to do more work at one time than another, as reflected by the passage of a given volume of water at different gauge heights is, for the purpose of this paper, termed its "efficiency."

It is generally recognized that the system used in taking discharge observations of large rivers, especially during high stages, is subject to error, but that it is sufficiently accurate for practical purposes. It is impossible to separate the factor of error in discharge measurements and the factor of river efficiency; both must be considered in river work. Therefore, it is consistent to embody the two in the term, "efficiency," which is so used in this analysis.

The variation in gauge heights for the same volume of water due to the efficiency of the river is clearly shown at gauge stations not influenced by unrestricted diversion; that is, uncontrolled diversion of water from the parent river at all stages, such as that from the Mississippi River into the Atchafalaya River. Three gauge stations selected for this purpose are those at Columbus-Wickliffe, Ky., and Helena, and Arkansas City, Ark. These three stations were selected over any of the other gauge stations because they furnish more readings of the selected volume. An analysis of a discharge of 1 200 000 cu ft per sec at these three stations is afforded by reference to Tables 1(*a*), 1(*b*), and 1(*c*). A summary of these data is given in Tables 2(*a*), 2(*b*), and 2(*c*).

Columbus, Kentucky, Gauge

All the discharges used were measured with current meters and those varying by more than 25 000 cu ft per sec from a volume of 1 200 000 cu ft per sec were rejected. Discharges measured with float or rod were not used in any of the studies of this paper. At the Columbus gauge (see Table 1 (*a*)), the readings were adjusted to a basis of 1 200 000 cu ft per sec, using 60 000 cu ft per sec per ft of gauge, as shown by the 1929 discharges. Only actual observed discharges for 1929 were used for the analysis of this record and no crevasses that would affect the readings were reported.

** Sufficient readings not available to determine maximum variation during the same flood

Referring to Table 2 (*a*), the highest gauge of 1892 is 1.7 ft lower than the lowest gauge of 1929. This indicates that the two different floods, although rated at two different "efficiencies" at this station, were at one time discharging the same volume of water at the same gauge height. In other words, between 1892 and 1929, no appreciable silting occurred at this station. The limited number of observations during any one year at this station (Table 2 (*a*)) does not reflect the gauge variation that can be expected during a flood, due to "efficiency." For a 37-yr period, the greatest range on the gauge to discharge the same volume of water, is 3.8 ft (see Table 2 (*a*)) which is a measure of the effect of "efficiency" at this station, for all floods recorded (see Table 1 (*a*)).

Helena, Arkansas, Gauge

Referring to the Helena gauge (Table 2 (*b*)), 55 000 cu ft per sec per ft of gauge was used in adjusting readings to a discharge of 1 200 000 cu ft per sec. As in the case of the Columbus-Wickliffe gauge only actual observed discharges during 1929 were used.

Crevasses occurring within 50 miles above and below Helena prior to the discharge rates listed in Table 1 (*b*), in general did not affect the recorded gauges. Records of crevasses that may have occurred in 1882 were not available to the writer. The recorded gauges of 1893 that were not affected by crevasses, however, are practically the same as those for 1882. From this evidence and the fact that the discharge is close to bank-full stage, the discharge of 1882 is considered to be unaffected by crevasses. In other words, it would not affect the analysis if the discharges of 1882 or 1893 were used.

Reference to Table 2 (*b*) demonstrates that, in the two different floods, 47 yr apart, the same volume of water was passing at the same gauge height, which indicates that there has been no filling or silting in the channel at this station. The greatest variation in discharging the same quantity of water occurred in 1929. The difference of 2.6 ft between the lowest and highest gauge of this year reflects the effect of "efficiency" during the same flood. For the 47-yr period, the greatest range on the gauge for discharging 1 200 000 cu ft per sec is 2.6 ft, which value measures the influence of "efficiency" at the Helena gauge for all the floods recorded. It is to be noted (see Table 2 (*b*)) that the lowest and highest gauges of any of the years recorded occurred in 1929.

Arkansas City, Arkansas, Gauge

Effect of Crevasses on the Gauge Study.—Prior to the discharge reading of March 14, 1890 (see Table 1 (*c*)), there was a crevasse of 35 000 cu ft per sec, 8 miles above the Arkansas City gauge on March 9, 1890, and another of 6 055 cu ft per sec, 35 miles below on March 7, 1890 (see Table 3). These crevasses were too small to affect the gauge reading as shown by the increase of 0.3 ft in the gauge height by March 25, 1890. In other words, the gauge height increased despite the occurrence of two additional small crevasses (19 901 cu ft per sec) 4 miles above, and two of 35 000 and 31 000 cu ft per sec,

7 and 40 miles, respectively, below the Arkansas City gauge. Prior to the gauge reading of April 11, 1890 (see Table 1 (*c*)), in the 50-mile reach above this gauge, nine crevasses occurred, discharging 515 901 cu ft per sec; and, in the reach 50 miles below, six crevasses occurred, having a discharge of 242 255 cu ft per sec, or a total of 758 156 cu ft per sec. A comparison of the gauge of April 11, 1890, with that of March 14, 1890, shows a reduction of only 0.6 ft to discharge the same volume of water (1 200 000 cu ft per sec) with more than 700 000 cu ft per sec of water diverted through crevasses within 50 miles above and 50 miles below the gauge. This small variation proves that there was little, if any, effect from crevasses, which conclusion is further supported by a comparison of the gauges of 1890 and 1891.

Prior to July 1, 1892 (see Table 3 (*a*)), four crevasses, occurred within a reach of 50 miles below the Arkansas City gauge, with a total discharge of 146 913 cu ft per sec. The recorded readings in this year were not appreciably more or less than those for years that were not affected by crevasses.

The highest gauge of 1890 (see Table 2 (*c*)) is 0.1 ft lower than the lowest gauge of 1929, showing that at one time the two different floods were discharging the same volume of water at practically the same gauge. Again, this shows that no appreciable silting had occurred at this station in the 39-yr period. For the same discharges, the year 1923 showed the greatest variation in gauge heights. The difference of 2.0 ft (see Table 2 (*c*)) between the highest and lowest gauge of this year, for an adjusted discharge of 1 200

cu ft per sec, reflects the effect of "efficiency" during the same flood. For the entire 39-yr period, the greatest range on the gauge for discharging this same volume of water is 3.2 ft, which, likewise, measures the influence of "efficiency" at the Arkansas City gauge for all the floods on record.

Summary: Columbus-Wickliffe, Helena, and Arkansas City, Gauges

Flood Efficiency.—The foregoing data show that the maximum variation is 2.6 ft for the same volume of water during the same flood at these three gauge stations. A variation in flood "efficiency" of approximately 3 ft can be expected at these stations. Floods divide themselves into the following three classes: (1) Those of poor "efficiency" (high gauge height for a given discharge); (2) those of normal "efficiency" (medium gauge height for a given discharge); and (3) those of high "efficiency" (low gauge height for a given discharge). Certain of the ordinary causes that influence the class of each flood for the same volume of discharge are: (*a*) The relationship between the velocity of the main stream and the sediment introduced by tributaries; (*b*) control of sediment carried by tributary streams; (*c*) channel stabilization on the entire river system; (*d*) extent to which the main channel has been flushed by intervening water stages; (*e*) the effect of winds in the direction of flow; (*f*) the effect, on a gauge in the main river close to the mouth of a tributary stream, of the discharge of a large volume of water; and (*g*) change in slope for rising and falling stages of the river.

There is a relationship between velocity and quantity of sediment carried (Cause (*a*)). If the velocity of the main river, required for carrying sediment, is not overtaxed by the sediment contributed by the tributaries the deficiency is picked up from the channel of the main river, causing lower gauge heights. On the other hand, if the sediment contributed is greater than can be transported by the parent river, it is deposited and causes a higher gauge. As for Cause (*b*), an attempt to control the sediment carried by the tributaries, in order to assist the parent river, by protecting it against erosion is advisable. This policy has been adopted, to some extent, for reasons far removed from flood-control purposes, such as the terracing of cultivated fields in hill farms required by the Federal Land Banks and vigorously pursued by the United States Department of Agriculture in erosion control and forest protection. Channel stabilization by protecting the banks on both the main river and the tributaries (Cause (*a*)) is also an aid in reducing the quantity of sediment. Prevailing winds in the direction of flow (Cause (*e*)) will lower the gauges for the same discharge, whereas prevailing winds in the opposite direction will raise them The change in rate of rising stages over falling stages (Cause (*g*)) affects the slope at corresponding gauge heights thereby producing different volumes of discharge. For slow falling stages the slope is flattened out from that produced by fast rising stages.

The extent to which Causes (*a*) to (*g*) act in unison controls, to a major degree, the class "efficiency" of the flood. It is not unusual for a combination of the adverse causes to occur at the same time, creating a flood of poor "efficiency."

The greatest variation at the three gauge stations between the earliest and latest flood-years is 1.7 ft, showing that the two floods are of different efficiency. Each flood, although 37 yr apart, passed the same volume of water at one time during the flood interval with a difference of 1.7 ft. As this is within the expected range of maximum gauge variation, due to the influence of "efficiency," the river is not silting up at these gauge stations and causing higher flood elevations. This is further substantiated by the cross-sections taken at various intervals by the Mississippi River Commission. Comparison of cross-section elements of the general survey of 1894 to 1904 with those of the survey of 1911 to 1913 covering the section of the river from Cairo to Red River shows that, at bank-full stage, the average area increased 2.3%, the average width increased 3.9%, and the average mean depth increased 1.3 per cent[5].

The levee systems at these gauge stations have been improved gradually by raising and strengthening. These levee changes have not affected the gauge readings recorded. As will be demonstrated subsequently for the Atchafalaya River the gauge height for a given volume of water without levees is increased after levee confinement at some point; however, after once confined, further levee extension down stream from this point does not influence the gauge for the same volume of water.

Overbank Diversion.—During 1921 the Cypress Creek gap in the levee line was closed immediately above Arkansas City. Previously, flood water did escape from the Mississippi River through this gap at overbank elevations. Subsequent to this date, flood waters have been confined and could only escape by crevassing. The overbank flood-water escape of this frequency did not have any noticeable effect on the efficiency of the Arkansas City gauge.

Red River Landing (Angola, La.) Gauge

The gauge station at Red River Landing is situated on the Mississippi River approximately 1 mile below Old River (see Fig. 2). All the discharges used (see Table 4) were those measured with current meters. Those varying more than 25 000 cu ft per sec from a volume of 1 100 000 cu ft per sec, were rejected. At this gauge, the readings were adjusted to 1 100 000 cu ft per sec, using 35 000 cu ft per sec per ft of gauge, as shown by the 1929 discharge, and only the actual discharges during that year were used.

The major crevasses that occurred within 50 miles above or below Red River Landing prior to the discharge dates in Table 4, are given in Table 3. Data concerning crevasse occurrence in 1882 were not available. The Morganza crevasse, 16 miles below the gauge station at Red River Landing, which occurred on April 16, 1874, was not closed until February, 1884. It breached again on March 14, 1884, and was closed in January, 1887; breached once more on April 22, 1890, was closed in March, 1891, and has remained closed since.[6] The levee breach at Morganza was open during the recorded

readings of 1882 and 1885. There are no data as to discharge through this breach for these two years. It is estimated that the crevasse of March 14, 1884, was discharging 211 000 cu ft per sec on March 25; the approximate gauge at Red River Landing on this date was 46.0. The recorded gauges for 1882 and 1885 are from 4.2 to 5.8 ft lower than this gauge, and the diversion through the Morganza opening at these low stages would be small and would not influence the gauge at Red River Landing 16 miles above.

In 1890 (see Table 3), there were no crevasses prior to April 1, close enough to Red River Landing to affect the gauge, the nearest being at Nita (899 miles below Cairo) on March 14. The crevasse at Ames on March 16, 1891 (see Table 3(*b*)), was too far down stream to affect this gauge. In the period from 1892 to 1903, no crevasses occurred prior to gauge readings that would affect the observed height.

Bougere crevasse, 35 miles above Red River Landing, which occurred on March 14, 1903, was 9 300 ft wide. There is no record of discharge of this crevasse, but it did not affect the recorded gauge readings because it served only to divert a portion of the main river into the back-water reservoir of Black River at a point about 30 miles up stream from where it would have

been diverted into the reservoir at the end of the levee. In the period, 1904 to 1932, no crevasses occurred prior to readings that would affect the gauge at Red River Landing.

Referring to Table 2 (*d*), the variation of 6.9 ft for discharging the same volume of water in the two different floods, 50 yr apart, shows that excessive silting occurred in the river channel at this station. The year 1913 had the greatest variation for discharging the same volume of water. The difference of 4.5 ft between the highest and the lowest gauge of this year for discharging 1 100 000 cu ft per sec is due in part to "efficiency" influence and in part to conditions created by diversion. For the entire 50-yr period the greatest range in gauge heights for discharging the same volume of water is 10.2 ft (see Table 2 (*d*)). This large variation is due in part to "efficiency" influence and in part to silting in the channel.

Summary: Red River Landing Gauge

Unrestricted Diversion.—The effect of unrestricted diversion from the Mississippi River at the gauge station at Red River Landing (Angola, La.), creates a condition at variance with that at the stations previously analyzed. At this location the Mississippi River has two outlets of levee-confined discharge to the Gulf of Mexico; one past New Orleans into the Gulf, the other through Old River into the Atchafalaya River and thence to the Gulf. This latter outlet through the Atchafalaya permits unrestricted diversion of water from the Mississippi River at all stages.

To follow the changes occurring in the Mississippi River at Red River Landing, it is necessary to consider the same volume of water during each flood-year. For this purpose, a volume of 1 100 000 cu ft per sec was selected because, in the early years, it was fairly close to bank-full stage and, therefore, was not affected by crevasses. Furthermore, a greater number of gauge readings was available for study.

Shreve's cut-off occurred in 1831 and the Raccourci cut-off, in 1847, being, respectively, short distances above and below Red River Landing. The earliest reading used at this gauge station occurred during 1882, being 51 yr and 35 yr, respectively, later than these cut-offs. Therefore, the rise in gauge to discharge the same volume of water at this station since 1882 cannot be attributed to the effect of these cut-offs.

Records of the gauge station at Red River Landing since 1882 show that the gauge for discharging the same volume of water has been raised by permanent silting in of the channel (see Table 2 (*d*)). A further increase results from temporary silting occurring during the same flood, which is either removed by that flood or by intervening waters. The rise in gauge for discharging the same volume of water caused by the permanent silting in of the channel is the difference between the highest gauge of 1882 and the lowest gauge of 1932, being 6.9 ft. Reference to Table 4 shows that this rise in gauge height since 1882 is the result of permanent silting during three distinct periods, the average gauge for each period being as summarized in Table 5 (*a*).

The greatest gauge variation of 4.5 ft (see Table 2 (*d*)) for discharging the same volume of water during any one year occurred in 1913. This variation is greater than would be expected normally as the flood of 1913 is the end of the second period and the beginning of the third period of silting transition. The low gauges that occurred during the first days of the 1913 flood have never been repeated. The high gauges recorded during the latter days of the 1913 flood became normal for the third period. Since 1913, the lowest gauge for discharging 1 100 000 cu ft per sec is 47.1 as against 45.9 during the first part of 1913, and the highest gauge is 50.4. Therefore, the range of "efficiency" is from 47.1 to 50.4 ft on the gauge, or 3.3 ft.

TABLE 5.—AVERAGE GAUGE HEIGHTS, GAUGE AT RED RIVER LANDING

Period No.	(*a*) Increase in Gauge Heights			(*b*) Peak-Flood Gauge Heights		
	Years	Average gauge, in feet, for a discharge of 1 100 000 cubic feet per second	Gauge increase, in feet	Years	Average peak-flood gauge, in feet	Increase for the period, in feet
1....	1882 to 1885	41.3	...	1867 to 1886	45.1	...
2....	1890 to 1909	45.0	3.7	1890 to 1907	48.7	3.6
3....	1913 to 1932	48.2	3.2	1912 to 1933	52.4	3.7

The greatest gauge variation for discharging the same volume of water is 10.2 ft for the 50-yr period of which 6.9 ft is the loss due to permanent silting and 3.3 ft reflects the influence of efficiency. A report of the Mississippi River Commission records the peak-flood gauges at Red River Landing.[7] The average of these peak-flood gauges, grouped as three periods in Table 5 (*a*), gives the increase in average peak floods for each of these three periods (see Table 5 (*b*)). This average period peak-flood gauge of 7.3 ft is practically the same gauge increase as the 6.9-ft increase in gauge height for discharging the same volume of water, showing a direct influence of flood height on the loss in discharge capacity below the point of diversion.

The actual changes in cross-section elements for the 2-mile reach below Old River, in the period, 1882 to 1924, are, as follows[8]: The bank-full width increased 535 ft; the bank-full area decreased 13 089 sq ft; and the bank-full mean depth decreased 9.6 ft.

A peak-flood height of 50.5 ft was never exceeded during the periods prior to 1912. During the period, 1912–1933, this gauge was exceeded eight times with the maximum peak gauge of 57.5 ft, which occurred in 1927. The main river at this point has adjusted itself to an average peak-flood gauge of 52.4 ft.

Loss in the cross-sectional area at Red River Landing during the same flood, and when diversion is occurring, was well illustrated during the high water of 1929. In this year the deposition of silt below the point of

[7] "Improvement of Lower Mississippi River for Flood Control and Navigation", Vol. 1, p. 104.

[8] *Loc. cit.*, Vol. 1, Table 6.

diversion restricted the cross-sectional area to the extent of holding it to the same area during the last 5-ft rise in flood height, as follows:

Gauge height, in feet	Area, in square feet
47.4	234 000
48.8	234 000
49.8	236 000
51.1	230 000
52.2	230 000
52.4	232 000

From the foregoing the deposition of the silt during the same flood is shown to act as a natural automatic valve to hold the cross-section to an area of about bank-full and against a rise in gauge, thus producing a steeper slope during the same flood. This silt is removed during the same flood or intervening waters. The gain in cross-sectional area at this station during the same flood, and when diversion from the Mississippi River is prevented by higher stages in the Red River, is shown by the 1932 flood in the Red River. During this flood a portion of Red River water was discharged into the Mississippi River and increased the volume carried by it. Discharge cross-sections during this year at Red River Landing show:

Gauge, in feet	Area, in square feet
46.6	245 000
48.8	260 000
50.9	267 000
52.1	271 000

The cross-sectional area of 271 000 sq ft at the peak gauge of 52.1 during 1932, as against a cross-sectional area of 232 000 sq ft at a peak gauge of 52.4 ft during 1929, shows a loss of 39 000 sq ft, or 17% of area, caused by diversion during the same flood at this gauge station.

The silting changes of these two floods were only local and did not materially affect the gauge for the same volume of water. The 1932 flood, with diversion eliminated, shows the power of the river to clean the channel and if given the chance, eventually to re-open the entire reach to its old cross-sectional area and produce lower stages for the same volume.

The changes at Red River Landing due to unrestricted diversion are illustrated at the two overbank diversions below New Orleans at Pointe a la Hache and Caernarvon, during the flood of 1927. Discharge observations were taken immediately above and below these diversions. At Pointe a la Hache, 57 miles below New Orleans, 10.5 miles of the Mississippi River levee was removed during 1924 in an effort to reduce flood heights at New Orleans. The 1927 flood discharge observations at Pointe a la Hache show that the velocity above the diversion increased over that below the diversion as the discharge through the levee gap increased. There was a maximum difference in velocity of 1.33 ft per sec, with the maximum diversion of 301 845 cu ft per sec. After diversion the cross-sectional area at the upper station was found to have increased 8 125 sq ft and that at the lower station

had decreased 8 169 sq ft. The increase in area of the upper section was caused by an increase in velocity induced by the suction through the levee gap, thereby increasing the sediment-carrying capacity of the river, adding to its load by scour from the channel within the zone of influence of the diversion. Contrarily, the loss in area at the lower section was due to the decrease in velocity, thus causing deposition of sediment in the channel.

The induced draft through the levee gap at Pointe a la Hache during the 1927 flood did not reach far enough up stream to relieve New Orleans, making it necessary for a further levee breach nearer that city. An artificial crevasse was then made at Caernarvon twenty miles below New Orleans. The greatest difference in velocity between the upper and lower stations at the Caernarvon diversion was 1.13 cu ft per sec for the maximum diversion of 326 446 cu ft per sec. The discharge measurements were not carried through the entire period of diversion and, therefore, cross-sectional comparisons are not possible. These effects from the drop in velocity, and the gain and loss in channel area caused by overbank diversion are noticeable at Red River Landing in the greater channel depth immediately above, and the shallow channel depth immediately below, Old River.

As the peak-flood gauge increased 7.3 ft caused by higher flood stages, due to increased height and strength of levees, larger volumes of water were diverted from the Mississippi River and forced down the Atchafalaya. The higher the gauge at Red River Landing the larger the volume diverted into the Atchafalaya. The Mississippi River, below the point of diversion, adjusted itself with silt deposition, progressively, with increased flood heights and consequent increase in diversion. The loss in mean depth for bank-full stage from 1882 to 1924 was 9.6 ft. Under this unrestricted diversion, it is apparent that the Mississippi River is adjusting itself to the loss in volume. Diversion into the Atchafalaya River is dividing the Mississippi River, and this results in a velocity drop below the point of diversion as compared with that above it. The larger the volume of water diverted the greater the velocity difference. This velocity change is causing a deposition of silt which forms a dam below the point of diversion, thereby adjusting the river to a new slope. This change in slope varies with the volume subtracted. The "efficiency" of the stream down stream from this point is diminished, and, the river at this point is almost continuously subject to diversion and only infrequently is its volume augmented by waters from Red River. The preponderance of influence is due to diversion occurring at all stages from the Mississippi into the Atchafalaya; therefore, there is no opportunity for the sediment-formed dam at Red River Landing to be cleaned out. As the volume of the main river is reduced by increased diversion through the Atchafalaya, the Mississippi River adjusts itself to an increased slope by the deposition of silt below, thus causing (since 1882) a rise in the gauge of 6.9 ft to discharge the same volume of water.

The adjustment at Red River Landing conforms to the hydraulic theory that "whenever silt-bearing streams flow through alluvual deposits, other conditions being the same, the slope is least where the volume is greatest, and,

conversely, the slope is found to be invariably increased as the volume is diminished."[9]

Carrollton, La. (New Orleans), Gauge Station

All available discharges used were measured with current meters and those varying more than 25 000 cu ft per sec from a volume of 1 100 000 cu ft per sec were rejected. Readings were adjusted to the basis of 1 100 000 cu ft per sec, using 60 000 cu ft per sec per ft of gauge, as shown by the 1929 discharge. Only actual observed discharges during 1929 were used.

The record of three crevasses that have occurred within 50 miles up stream and down stream from the Carrollton gauge is given in Table 3 (*c*). No records are available of crevasses that occurred in 1883. Between February 13 and March 26, 1890, ten small crevasses occurred, between Miles 973 and 1 000, down stream from Cairo. These breaks varied in widths from 15 to 540 ft and were too small to affect the gauge readings. Furthermore, gauges adjusted for 1 100 000 cu ft per sec before and after the Nita crevasse, which occurred on March 14, 1890 (see Table 3 (*c*)), do not show any influence. The Ames crevasse on March 16, 1891 (see Table 3 (*c*)), occurred after the dates of the gauge readings under consideration. Between May 3 and June 13, 1892, seventeen crevasses are listed. All these breaks were small and closed within a few days of their occurrence, except Sarpy crevasse, 939 miles from Cairo (see Table 3 (*c*)). A comparison of the adjusted gauge readings for this year with those of 1893 (which were not affected by crevasses) shows no influence.

Referring to Table 2 (*e*), the same volume of water in the two different floods, 49 yr apart, was passing the gauge at heights only 1 ft apart, which shows that the channel had not silted appreciably in that time. The greatest variation for discharging the same volume of water in a single year, occurred in 1913. The difference of 2.6 ft between the highest and lowest gauges of this year, adjusted for a discharge of 1 100 000 cu ft per sec, reflects the effect of "efficiency" during the same period. For the 49-yr period, the greatest variation on the gauge for discharging the same volume of water, is 5.3 ft (Table 2 (*e*)). This large variation is due in part to "efficiency" influence, and in part to conditions created by unrestricted diversion at Red River Landing.

Summary: Carrollton, La. (New Orleans), Gauge Station

The study at the Carrollton gauge station is based on a discharge of 1 100 000 cu ft per sec, details of which are recorded in Table 1 (*d*). This volume of water is close to bank-full stage and recorded gauge readings are not affected by crevasses or levee changes.

The variation of 1 ft between the lowest gauge of 1932 and the highest gauge of 1883 (see Table 2 (*e*)) shows that at one time during these two floods, 49 yr apart, the same volume of water was passing within a foot on the gauge. This variation is within the range of "efficiency" influence

[9] Letter from the late James B. Eads, F. Am. Soc. C. E., to Mississippi River Comm. dated April 12, 1882.

and the channel has not silted. The greatest variation for discharging the same volume of water occurred in 1913. The difference of 2.6 ft between the highest and lowest gauge of this year for discharging 1 100 000 cu ft per sec, is due in part to "efficiency" influence. This variation of 2.6 ft is greater than can normally be expected due to efficiency influence, as the conditions set up during the flood of 1913 at Red River Landing caused an abnormal gauge fluctuation at Carrollton. Prior and subsequent to the flood of 1913 the greatest gauge variation during any one year for discharging this same volume of water is 1.5 ft. For the 49-yr period the greatest range in gauge for discharging this same volume of water is 5.3 ft. The increase in gauge for discharging the same volume of water at this station

† Sections normal to stream computed where necessary.

is between 3 and 4 ft. This may be caused by conditions set up by unrestricted diversion at Red River Landing. Definite proof is not available at this time, however, but it is thought that future studies will throw additional light on this subject.

The Discharge of the Atchafalaya River

The cross-sectional elements of the Atchafalaya River for the upper 68 miles, as taken by the Mississippi River Commission for various years (Table 6), show that this stream has increased an average of 47% in area at bank-full stage from 1904 to 1932. (Levees have been constructed along the first 51 miles of this river.) In order to determine the effect, if any, that this large increase in cross-sectional area has had on the discharge capacity of the stream, it is necessary to consider the passage of the same volume of water through the various flood-years. To obtain a sufficient number of readings for consideration, a volume of 300 000 cu ft per sec is used as reported at the Simmesport Discharge Observation Station (see Table 1(*e*) and Table 2 (*f*)). As in the case of gauge records previously reported in this paper, all discharges in Table 1 (*e*) were measured with current meters and those varying more than 15 000 cu ft per sec from a volume of 300 000 cu ft per sec were rejected. At this gauge the readings were adjusted to a basis of 300 000 cu ft per sec, using 13 000 cu ft per sec per ft of gauge, as shown by the discharge rating curve issued by the Corps of Engineers, U. S. Army, for this station. Readings from 1890 to 1893, which are published with the zero of the gauge at 3.88 ft above mean Gulf level were corrected to a gauge with its zero 5.79 ft above mean Gulf level, thus referring all readings in Table 1 (*e*) to the same datum plane. A record of the more important crevasses along the Atchafalaya River is presented in Table 7.

There is wide variation in the "efficiency" of the Atchafalaya River. The difference of 6.1 ft between the 1920 and the 1928 readings, eight years apart (see Table 2 (*f*)), shows the influence on "efficiency" by the sediment deposited in the stream as a result of diversion. The flood of 1927 formed crevasses in the Atchafalaya River levees, flushing the river channel sediment at different

points and allowing efficient handling of the 1928 water at low gauges. The flood in the Red River during 1932 established the highest gauge of record at Alexandria, La. This high stage of the Red River prevented the diversion of the Mississippi into the Atchafalaya and cleaned the Atchafalaya River to greater depths than recorded by surveys since 1880–1881. This flushing increased the Atchafalaya "efficiency," allowing the early part of the 1933 water to pass at low stages.

The gauge variation of 1.7 ft during the 43-yr period, 1890 to 1933 (see Table 2 (*f*)), develops the fact that no material change occurred in the discharge capacity of the stream, even in the face of a 47% increase in cross-sectional area. The velocities in Table 1 (*e*) show that as the river expanded in cross-sectional area there was a reduction in velocity from about 5 ft to less than 4.5 ft per sec caused by slope adjustment of the stream. The head is fixed by the water elevations in the Mississippi River at Red River Landing, and, therefore, the slope is reduced because of the increased silt deposits below the lower end of the levees. Proof of this silting is shown[10] in Table 8. Melville is at the lower end of Reach *B*; and the lower end of Reach *E* is approximately at the end of the east levee. No change in gauge for the discharge of the same volume of water has occurred since 1890; therefore, the increase in cross-sectional area has kept pace and has offset the slope reduction. The theory that with an increase in the volume of a silt-bearing stream the slope will diminish, is borne out by the actions of the Atchafalaya River.

TABLE 8.—ATCHAFALAYA RIVER: CHANGES IN AVERAGE BANK ELEVATION (IN FEET), AS SHOWN BY SURVEYS

SIMMESPORT, LA., GAUGE

In 1890, the east levee on the Atchafalaya River extended to 26 miles below Simmesport (see Fig. 2), the west levee extending to 11 miles below. Levee extensions since 1890 have not affected this gauge for the same volume of discharge. For the various flood-years when the high gauge of 50 ft was reached in the Mississippi at Red River Landing, the record of discharge in the Atchafalaya River at Simmesport for corresponding dates is given in Table 9. The discharges vary with the silted condition of the channel and are not upset or influenced by crevasses.

[10] "The Improvement of the Lower Mississippi River for Flood Control and Navigation", May, 1932, prepared under the direction of the President of the Mississippi River Commission, Vol. 1, p. 126.

The Atchafalaya discharge of 376 000 cu ft per sec during 1932 at a gauge of 49.5 ft at Red River Landing (see Table 9, Item No. 7) is within reasonable

limits of the 390 000 cu ft per sec discharged during 1897 at a gauge of 50.0 ft at Red River Landing. (The year, 1897, is the earliest on record in which a gauge of 50.0 ft was reached at Red River Landing.) This further substantiates the flattening of the slope in the Atchafalaya River; it offsets the 47% increase in cross-sectional area; and the volume of water diverted into

TABLE 10.—INCREASE IN THE DISCHARGE OF THE ATCHAFALAYA RIVER

Period	Dates	Mississippi River, Red River Landing: Gauge height, in feet	Mississippi River, Red River Landing: Discharge, in cubic feet per second	Atchafalaya River, Simmesport discharge, in cubic feet per second
1	1882–1885	41.3	1 108 600	184 421
3	1913–1932	48.2	1 105 000	313 866
Increase	....	6.9 ft	....	129 445

the Atchafalaya is dependent upon water elevations in the Mississippi River. The increase in discharge of the Atchafalaya River due to the increase of 6.9 ft in the Mississippi for discharging the volume of 1 100 000 cu ft per sec is shown in Table 10.

MELVILLE AND KROTZ SPRINGS GAUGE STATIONS

Discharge observations are not made in the Atchafalaya River, at Melville and Krotz Springs, La. (see Fig. 2). To study the action of the river at these two points gauge heights are listed in Table 11 for the day following the approximate discharge of 300 000 cu ft per sec at Simmesport. The dates for the gauges at Melville and Krotz Springs are one day later than those for the gauges at Simmesport to correspond with a discharge of 300 000 cu ft per sec. The zero for 1933 values on the Melville gauge is 0.2 ft above mean Gulf level. To convert the gauge readings for previous years to the same datum plane as 1933, subtract 0.3 ft from the readings in 1890 and 1892, and add 0.2 ft to the readings in 1907 and 1929. The gauge readings in Table 11 are not adjusted to an even 300 000 cu ft per sec.

At Melville the gauges from 1907 to 1933 do not show any noticeable changes other than those due to "efficiency" influence. The average of the gauge readings prior to 1907 is 5.2 ft lower than the average of those after

that year. This increase in gauge between 1892 and 1907 is due to levee confinement. In 1893 the west bank of the Atchafalaya River had a continuous levee line extending to Melville and the east levee line ended 8 miles up stream from this point. Between 1893 and 1907 the west levee was extended to 12 miles below Melville and the east levee extended to 13 miles below that point. This confinement caused the increase in gauge heights of approximately 5 ft at Melville.

The gauge at Krotz Springs from 1912 (the earliest gauge reading available) to 1933 does not show any noticeable change other than that due to "efficiency" influence. In 1912 the east levee ended 3.7 miles below this station and has since been extended to 4 miles below it (see Fig. 2). In 1908 the west levee ended 1 mile below this station and has since been extended to 9 miles below it. These levee extensions have not affected this gauge for the same volume of discharge.

HISTORY OF THE ATCHAFALAYA RIVER BASIN[11]

In 1804, the channel of the Atchafalaya River was choked with rafts of driftwood extending from bank to bank, beginning on the north at a point 30 miles from the Mississippi River and extending down the Atchafalaya about 20 miles. They clogged the river channel completely, making navigation impossible. Trees were growing around these rafts, the largest being about 10 in. in diameter. Driveways crossed them at different places. These rafts rose and fell with the water and, apparently, they were effective in checking any natural opening of this channel between Old River and the Gulf.

About 1840 the State of Louisiana, in order to open a navigable channel, began cutting channels through the rafts with a view to their complete removal. This work continued to the beginning of the Civil War period. Immediately upon the removal of the rafts the channel enlarged rapidly at bends in the river and on both sides of the narrow straight reaches. Lands in the Atchafalaya Basin which had been exempt from overflow were flooded annually until, in 1881, the Upper Atchafalaya Basin "had gone back to Nature."

[11] Comp. from Repts. of the Mississippi River Commission.

Along the river were to be seen ruined dwellings and sugar houses, buried fence lines, broken levees, hardwood timber killed by standing water, and cypress swamp growth started. Navigation, however, was excellent in 1881. The change in the characteristics of the river at its head between 1851 and 1879, is illustrated by reference to Table 12.

TABLE 12.—CHANGES IN THE CHARACTERISTICS OF ATCHAFALAYA RIVER

Year	Cross-section area of channel, in square feet	DIMENSIONS OF CROSS-SECTION AT HIGH WATER, IN FEET	
		Width	Depth
1851	24 400	730	52
1859	28 700	830	63
1874	39 160	891	114
1879	52 100	940	130

In 1881, the channel of the Atchafalaya River had enlarged to a point at which it had a discharge nearly equal to that of the Red River and afforded that stream the line of least resistance for flow to the sea. In 1881, the elevation of the water surface at Red River Landing was almost constantly above that at the head of the Atchafalaya, being 7.3 ft above the latter point on October 13, 1891. At this time there was a marked tendency to increase the channel from the Mississippi to the head of the Atchafalaya. Quoting from the report of the Commission:[12]

"No decrease in flood heights in the Mississippi River has been observed, although a diversion of one-sixth of the Mississippi River discharge has taken place. However, there has been a decrease of flood heights on the Atchafalaya."

The report of the Mississippi River Commission of 1881 contained a recommendation that a sill dam be built across the mouth of Old River between Turnbull's Island and the Mississippi, and, also, that a study be made of the proposal to divorce completely the Mississippi River from the Red and Atchafalaya drainage. During 1882 actual work at the head of the Atchafalaya was confined to dredging bars at the mouth of the Red River and the head of the Atchafalaya, creating a 16-ft channel from the Red River through Old River and a 6-ft channel connecting the Red with the head of the Atchafalaya River, thus making navigation conditions very satisfactory. In 1884 the Commission reported[13] that the formulation of a comprehensive plan for the treatment of the Atchafalaya situation had been deferred from time to time on account of the necessity for further observation, experience, and study. It was prepared to present a plan which was stated to be the best that could be devised in point of practicability, safety, and economy; a plan that should include "the prevention of the diversion of the Mississippi into the Atchafalaya Basin and the closure of any depleting outlet in that point, either now existing or likely to be induced by the changes reasonably to be anticipated and also the preservation of navigation of the Red and the Atchafalaya Rivers."

[12] Progress Rept. of the Mississippi River Comm., 1881, p. 13.
[13] Rept. of the Mississippi River Comm., 1884, p. 2554.

At that time Major Amos Stickney, Corps of Engineers, U. S. Army, was in charge of the lower district, and he recommended the construction of a series of brush dams to be placed in the Atchafalaya River, the upper one to be below the Bayou des Glaizes and the others at intervals not exceeding ½ mile. These dams were to be built to a point just below low water; they were planned not to interfere with navigation, and to regulate the discharge of the Atchafalaya so that it would take care of the flood discharge of the Red River. These dams were to be supplemented by levees to prevent the overflow into the Atchafalaya Basin of water from the Mississippi. At this time a dam was also recommended across Old River between the Atchafalaya and the mouth of the Red near Turnbull's Island. This was in order to force the Red River down the Atchafalaya. Apparently, no action was taken by Congress on this recommendation and the report of 1885 again recommends the construction of these sill dams in the Atchafalaya as soon as the water stage permits and money is available. Quoting the report:[14]

"The work to be done would have for its object the gradual construction and perhaps finally the complete closure of the Atchafalaya as an outlet of the Mississippi. Whether the treatment should be carried further than this, to the extent of making the Red a tributary of the Mississippi by the construction of a high dam across the head of the Atchafalaya River and its basin, thus cutting the latter off from navigation of the Red and Mississippi, is a consideration of great moment. Determination can be deferred. The Commission is distinctly committed to the idea of closing all outlets as part of the plan for the improvement of the Mississippi River, both low-water outlets and breaks in the levees, and has consistently opposed the fallacy known as the outlet system because it stands in sharp antagonism to all the fundamental laws of hydraulics. When the Atchafalaya shall cease to be an outlet the discharge of the Mississippi below the mouth of the Red will be decreased from 40 to 50 per cent. by the addition of volume now substracted by the outlet."

The report of the Commission of 1886 states that "no instructions have been received for carrying out the foregoing plan." During 1888 construction on the sill dams in the Atchafalaya below Simmesport, La., was started, in line with recommendations previously made by the Commission. The first sill dam was located 500 ft below the mouth of the Bayou des Glaizes. This report contains complete descriptions and analyses of a number of plans for handling the Red River-Atchafalaya Basin problem. These data appear to be segregated about as follows: (1) Major Stickney's plan (six submerged sill dams); (2) Eads' plan (to cut off the Atchafalaya River with a high dam at the head); (3) canal and lock plan (cut the canal, Mississippi to Atchafalya Rivers, with locks therein); (4) Mississippi River Commission plan (includes Plan (1) and also a plan to shut off the connection between the mouth of the Red and the Atchafalaya Rivers with a sill dam on the west side of Turnbull's Island); and (5) variation of Plan (4) (includes a long jetty from the lower point of Turnbull's Island extending into the Mississippi to prevent direct flow from the latter into Old River).

---

[14] Annual Rept. of Mississippi River Comm., 1885, p. 2872; Appendix WW of the Annual Rept. of the Chf. of Engrs., 1885.

The report of 1889 indicates that Plan (5) had been adopted for handling the situation. During the year the upper sill dam in the Atchafalaya was practically completed and the second sill dam had been commenced. This second dam is located 1 750 ft down stream from Sill Dam No. 1. The report of 1890 shows the completion of the second sill dam on August 27. During the months of September, October, and November, 1890, the sill or lower course of a sill dam was constructed across Old River, $\frac{3}{4}$ mile down stream from Sugar House Chute. The reports of 1891 and 1892 show progress on the construction of this sill dam, which was practically completed in 1892.

To summarize, then, from 1804 to 1840, the Atchafalaya was completely blocked by rafts and received very little flood water from the Mississippi River. In 1852, according to an estimate by Charles Ellet, a Civil Engineer employed by the Government, it was handling one-twelfth of the Mississippi discharge. In 1882, Mr. Eads estimated that it was carrying approximately one-sixth of the Mississippi River outflow. At present (1935) the Atchafalaya is discharging, during flood periods, a levee-confined volume of about 500 000 cu ft per sec, or one-third of the discharge of the Mississippi River below Red River Landing. The sill dams, the construction of which has been mentioned previously, were designed and built in order to restrict the discharge of the Atchafalaya to about 200 000 cu ft per sec, which was estimated to be the discharge of the Red River while in flood at that time (1882). These dams did not restrict the Atchafalaya to a capacity of 200 000 cu ft per sec, due to later increased flood heights caused by the construction of higher and stronger levees. Both sill dams are alike in design and construction. The base or sill consists of a willow mattress, 3 ft thick, and 304 ft long, up stream and down stream, loaded with rock. Upon this sill were built three courses of willow mattress, 100 ft, 66 ft, and 30 ft in width, respectively, each course being covered with successive layers of hard clay and gravel. The up-stream edge of the dam is 20 ft below the upper edge of the sill. The entire structure was given a heavy covering of rock.

Conclusions

Except where indicated the gauge and discharge readings in this paper are not affected by crevasses, cut-offs, levee extensions, or enlargements. At the gauge stations along the Mississippi River, at Columbus, Ky., Arkansas City, Ark., and Helena, Ark., the flow is not subjected to unrestricted diversion and the same volume of water is now passing at the same elevations as in earlier years. At these points the river is not silting, but a variation in gauge due to "efficiency" influence of approximately 3 ft can be expected for the same volume of water. Overbank diversion occurred at the Arkansas City gauge station prior to 1921 through the gap at Cypress Creek, a short distance above, without affecting the gauge in passing the same volume of water.

At Red River Landing, the Mississippi River is divided into two levee-confined outlets to the Gulf, permitting diversion from the Mississippi into the Atchafalaya River at all stages, except when higher stages occur in the Red River. The higher stage in Red River is infrequent compared to diversion from the Mississippi. This division of the river causes a drop in velocity

below the point of diversion over the velocity of that above, the difference being greater as the volume diverted increases. This checking of the current in flood time causes a deposition of some part of the silt load, and it is in this manner that Nature provides the means of the river's adjustment. The greater the diversion, the greater will be the difference between the velocity above and below, and, consequently, the greater the deposition of silt below the point of diversion. The levees on the main river were raised and strengthened, thus causing levee confinement to larger volumes of water. Increased flood heights resulted and raised the average flood peaks at Red River Landing 7.3 ft between the periods 1867 to 1886 and 1912 to 1933. This peak-flood increase caused larger volumes of water to be diverted from the Mississippi through the Atchafalaya. The Mississippi River below the point of diversion, adjusted itself progressively with increased flood heights and consequent increase in diversion by the river channel being partly closed by a silt-deposited dam. This dam increased the river slope for the loss in volume diverted and raised the gauge 6.9 ft to discharge the same volume of water since 1882. The close relationship between the increase in peak-flood heights and the increase in gauge for discharging the same volume of water is apparent as only a difference of 0.4 ft exists.

At Carrollton the gauge has been raised between 3 and 4 ft since 1882 in passing the same volume of water. Definite proof as to the cause of this increase is not available. The head of the Atchafalaya is fixed by the water elevation in the Mississippi River at Red River Landing. Consequently, the slope has been adjusted by silt deposited below the lower limit of the levee influence. Although the velocities have decreased in the Atchafalaya with the diminished slope the increase in bank-full cross-sectional area of 47% since 1904 has kept pace and offset the effect of slope reduction, so that the same volume of water at this time is passing the same gauge height as it was in 1890. This balancing of the lessened slope by the enlargement in cross-sectional area has made it possible to increase the volume of discharge through the Atchafalaya only by increased flood heights in the Mississippi River. This is definitely shown by the discharges of the Atchafalaya River at Simmesport for a high gauge of 50 in the Mississippi River (see Table 9, Items Nos. 1, 2, 4, and 7).

The distance from Red River to the sea *via* the Mississippi River is 310 miles and *via* the Atchafalaya River, 125 miles. The shorter distance and steeper slope afforded by the Atchafalaya appears to be a logical course for the Mississippi River to follow. This condition existed for centuries before Man made levees, giving every opportunity for the Mississippi River to take advantage of this short route to the sea if Nature so desired. Through the manner in which the river treats the silt load the shorter route to the sea is blocked and, in addition, makes it necessary to increase the head to increase the discharge. The discharge of the Mississippi River at Red River Landing is 35 000 cu ft per sec per ft of gauge. The increase of 6.9 ft in gauge since 1882 at Red River Landing for a discharge of 1 100 000 cu ft per sec means that the Mississippi River has lost 240 000 cu ft per sec in discharge capacity. At the same time, the discharge of the Atchafalaya River at Simmesport

increased 129 000 cu ft per sec, due to this additional head of 6.9 ft. The combined loss in discharge capacity of 111 000 cu ft per sec results from unrestricted diversion.

The Mississippi River has conformed itself to the hydraulic theory and increased its slope as the volume has been diminished through diversion. Likewise, the Atchafalaya River has conformed itself to the hydraulic theory and flattened its slope as its volume increased through diversion. It is obvious that the vicious cycle of conditions set up through unrestricted diversion from the Mississippi into the Atchafalaya results in a large loss in "efficiency."

The treatment of the silt load by a silt-bearing stream is its powerful agency of adjustment to changed conditions. The detrimental effects resulting from this power to adjust itself to changed conditions is reflected clearly in the loss in discharge capacity of the Mississippi River at Red River Landing due to unrestricted diversion at all stages. By eliminating diversion below bank-full stage a major portion of this power of adjustment is overcome as it will disturb to a minor extent the greater portion of the silt load that is handled along the bed of the channel. Furthermore, the agency is provided for waters below bank-full stage, acting for 365 days to clean out any deposition of silt left after the short duration of over-bank diversion. This method of diversion will practically restore the channel to its original discharge capacity and so maintain it. The slight loss in cross-sectional area during overbank diversion at Pointe a la Hache and the fact that overbank diversion occurred at Arkansas City for a number of years did not reduce the discharge capacity of the river, substantiate the conclusion that overbank diversion will not cause the ill effects suffered from diversion at below bank-full stages.

DISCUSSION

LEO M. ODOM,[15] ASSOC. M. AM. SOC. C. E. (by letter).—Certain proofs and deductions are set forth in this paper, based on data and theory, which merit the consideration of students of the subject of the control of the Mississippi River and its tributaries. Among such students may be counted, to a greater or less extent, practically every engineer who resides in the Mississippi Valley.

Apparently, the author begins with the hypotheses: (1) That at points on the Mississippi River not affected by diversion operative at all stages, the same volume of water is now passing at the same elevation as in earlier years; (2) that the Mississippi River has conformed itself to "the" hydraulic theory and increased its slope as the volume has been diminished by diversion; and (3) that the Atchafalaya River has conformed itself to "the" hydraulic theory and has flattened its slope as its volume has been increased through diversion. The hydraulic theory from which the second and third premises were deduced is presented with discussion to show how it was interpreted to arrive at the hypotheses and to explain the causes underlying the action. Selected data from the records of the Mississippi River Commission for the years 1882 to 1932, inclusive, are presented and discussed. By consideration and interpretation of the data, the author concludes: (*a*) That the hypotheses are correct; (*b*) that the first is correct through simple consideration of the data presented; (*c*) that the data presented show that the Mississippi River has actually increased its slope and that the Atchafalaya River has actually decreased its slope during the period in which records were examined, as set forth in the second and third premises; and (*d*) from the fact that the first premise is true, and from consideration of the theory cited, that the cause of the noted phenomena in connection with the second and third premises is the fact that diversion is permitted from the Mississippi River into the Atchafalaya River at practically all stages.

Besides concluding that his hypotheses are proved, the author arrives at certain other conclusions and hypotheses. He deduces from data presented as to the Pointe a la Hache crevasse and study of the discharge measurements at Arkansas City, Ark., near which many crevasses have occurred, that overbank diversion does not cause the same action as "year-round diversion" and that if overbank diversion were substituted for the present continuous diversion through Old River, the main channel below that point would be practically restored to its original discharge capacity. He theorizes that the difference in effect between year-round diversion and the overbank diversion is due to the fact that (1) the greater portion of the silt load that is handled along the bed of the channel is accorded less disturbance with overbank diversion only; and (2) with diversion occurring only at stages above bank-full, an agency exists, acting for 365 days per yr, to clean out any deposition of silt left after the short duration of overbank diversion, which agency presumably does not exist in full force at points of year-round diversion.

[15] Asst. Engr., 2d New Orleans Dist., U. S. Eng. Office, New Orleans, La.

He concludes from the fact that the Mississippi River had not previously taken the shorter course to the sea offered by the Atchafalaya, that the normal action of the stream, determined by its silt load, caused the longer route to be followed and the shorter to be blocked. He deduces from comparative data that the total discharge of both rivers at equivalent gauge readings is less now than formerly, which he explains to be the result of the action set forth in his hypotheses.

The writer concludes from the remarks in the content of the paper that the first premise as stated in the "Synopsis" should also include cut-offs as well as the diversion referred to, as affecting the author's choice of gauge stations for analysis in this regard. Except for this fact, and the warning that the premise can hardly be supposed to be proved by consideration of so few stations in the total length of the river, no more will be said about this premise.

As to the last two premises, proof will be offered in this discussion that "the" hydraulic theory referred to therein is not at present generally accepted and that evidence is against its application to the Mississippi River. The possibility of other interpretation of the data presented will be advanced, and the probability of causes other than the fact of diversion for the bar below Red River Landing will be discussed.

The hydraulic theory referred to in the second and third premises is apparently the theorem of Guglielmini[2] cited under the heading, "Introduction." Commenting on this theorem, Humphreys and Abbot did not state as a fact the quotation attributed to them in the paper. The entire discussion in the "Report on Physics and Hydraulics of the Mississippi River", which contains the statement of Guglielmini's theorem and the aforementioned quotation is stated therein at the beginning of the paragraph to be an "extract from the writings of Maj. J. G. Barnard, Corps of Engineers, U. S. Army", and is given for the express purpose of refutation.

Commenting on this theorem and Major Barnard's remarks, Humphreys and Abbot state: "It will be noticed that two important assumptions are necessary to support this reasoning: First, that the bottom of the Mississippi River is composed of its own alluvion, which can be readily acted upon by the current; and, second, that its water is always charged to the maximum capacity allowed by its velocity."

The first assumption is then attacked on the grounds that the bed of the river is not composed of its own alluvion, but of a tough and stiff clay which they suppose to have had its origin in a more ancient geologic period than that of the river itself. This supposition as to the ancient geologic formation of this clay probably is incorrect, but it is still a fact that there is a very extensive clay stratum interspersed with shell and sand pockets throughout the entire valley from the ancient delta to the sea. This clay was more probably formed by the deposition at its mouth of the fines and colloids in the sediment carried by the river as it came into contact with the salt water of the ancient bay. Regardless of its origin this clay exists; it is quite compact and is not readily scoured, and forms the bed of both the Atchafalaya and

the Mississippi Rivers. The existence of this difficultly erodible clay has been the cause of the failure of the Atchafalaya to cut itself an hydraulically efficient channel to the Gulf and has resulted in the spreading of that stream, past the confining influence of its levees, into numerous shallow branches (which in times of flood overflow over the entire basin), the frictional resistance of which system retards the velocity in the channel and prevents its discharge from increasing in the same ratio as if it, too, had a single channel to the sea.

The second assumption that Humphreys and Abbot state is necessary for the river action to conform to the hydraulic theory—that its water is always charged to the maximum capacity allowed by its velocity—is proved by them to be wrong by presentation of the analyses of sediment content of the river water at various velocities, which analyses were conducted in 1851-52 and 1858 at Carrollton, La., and Columbus, Ky. They state that, "at the date of highest water the river held in suspension little more sediment than at dead low water." They state[16], also, referring to tests made in 1851: "When the quantity of earthy matter held in suspension was greatest, the velocity was 2 feet per second less than the greatest velocity."

In a paper on "Permissible Canal Velocities" by the late Samuel Fortier, M. Am. Soc. C. E., and Fred C. Scobey, M. Am. Soc. C. E., which constitutes a final report of the Special Committee of the Society on Irrigation Hydraulics, the following statement[17] is made:

> "It is believed that there is a broad belt of velocities between the two 'critical' velocities, within which silt already loosened or brought in through a head-gate will remain in suspension while the bed nevertheless will remain undisturbed as regards scour. It is easy to show the absurdity of accepting the laws of silting as giving immediate answer to the laws of scour."

Any number of references and detailed sediment analyses disproving the theorem of Guglielmini could be cited from published documents of the U. S. Corps of Engineers, but it is believed that, with the complete citation of one of the author's own authorities and the foregoing additional reference, the writer has shown that part of the progress of the science of river hydraulics since the Seventeenth Century has consisted in the abandonment of the erroneous theorem.

The data presented are found to have been accurately copied from the published documents of the Mississippi River Commission. The choice of bank-full stage as the proving ground for the hypotheses and the "efficiency" assumption will be accepted although bank-full stage occurs too seldom in the 365 days to be sure that it is as logical a stage on which to base the proof as a lower one.

If the theory by which the author arrived at his hypotheses had been one generally accepted by the Engineering Profession and data had been presented for down-stream points which bore some relation to the data presented for Red River Landing, the writer would have been more inclined to have

[16] "Physics and Hydraulics of the Mississippi River", p. 674.

[17] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 941.

accepted the second hypotheses as borne out by the data. Without adequate theoretical basis, however, the statement that the Mississippi River has increased its slope as the volume has been diminished by diversion, rests entirely upon the gauge records at Red River Landing. At Carrollton—the only down-river point treated—the gauge height for bank-full discharge has not varied appreciably in the last 45 yr. As one outstanding example of a case wherein the data do not even show a continuous growth of bar at this point, the interpolated gauge height given for the chosen discharge at Red River Landing was 49.4 in 1903, whereas, in 1932, it was 49.0. The entire period of study was less than twice this interval. That a bar has formed and at times washed out below Red River Landing is evident and known to every one familiar with the river. The formation of this bar might as well be due to the angle of diversion or to the bend in the river, or both, as to the mere fact of diversion.

There are three points in the lower river where diversion occurs at all stages: Baptiste Collette's Bayou, 83 miles below New Orleans in the east bank; Cubit's Gap, 91 miles below New Orleans, in the east bank; and The Jump, 84 miles below New Orleans in the west bank. No records are kept on these streams ordinarily. Measurements during the flood of 1927 show a maximum discharge through Baptiste Collette of 13 689 sec-ft, through Cubit's Gap, of 134 288 sec-ft, and through The Jump, of 32 511 sec-ft. No shoaling of the main stream in the vicinity of these outlets has ever been noted.

At Head of Passes, 94½ miles below New Orleans, the river breaks up into three principal outlets: Pass a l'Outre, South Pass, and Southwest Pass. The average discharge through the passes in percentage of the total volume at Head of Passes is approximately: Pass a l'Outre, 42.5%; South Pass, 17.5% and Southwest Pass, 42 per cent. A point bar forms at the head of Southwest Pass and a tendency to scour is noted at the heads of the other two passes. Sills were placed across the head of Pass a l'Outre in 1876 and 1900 in an attempt to increase the flow through the other passes. The record of the action has been that the discharge through Pass a l'Outre was not reduced, but a turbulence was created which scoured the bottom of the channel to a depth of 122 ft between Pass a l'Outre and South Pass. A mat sill placed across the Head of South Pass in 1917 for the purpose of holding stationary the discharge in South Pass which had increased from 7% of the river's flow in 1891 to 14.7% in 1917, did not succeed in its purpose, but produced a hydraulic jump that scoured the bottom of the channel of the pass below the sill to a depth of 129 ft. The sill dams mentioned were similar in construction to that referred to by the author.

It is seen from the foregoing that the fact of diversion does not necessarily create bars in the main stream. The point bar which forms across the head of Southwest Pass is due to the direction of the thread of the current across Head of Passes and the fact that Southwest Pass takes off on a curve from the course of the river above this point.

It is also apparent that sill dams have not been found to be efficacious in the control of discharge. The percentage of discharge has been found to be

regulated by the total resistance to flow offered by a channel and regulatory works offering resistance relatively minor in comparison to this total have little or no effect.

As to the third of the three premises, practically no proof is offered. Much is made of the fact that the average cross-sectional area of the stream increased 47% during the period embraced by the study. It is evident that practically all this large increase in average cross-sectional area is caused by the enlargement in the lower end due to extension of levees. At Reach 6, for instance, the enlargement has been only 4.17 per cent. The author is correct in stating that the capacity of the Atchafalaya has not been increased by its increased cross-section since this increased cross-section has not extended to a point where the stream can finally discharge freely. Increased cross-section will be of advantage only when and if levees are extended to Grand Lake and a pilot cut furnished between them, as the Atchafalaya probably never will be able to cut itself an efficient channel through the stiff clay of the basin. Its enlargement at its source, due to scour, when it acts as the outlet for the relatively clear back-water area of the upper basin, is also useless as far as getting any water out the other end is concerned.

The author concludes that the fact that the Mississippi has never taken the shorter course to the sea offered by the Atchafalaya proves that the longer route is the one determined by Nature in its handling of the silt load. Another hypothesis is offered herein taking into account observed action at the Passes, a study of the course of the Mississippi River below Red River Landing, and the conclusions of geologists.

Geologists state that at one time the Mississippi River discharged into an estuary which reached farther north than Red River Landing and that in time it has completely filled this estuary and extended its delta out into the Gulf. The material of which this fill is formed, to approximately mean Gulf level, is preponderantly a stiff silty clay interspersed with sand and shell pockets with apparent remains of ancient forests found at different levels below mean low Gulf level. The toughness of this clay is attributable to the flocculation of the colloids when the silt-laden waters came in contact with the Gulf. The remains of forests give rise to the assumption that the old fill has settled and compacted and that new fill has formed on top of it in a manner similar to that occurring at the mouths of the river to-day.

As the river built itself out of its estuary, it became more and more acted upon by the littoral currents and littoral drift and the prevailing winds. The effect of these agencies is quite apparent at the mouth of South Pass. There, the sea channel at the entrance makes an angle of 36° with the axis of the Pass, and the sediment of the river is piled up on the west bank of the channel. The river does not flow into this sea channel, which is kept clear by the littoral current, but spreads out in a fan-shaped area on top of the salt water. When the bar becomes so extensive to the west that the friction is greater than the force it would take to move the salt water out of the channel, the river water will penetrate farther into the channel and thus its bed is continued on out to sea.

From Baton Rouge, which is near the limit of the ancient estuary, to the Gulf, the easterly trend is particularly to be noted, as past this point the mouth of the river was subject to the full action of the winds and Gulf agencies. From Red River Landing to Baton Rouge it will be noted that the river is near the eastern limit of the estuary with the main delta to the west.

It is believed that this hypothesis offers a better explanation for the present location of the main river than that based on the theorem of Guglielmini offered by the author; especially since it is evident that it has not always been 310 miles from Red River Landing to the Gulf by way of the Mississippi River.

The land structure now existing between the head of the Atchafalaya River and the Gulf creates an entirely different condition than that which existed when the mouth of the Mississippi was in the vicinity of Red River Landing. The sea agencies and prevailing winds which closed off the westerly outlets at that time would now affect only the mouth of the Atchafalaya.

As to the conclusion of the author that overbank diversion offers a solution to the evils attributed to continuous diversion, it is remarkable that he should have chosen as his basis for argument against continuous diversion the same theory advanced generations ago against overbank diversion.

E. W. LANE,[18] M. AM. SOC. C. E. (by letter).—Briefly stated the author's contentions are:

(1) That the discharge capacity of the Mississippi River below Red River Landing has deteriorated considerably during the past fifty odd years.

(2) That this deterioration has resulted from a deposit of silt in this stretch which has reduced the channel area.

(3) That no corresponding deterioration has occurred in the channel capacity above Red River Landing.

(4) That the deposit below Red River Landing has occurred due to the diversion of water from the Mississippi at all stages through Old River, in conformity with the hypothesis of Guglielmini.

(5) That the slope of the Atchafalaya River has decreased in agreement with this same hypothesis.

The writer's discussion will cover these five points in order.

If, as the author contends, a reduction has occurred in the discharge capacity of the Mississippi River below Red River Landing in the 50 yr following 1882, of about 7 ft for a discharge of 1 100 000 sec-ft (which is equivalent to a reduction in discharge of about 250 000 cu ft per sec), it is a matter of major importance in connection with the flood control of the Mississippi River. Should this continue in the future, continuous construction will be necessary to prevent a progressive decrease in the degree of flood protection given by any system of works which does not remove the cause.

The method used by the author to prove this contention is sound, although so far as the writer knows it has not heretofore been used extensively, if at all.

---

[18] Prof. of Hydr. Eng., State Univ. of Iowa, Iowa City, Iowa.

In order to check his results the writer has investigated the effect in a similar manner for the same discharge, and for discharges other than those used by the author. All current meter measurements, available to the writer, between 1 150 000 and 750 000 cu ft per sec have been used. The stages for each discharge within 50 000 of the even 100 000 cu ft per sec were adjusted to the nearest even 100 000 by using the discharge increment corresponding to that discharge, in a manner similar to that used by the author. All measurements that might have been affected by crevasses have been eliminated, except in 1882. Since the stages used in this year are so little, if any, above the bank level, the effect of crevasses on discharge would be negligible.

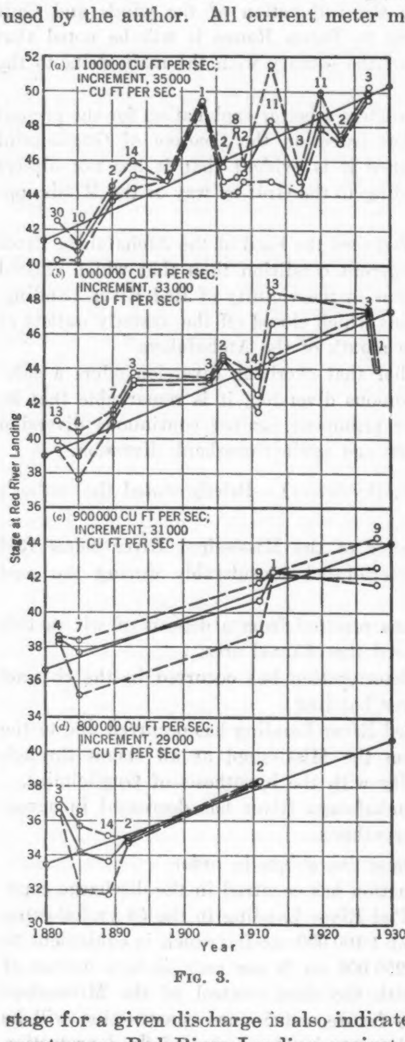

FIG. 3.

The results of these studies are shown on Fig. 3 in which the adjusted stages are plotted against their respective years for each of the four discharges. The solid line joins the points indicating the mean of the adjusted stages in each year. The lower dotted line joins points showing the lowest adjusted stage and the upper dotted line joins the points giving the highest adjusted stage. Above each set of points is given the number of observations on which the points were based. For each discharge a mean line has been drawn showing the general trend.

In each case the trend is unmistakably upward, the slope magnitude increasing somewhat with the discharge. This increase of stage for a given discharge is also indicated by plotting the discharge measurements near Red River Landing against stage, which is just another way of presenting the same data. A similar indication may be noticed in the Carrollton gaugings.

In Fig. 4 are plotted discharge rating curves for the years 1880 and 1930—based upon points taken from the mean lines of Fig. 3 at those years—for

the four discharges investigated. These curves have been extended by dotted lines to zero discharge at Gulf level (Elevation − 3.57 on the gauge) to indicate approximately the difference at other discharges. A comparison of these rating curves indicates very strongly that a reduction of the discharge capacity has occurred. The curves indicate a decrease of discharge capacity in 50 yr, at a 40-ft stage, of about 250 000 cu ft per sec.

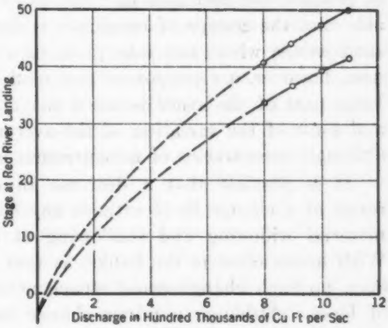

FIG. 4.—DISCHARGE RATING CURVES FOR 1880 TO 1930.

The evidence presented by the author that the maximum stages reached during the years since 1867 were tending to increase also is evidence pointing to deterioration, but is not so definite as the evidence based upon discharge, since the maximum stage reached in high-water years depended upon the strength of the levees, as the author states under "Conclusions." However, since the great flood years are few in number, the effect of the increasing strength of levees would probably be small. The value of 7.3 ft found by this method is not exactly comparable to the 6.9 ft found by the hydraulic method, since, assuming a uniform rate of deterioration, the 7.3-ft rise would occur between the middle of the first and the middle of the last period for which the stages were averaged, or 56 yr, whereas the period covered by the discharge method was 50 yr. The rise for 50 yr instead of 56 yr, assuming a uniform variation, would be 6.5 ft.

The author's second contention is that the deterioration of channel capacity below Red River Landing is due to a reduction of the channel area caused by a deposit of silt. A general form of equation for the discharge capacity of a river is:

$$Q = C\,A\,R^m\,S^n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

A reduction in capacity can result from a decrease in one or more of the elements, C, A, R, or S. For the Mississippi River below Red River Landing it can scarcely be due to a decrease in the slope, S, since the river discharges at a constant elevation into the Gulf of Mexico, and, for a given stage at Red River Landing, the average slope through this section of the river must be constant, both the fall and the length remaining the same. Small local or temporary changes of slope occur, but these changes tend to re-adjust themselves since the average slope cannot change. It seems improbable that a change in capacity could have resulted from a change in the value of C, the roughness factor. Except for the negligible increase in roughness, which no doubt occurred as a result of the construction of wharves and other works of Man, no reason is apparent to cause a permanent change of roughness in this section of the river, and so far as known, no one has ever suggested that one has taken place. Temporary changes of roughness, described by the author

as changes of "efficiency" however, do occur. The writer believes that these changes are to a greater extent due to changes in roughness than to deposits of silt, since the silt load of the river is insufficient to cause enough deposit to produce the decreases in "efficiency" as rapidly as they occur. It is probable that the change of roughness is due to the formation and obliteration of sand waves, which can take place in a short time. These changes of roughness, however, are temporary and tend to equalize over a period of years. A large part of the space between the upper and lower dotted lines in Fig. 3, and some of the variation of the average line, is no doubt due to this cause, although inaccuracies of measurement also form a part of this difference.

It is possible that a decrease in discharge capacity could occur as a result of a change in R without any change in A. This could result from a material widening and shallowing of the river without a change in area. With levees close to the banks, as they are in this stretch of the river, however, no such change could escape notice, as it would endanger many miles of levee. Although a minor change in width may have occurred, since no general widening has taken place, it seems safe to conclude that no appreciable deterioration has resulted from a change of the hydraulic radius except as it may have occurred as a result of a decrease in the channel area. Since the other possibilities seem to be eliminated, it is very probable that any deterioration that has occurred in the channel capacity below Red River Landing has been caused by the deposit of silt in the river bed, causing a decrease in the area, A, and a corresponding decrease in the hydraulic radius, R.

The stage-discharge curves of Fig. 4 indicate that the increase in stage is different for each discharge. This shows that the amount of the filling of the bed cannot be determined by taking the difference in the stages at the ends of the period for any given discharge since the result obtained would depend upon the discharge selected. It should be possible, from the dimensions of the channel, and the slope at the beginning of the period, to compute the amount of the filling (assuming it to be distributed in proportion to the distance from the Gulf) which would cause the deterioration indicated, but it cannot be determined from the stage differences alone.

The third contention—that no material deterioration has occurred above Old River—seems well established, since it is supported not only by the discharge measurements but also by the measurement of great numbers of cross-sections, which show a small increase in area. Because of the variation that may occur at any one cross-section in the river (due to the passage of a sand wave or from a number of other causes) reasoning regarding the action of the river bed based upon a few measurements at one cross-section, or in a stretch of river, while useful as evidence, is not very conclusive. For this reason too much weight should not be given the data presented by the author showing the loss of cross-section at Red River Landing during the high waters of 1929 and 1932; nor to the measurements of the areas at the two ends of the Pointe a la Hache diversion. However, when arguments are based upon hundreds of cross-section measurements scattered over a stretch of river

and, to a lesser extent, on many measurements at a given locality spread over a long period of time, they should carry considerable weight.

The fourth contention (that the deposit below Old River was caused by the diversion of water from the Mississippi at all stages through Old River, in conformity with the hypothesis of Guglielmini), is likely to provoke considerable discussion. Probably no engineering controversy has continued so long and resulted so inconclusively as that dealing with the Guglielmini hypothesis and its application to the Mississippi River. As early as 1816 this hypothesis was used as an argument against spillways for flood control. It was strenuously combatted by Humphreys and Abbot, as a result of their studies, and strongly supported by Eads, who applied it with great success to the deepening of the South Pass at the mouth of the Mississippi by jetties in the years 1875 to 1879. Largely as a result of this success, the hypothesis was adopted by the Mississippi River Commission as a basic principle; but as a practical means of flood control it proved nearly a complete failure. Nevertheless, it exerted a strong influence on the policy of the Mississippi River Commission until the 1927 flood and was a considerable obstacle in the path of flood control by spillways until it was forced into the background by the strength of the sentiment for spillways which developed as a result of that flood. With the author's paper it has come to the fore again. It is greatly to be hoped that the truth or fallacy and the bearing of it may be established, as the uncertainty has been a serious obstacle in the way of establishing a sound flood-control policy for this great river.

Personally, the writer is now inclined to accept the Guglielmini hypothesis, although at one time he was very skeptical of it because of the difficulty (which has since been removed) of reconciling the apparently conflicting evidence when applying it to the Mississippi River. Of course, the wording of the Seventeenth Century does not fit in with the modern more exact conceptions, but it should be remembered that no such accurate conceptions existed at that time. Moreover, part of the inexact expression may have been caused by inapt translation. Perhaps the greatest argument against the hypothesis, as far as the Mississippi River is concerned, is its apparent failure when applied by the Mississippi River Commission to flood protection. By plotting a mean relation of the silt load carried by the Mississippi and applying this relation to the discharge of past floods as they would have occurred had no levees been built, and again to these same floods under conditions of confinement actually produced by levees, it can be shown that the small enlargement which has taken place in the river is all that the Guglielmini hypothesis would indicate.

The error of the members of the original Mississippi River Commission, therefore, was not in believing in the Guglielmini hypothesis, but in not using the data available to them and applying the hypothesis quantitatively to their problem. It is believed that an application of the foregoing method to the conditions in the relatively short stretch at the mouth of the river covered by jetties (where the action went on for 365 days per yr) would show that it should succeed in that case when it failed in the case of flood control. A similar application to the reduction of flow in the Mississippi

below Red River Landing, due to the greater discharge down the Atchafalaya, would throw valuable light on the action of the river in that stretch.

Another argument against the Guglielmini hypothesis is that used by Humphreys and Abbot based on the fact that they found no exact relation between the discharge and the silt load of the river. Recent studies[19] have shown why this is not necessarily a disproof of the theory. The writer believes that when applied quantitatively, with due regard to the time element involved, the Guglielmini hypothesis will be found to be a sound general relation as far as it goes, although of course many other factors may enter to prevent its working out in special cases. The hypothesis is incomplete, in that it does not consider the variation of the solids load as a factor, and to make accurate prediction this factor also must be added.

Independent, however, of the soundness of the Guglielmini hypothesis, if silting is progressing below Red River Landing and not above that point, it is logical to expect the cause of this silting to be something operating below that point and not above it. One of the strong arguments in favor of the applicability of the Guglielmini hypothesis to this case would seem to be the difficulty of explaining the apparent decrease of capacity below Old River without utilizing it.

Diversion through Old River, however, is not the only phenomenon that might cause the deposition below that point, according to the hypothesis of Guglielmini. Before the removal of the raft from the Atchafalaya River, probably the greater part of the flow of the Red River reached the Mississippi; now only a very small part of it reaches that river. This diversion to the Atchafalaya of the greater part of the flow of the Red River may have a greater effect on the Mississippi channel below Red River Landing than the flow that passes out of the Mississippi through Old River. Judging from the size of the trees said to be growing around these rafts and the damage that followed the removal of the raft, it is reasonable to suppose that the flow down the Atchafalaya had been small for many years, and, therefore, that the greater part of the Red River flow had passed down the Mississippi. In a long period of time the Mississippi would have adjusted itself to this flow and when it was practically discontinued as a result of the enlargement of the Atchafalaya, the effect would be much the same as if that quantity of water had been abstracted from the Mississippi through Old River. In considering the action of the Guglielmini hypothesis on the Mississippi below Red River Landing, therefore, it is necessary to consider not only the actual diversion of water from the river through Old River, but also the diversion of that part of the Red River flow which formerly entered the Mississippi, but now passes down the Atchafalaya. In this problem the character of the solids load of the Red River is a factor and would have to be considered to arrive at accurate quantitative results.

A silting up of the river might take place during a series of dry years, but this would be expected to occur along the length of the stream not just in one part. However, the bottom of the river in the section below Old

[19] *Engineering News-Record*, Vol. 115, October 17, 1935, p. 538.

River is considerably below sea level and the flow section there would not decrease with decreased flow as rapidly as in sections of the river farther up stream. This would give rise to relatively lower velocities below Old River in low-flow periods, and hence more tendency to silt. Whatever the cause of the decreasing capacity, it seems to have been acting fairly continuously throughout the past fifty years, and if it is due to a long-continued drought it would be necessary to have longer rainfall records than are available to prove it. Some light might be cast on this question by tree-ring studies if they covered the entire drainage area of the river.

The author's proof of his fifth contention, that the slope of the Atchafalaya River has decreased in agreement with the Guglielmini hypothesis, is not very complete. He has shown that the Atchafalaya has enlarged materially in cross-section, that the bank elevations along the stream have become higher, and he has given data tending to prove that a discharge of 300 000 cu ft per sec occurred at substantially the same stage from 1890 to date. Since the area was increased and the discharge remained the same, the velocity has been reduced, and he concluded, therefore, that the slope had been reduced enough to cause this decreased velocity. As previously stated, the general discharge relation is $Q = C\ A\ R^m\ S^n$. If Q remains the same, the increase in area (and presumably the consequent increase in R) can be offset by a decrease in either, or both, C or S. Although it seems improbable that the value of C has changed in the Mississippi it is by no means improbable in a river scouring as actively as the Atchafalaya was during the period under consideration. The irregular cutting of the banks and bed which occurred under such circumstances might easily cause an increase in roughness. The great turbulence of the river is very noticeable at high flows, and the computed roughness factors show considerably higher values than an ordinary river channel.

The upper section of the Atchafalaya River has a comparatively steep slope and the lower section, which is composed largely of shallow lakes, has a very flat slope. The material scoured from the upper end as the river enlarged, and a considerable part of the silt load brought into the upper end of the river, has been deposited in the upper end of the shallow lakes and has formed a delta. This condition has caused a rise in the water level at this point and, to this extent, a decrease in the slope of the Atchafalaya. The rise in level has been strikingly shown by the tendency of the water about 1926 to flow to the Mississippi through the Plaquemine Lock, whereas, formerly, it always tended to flow in the opposite direction. It is probable, therefore, that there is some decrease in slope of the upper end of the Atchafalaya, due to its tendency to form a delta at the head of the lakes; but it seems doubtful whether this would be enough to offset the increase in both area and hydraulic radius which occurred as a result of the enlargement of the river bed. The late John Augustus Ockerson, Past-President, Am. Soc. C. E., has shown[20] that the enlargement of the river was due largely to the concentration of velocities that occurred as a result of the steep slopes where the water spread

[20] *Transactions*, Am. Soc. C. E., Vol. LVIII (1907), p. 1.

out at the end of the leveed section of the river, and the progressive moving down of this high-velocity section as the levees were extended. It is probable that the decrease of slope which offsets the increased area is due largely to the extension of the confinement of the river by levees, which occurred during the period of river enlargement. Immediately preceding Table 11 the author states that the increase in gauge height at Melville between 1892 and 1907 is due to levee confinement. An increase of stage at Melville, the level at the upper end of the river remaining the same, would result in a flatter slope.

On the whole the author has presented a strong argument to support the contention that the discharge capacity of the Mississippi below Old River is decreasing. As a result of his studies of Mississippi River hydraulics, however, the writer has learned that different, apparently equally good, lines of proof sometimes lead to directly opposite conclusions and, therefore, every available method should be used before a final conclusion is formed. It would seem that the best way to prove or to disprove a contention that the stretch of the Mississippi below Old River had been filling would be to make another cross-section survey similar to that made from 1893 to 1898. The writer could find no published record of such a survey since that date. This method and any other possible method of indicating the deterioration, should be investigated so that its existence can be established or disproved as conclusively as possible. Other possible investigations that might throw light on this subject are a study of the frequency of the various stages below Old River throughout the period of record and a comparison of the area below a certain datum in the cross-sections shown by the discharge measurements at Red River Landing. A comparison of stage relations below Red River Landing, however, would probably not indicate the deterioration as the stages at all points are likely to be changed proportionally. In this section of the river, also, a comparison of low-water stages would not indicate deterioration because of the great depth of the water, even at the lowest flows.

Assuming that the deterioration is proved conclusively, it would seem that serious thought should be given to Mr. Eads' proposal to place a dam across the upper end of the Atchafalaya and force the ordinary flow of the Red River down the Mississippi. The dam should be provided with gates which could be opened during floods to make available the discharge capacity of the river. A lock would have to be provided at this dam, and perhaps another lock and dam farther down stream would be required to take care of navigation.

If the deterioration is due to the working out of the Guglielmini hypothesis, any increase in the diversion down the Atchafalaya River at low or medium flows would increase the rate of deterioration and thus offset a part, or all, of the benefit from the increased diversion. Of course, it would be possible to increase the Atchafalaya capacity fast enough to keep ahead of the deterioration, but in the present state of the knowledge of such action it would be a race with an uncertain outcome.

The Guglielmini hypothesis has been used so often as an argument against flood control by spillways that an argument for the hypothesis might errone-

ously be considered to be an argument against spillways. The writer believes that much of the argument against flood-relief spillways based on the Guglielmini hypothesis has not considered the entire situation. When the first flood-control works were built on the Mississippi, the river had carved for itself a channel of a size which was a result of the action of a great variety of conditions in the past decades and probably did not change materially over a period of years. The construction of levees tended to confine the water and has caused an enlargement of the river channel. This enlargement is so much smaller than the proponents of the confinement theory expected that it has not been seriously considered, but it is all that the theory indicates should take place. A flood-relief spillway will cause some deposit in the river down stream from it, but here, again, the amount will probably be much smaller than the opponents of spillways anticipate. Since these spillways will operate only for short periods with considerable intervals between (during which time the channel will often carry increased flows due to the confinement by the levees of all the floods which do not bring the spillways into action) it is probable that the increased scouring caused by the levees will take care of the deposit caused by the spillway. Of course, the river below the spillway will not enlarge as rapidly as it would if no spillway was present, and the flow continued to be confined between levees; nor would it enlarge as fast as the river up stream from it, but there would probably not be a decrease in section. That the result would be a net enlargement is indicated by the increase in section area that has occurred in the river above Red River Landing in spite of the frequent occurrences of crevasses (which have the same effect as spillways).

The three effects, enlargement due to confinement by levees, deposit below spillways due to diversion through them, and deposit due to constant diversion or subtraction of tributaries, can be considered to act largely independently of each other. Whether the river fills or enlarges depends on the relative magnitude of the effects. Above Old River the enlargement due to confinement has been greater than the deposit resulting from crevasses. Below Old River the effect of the diversion and subtraction of tributaries, plus the deposits caused by crevasses, seems to have been greater than the enlargement due to confinement.

At present, it is not possible to give quantitative answers to what the effects of these various changes being made on the river will be, but with the rapid advance of knowledge of solids transportation in the last few years, and with the collection of a reasonable amount of data on the characteristics of the bed and suspended load of the Mississippi and its principal tributaries, it should soon be possible to make definite quantitative predictions based on adequate data and sound reasoning.

E. F. SALISBURY,[23] M. AM. SOC. C. E. (by letter).—The frank criticism and constructive comments in the discussions are appreciated. The discussion by Professor Lane assists materially in clarifying the paper and the writer is practically in complete agreement with his views.

[23] Chf. Engr., L. & A. R. R., Minden, La.

Professor Lane points out that, prior to the removal of the rafts from the Atchafalaya River, probably the greater portion of the flow of the Red River reached the Mississippi River and that now (1936) only a very small part of it reaches the main river. This diversion to the Atchafalaya of a greater part of the flow of the Red River may have much more effect on the channel below Red River Landing than the flow that passes out of the Mississippi through Old River.

The writer is not completely in accord with this view. If, during the period of this analysis, increasing volumes of water from the Red River were being diverted through the Atchafalaya, a resulting detrimental effect on the main channel is not questioned. However, although the Atchafalaya River has greatly increased in cross-sectional area, during the period of this study, it has not increased materially in discharge capacity; therefore, the conditions controlling the draw from the Red River have not changed during the time under consideration. The removal of the rafts in the Atchafalaya began about 1840 and was completed in the early Sixties; so there were from 20 to 40 yr for any channel adjustment before the earliest date used in the paper if the removal of the rafts would have the effect of drawing off more of the Red River discharge through the Atchafalaya than formerly. Consequently, it is believed that deterioration in the main channel below Red River Landing is due solely to diversion of water from the Mississippi through Old River.

In commenting on the slope of the Atchafalaya River, Professor Lane, states in part:

"Although it seems improbable that the value of C has changed in the Mississippi, it is by no means improbable in a river scouring as actively as the Atchafalaya was during the period under consideration. The irregular cutting of the banks and bed which occurred under such circumstances might easily cause an increase in roughness. The great turbulence of the river is very noticeable at high flows and the computed roughness factors show considerably higher values than an ordinary river channel."

For some time the writer has been of the opinion that when the silt load of a heavily laden stream is subjected to a major disturbance, causing either a considerable increase or a considerable loss in the silt load, such as that produced by a diversion of the flow, a material increase in roughness factor is immediately produced over that customarily used for ordinary river channels. Definite proof as to this thought is not available at this time. The observations of the effects at the cut-offs being made in the Mississippi River may produce valuable data in this direction.

Mr. Odom is correct that the reference to the Guglielmini hydraulic theory as mentioned in the Humphreys and Abbot report on the "Physics and Hydraulics of the Mississippi River" is an "extract from the writings of Maj. J. G. Barnard, Corps of Engineers, U. S. Army." The writer is indebted to Mr. Odom for clearing up this reference.

In preparing the paper it was the writer's intention to interpret correctly that which the Mississippi River is recording in so far as the data apply to the subject treated. To the writer's knowledge no data have been inten-

tionally selected or omitted. With this premise the data presented cannot be considered as selected as was intimated by Mr. Odom. On the basis of interpreting that which the river has recorded, it is premature to conclude that the "Synopsis" should include cut-offs as well as diversion. The further recordings of the river will be the answer to this separate problem. The reasons advanced by Mr. Odom as to the existence of a compact, and not readily scoured, clay in the bed of the Atchafalaya and Mississippi Rivers, are generally accepted. Furthermore, they apply to other silt-bearing streams and canals under certain conditions.

Below Red River Landing, the Carrollton gauge is the only recorded gauge and discharge study that provides data for analysis. Mr. Odom's statement that "at Carrollton the gauge height for bank-full discharge has not varied appreciably in the last 45 yr", depends upon the limitations as defined by the word, "appreciably." That the gauge has increased for the same volume of water is apparent from the gauge study. The increase in gauge for the same volume of water at Carrollton could not be expected to be of the same magnitude as that at Red River Landing as it is about 191 miles down stream on the slope. Furthermore, it could be expected that the gauge increase at Baton Rouge for the same volume of water will be less than at Red River Landing as it is about 60 miles below, and yet greater than at New Orleans, which is 124 miles farther down stream. Discharge observations are not taken in the Mississippi River at Baton Rouge. To study the action of the river at this point, gauge heights were listed for the day prior to the discharge of 1 100 000 cu ft per sec at the Carrollton gauge station. Table 13 shows the result of

TABLE 13.—COMPARATIVE GAUGE STUDIES

Location	Period	Years	Average gauge, in feet, for a discharge of 1 100 000 cu ft per sec.	Gauge increase, in feet
Red River Landing	1	1882–1885	41.3	...
	2	1890–1909	45.0	3.7
	3	1913–1932	48.2	3.2
Total	.....	....	....	6.9
Baton Rouge	1	1883–1891	34.0	...
	2	1892–1912	36.0	2.0
	3	1913–1932	38.3	2.3
Total	.....	....	....	4.3
Carrollton (New Orleans)	1	1883–1891	15.0	...
	2	1892–1912	16.6	1.6
	3	1913–1932	17.5	0.9
Total	.....	....	....	2.5

the gauge study at Baton Rouge, together with the studies at Red River Landing and Carrollton. It demonstrates clearly, the increase in gauge for discharging the same volume of water at three points on the Mississippi River below the diversion through Old River.

Prior to the flood of 1922 the largest reliable discharge recorded as passing New Orleans was 1 351 000 cu ft per sec, in 1897, at a gauge of 18.6 ft. The

flood of 1922 produced a gauge of 21.2 ft for a smaller discharge of 1 281 000 cu ft per sec. During the flood of 1890, a volume of 1 292 000 cu ft per sec passed on the gauge at 16.0 ft, whereas, in 1922, a volume slightly less passed at a gauge of 21.2 ft.

The volume of water diverted into the Atchafalaya is dependent upon the flood height in the Mississippi River. The higher the gauge in the Mississippi at Red River Landing the larger will be the volume of diversion, and the greater the deposition of silt below the point of diversion. The growth or change in the bar below Old River, therefore, is regulated by flood heights and will increase or decrease in extent with the increase or decrease of the average of peak-flood heights. The average peak-flood heights for the period, 1890 to 1907, is 48.7 ft. The flood of 1903, which falls within this group, had a flood peak of 50.1 ft. at Red River Landing, the second highest flood of record to this time. It would be expected, therefore, that the gauge for discharging the same volume of water during this peak-flood year would be reflected by a high gauge.

The locations of diversion as mentioned by Mr. Odom where shoaling in the Mississippi River is not noticeable, are immediately adjacent to the Gulf and below the leveed section of the river, and are not comparable with the effects noted at Red River Landing where the river is confined by levees and subjected to a variation in water elevation of about 50 ft. Baptiste Collette's Bayou is immediately below the end of the East Levee line of the Mississippi; the Jump at the end of the West Levee; Cubit's Gap and Head of Passes are below the end of the levee system about 7 and 10 miles, respectively. The greater part of the variation in water levels at these points is due to Gulf tides and wind. The river channel has adjusted itself to this condition. On the other hand, if the maximum variation was due to flood heights and if flood heights were increased, causing consequent increase in diversion, shoals would occur. In 1922 the elevation of high water above Mean Gulf Level at these points, were[22]:

Baptiste Collette	4.3
The Jump	4.1
Cubit's Gap	2.0
Head of Passes	2.0

The data presented for the Atchafalaya, which are recorded by the river itself in substantiation of the hydraulic theory, are that since 1890 the same volume of water has been discharging at the same gauge heights as it was in 1933, although the leveed section of the river, including about 17 miles beyond, shows large increases in cross-sectional area. This is further substantiated by the fact that the discharges are the same for the period, 1897 to 1932, for a high gauge of 50 ft at Red River Landing. The velocity during this period shows a slight decrease. Mr. Odom considers that these data are practically no proof and substitutes therefor his opinion, that, when the stream is permitted to discharge freely into Grand Lake by the extension of the levees and

[22] Data furnished by Louisiana State Board of Engrs.

the cutting of a pilot channel between them, the full advantage of the increased cross-section will be available. Evidently, he does not consider the inefficient channels below the end of the levee system as being due to the silt load deposited by the Atchafalaya River, and that, after this immediate section of hydraulically inefficient channels is eliminated by the work he suggests, no more will be formed beyond the levee extensions as proposed. If the river's power of adjustment in the handling of its silt load is changed by some method of disposal foreign to the river's treatment, it may create an entirely different condition.

The Atchafalaya is similar to other silt-bearing streams in having numerous hydraulically inefficient channels beyond the end of the levee system. With the drop in velocity, silt is deposited at the levee end, filling in and building up the area below. Due to the presence of colloids, this freshly deposited silt, consolidates and hardens, and requires higher velocities to dislodge it again than it did to keep it moving. This process of land building below the levee end is the foundation utilized by the Louisiana State Board of Engineers in the levee extensions on the Atchafalaya. The levees have been extended in progression with the forming of this foundation by the deposition of silt. The confinement of waters between the extended levees produces sufficient velocity to pick up the consolidated clays again, thereby materially increasing the cross-sectional area of the stream, and transferring the land-building process down stream. If the past is any criterion, that which is now the portion of Grand Lake will, under Mr. Odom's plan, be the location of the numerous hydraulically inefficient shallow branches when the levees have been extended a sufficient distance and the problem of obtaining a single hydraulically efficient channel will still be present.

The greatest increases in cross-sectional areas of this river are in the lower reaches and are due to levee confinement, as stated by Mr. Odom. In the upper 28 miles of the leveed portion (Reach 0 to 5) the cross-sectional area in 1932 ranged from 70 000 to 79 000 sq ft, being an increase in area from 26 to 35% over that in 1904. In the next following 25 miles (Reach 6 to 10) the cross-sectional area in 1932 ranged from 55 000 to 59 000 sq ft, being an increase in area over that in 1904 from 4 to 203 per cent. The lower 16 miles (Reach 11 to 13) is below the levee system and, in 1932, the area for Reach 11 was 45 000 sq ft, diminishing to 24 000 sq ft for Reach 13, which indicates an area increase over 1904 of 201% and 56%, respectively. Cross-sectional areas are not available prior to 1904–05. Greater increases in area, than those listed, would occur for the period, 1890 to 1932, the period of gauge study. By 1896, the levee system ended within the limits of Reach 6 and was extended into the limits of Reach 8 prior to the cross-sectional survey of 1904–05. Because of this levee extension (which was made prior to the survey of 1904–05), Reach 6 would show a considerably larger increase in area for the prior period over that of 4% for the period since the survey of 1904–05. Therefore, it is logical to consider that the cross-sectional area of Reach 6 was greatly increased during the time of this gauge study (1890–1932) over that of the 4% recorded since 1904–05. This small increase of area for Reach 6,

as pointed out by Mr. Odom, is not the total increase in cross-sectional area for the period of this study, and, therefore, does not disturb the conclusions reached as to the adjustment of the river.

It is not the writer's intention to deal with causes of the formation of the present channel of the Mississippi River, but the theory advanced by Mr. Odom on this feature is interesting. The paper deals with the condition of the existing rivers and offers the reason why the Mississippi River is blocked from diverting its flow from its present channel through the Atchafalaya River even if the Atchafalaya is the shortest distance with steeper slopes to the Gulf.

Although the views expressed by Mr. Odom are appreciated, it is thought he did not produce data and conclusions warranting a change in the original deductions.

STABLE CHANNELS IN ERODIBLE MATERIAL

By E. W. Lane,[1] M. Am. Soc. C. E.

With Discussion by Messrs. R. C. Johnson, E. S. Lindley, J. C. Stevens, C. R. Pettis, Harry F. Blaney, Sigurd Eliassen, R. E. Ballester, Gerald Lacey, V. V. Tchikoff, W. M. Griffith, and E. W. Lane.

Synopsis

The design of the All-American Canal, which will divert 15 000 cu ft per sec from the Colorado River, required a thorough study of stable channel shapes. Data from various sources were conflicting and unsuitable for the unusual conditions on this canal. These data were analyzed and conclusions were drawn regarding the various factors controlling stable channel shapes, and the relation between them.

Introduction

For a canal to be stable the banks must not slough or slide, and the bottom and sides must neither silt nor scour. To establish these conditions the engineer must consider a number of factors.

The problem of controlling sloughing or sliding is not treated in detail in this paper, since stable slopes for the various soils are comparatively well known. To prevent scouring or the accumulation of silt in the bed, it is necessary that the velocity along the bed is sufficient to move all the material brought into the canal, and yet not be so high as to cause the subgrade of the canal to scour. Flowing water will not attack the subgrade unless its velocity is more than sufficient to move the material brought into the canal. The excess of velocity over that required to move this material, which will attack the canal subgrade, depends upon the material of which the subgrade is composed.

In order that the banks may neither silt nor scour, the velocities along them must be sufficient to prevent deposition but not sufficient to cause the material of which they are composed to scour. From a practical standpoint

Note.—Published in November, 1935, *Proceedings*.

[1] Prof. of Hydr. Eng., State Univ. of Iowa, Iowa City, Iowa.

a slight degree of silting on the sides is not especially detrimental, so that the important requirement is the prevention of scour and excessive deposition. The maximum allowable velocity along the banks depends upon the material of which they are composed. The material on the sides is also acted upon by the force of gravity, which assists the water in tending to cause motion. The sides, therefore, will scour under velocities less than would be permissible along the bottom.

The ratio between the velocity acting on the sides and that on the bottom depends upon the ratio of the bed width of the canal to the depth. The greater this latter ratio the greater will be the ratio of the velocity acting on the bottom to that acting on the sides. The bed width-depth ratio required for a stable channel is that which will bring the proper ratio of velocity acting on the bottom to that acting on the sides. Conditions that require high velocities acting on the bottom, as compared with those that may be permitted to act on the sides, require high ratios of bed width to depth. For example, canals that carry a heavy bed load in friable material require high velocities on the bed to move the load and low velocities along the banks to prevent cutting them; in other words, such channels require a high ratio of bottom velocity to side velocity, and, therefore, a high bed width-depth ratio. Canals with small bed loads in friable material do not require such high velocities along the bottom to transport the bed load and, therefore, the ratio of this lower velocity, V_B, to the permissible side velocity, V_S, can be smaller. The correct ratios for other conditions can be determined by the application of these principles. This paper records an attempt to outline the major principles that control stable channel shapes and velocities.

The All-American Canal

The All-American Canal is planned to take water from the Lower Colorado River and carry it to the lands lying in the Imperial and Coachella Valleys by a route lying entirely within the United States. The Imperial Valley is now (1935) irrigated from the Colorado River by a publicly owned canal system, of which a large part of the main canal lies within the Republic of Mexico. The difficulties of international administration, and the undesirable silt conditions connected with the existing canal has led to the instigation by the United States Bureau of Reclamation of the new All-American Canal project to be built entirely within the United States, which has been approved by Congress.

The Colorado River is a very silt-laden stream. It has a discharge varying from 2 500 to 190 000 cu ft per sec and a suspended silt content near the intake of the proposed canal averaging 0.90% by weight, and, at times, reaching 5.40 per cent. The suspended silt is extremely fine and the bed silt averages about 0.10 mm (0.004 in.) in diameter. The river slope is approximately 1.2 ft per mile. The use of this very silty water in the Imperial Valley has led to great difficulty and an expense estimated at approximately $1 400 000 per yr for dredging, canal cleaning, and land leveling.

Before the All-American Canal is finished, it is expected that the Boulder Dam, 303 miles above the proposed head-works, will be completed. This dam

will be 725 ft high and will form a reservoir, with a maximum capacity of 30 500 000 acre-ft, in which all the silt brought down to the reservoir will be deposited. Another dam will be built 155 miles above the intake, which will stop practically all the silt coming from above that point. The silt that reaches the intake, therefore, will be only that picked up from the banks and bed of the river below the lower dam, and the small quantity brought in by the tributaries to the river between the lower dam and the intake. An elaborate desilting works will be built to remove the coarser part of the silt load which will be carried into the canal. Consequently, the silt load in the canal will differ greatly from that now (1935) carried, and will create different stable channel shapes. To determine the shape best adapted to the new condition a thorough study of the subject was made, the results of which are described herein.

Notation

The symbols introduced in this paper are defined as follows (the English system of units being used unless otherwise stated):

a = a subscript denoting "average";
d = depth of flow; d_a = average depth;
f = silt factor = $8 \sqrt{D}$;
m = a subscript denoting "mean";
n = exponent in a formula of the Kennedy type;
s = a subscript denoting "near the sides";
A = area of water cross-section;
B = breadth, or width of channel; B_B = width at the bottom; B_m = mean channel width; as a subscript, B, denotes "at or near the bottom";
C = coefficient in a formula of the Kennedy type;
D = diameter of particles;
L = length;
P = wetted perimeter (not including water surface);
Q = flow, or rate of discharge;
R = hydraulic radius $= \frac{A}{P}$;
S = slope $= \frac{\text{fall}}{L}$
V = velocity; average velocity in a section; V_B = velocity near the bottom; V_s = velocity near the sides; and V_0 = critical velocity from the standpoint of silting.

History of Non-Silting Canal Section Studies

Most of the study of the problem of non-silting canal sections has been made by the British engineers in India, in connection with the large irrigation projects of that country. A certain amount has also been done in Egypt, in connection with the irrigation work on the Nile. Thus far, little has been contributed by the United States. In the last few years, however, a surprising interest in silt problems has developed in this country and it is now (1935) being attacked from many angles by a number of research engineers. From this interest, no doubt, future progress will become considerably more marked.

The first study of non-silting canal sections was made by Mr. R. G. Kennedy (1)[2]. His work is a classic in this field, and has resulted in the saving of millions of dollars in reducing the cost of cleaning irrigation canals in India and elsewhere. Unfortunately, like most outstanding studies, it came to have such prestige that for many years little further progress along this line was made.

Kennedy gave the result of measurements of bed widths and "full supply" depths on about twenty-two canals in the Lower Bari Doab Canal System, in which the channels had become stable and several more which had nearly reached this condition. He also gave the "full supply" discharge and the velocity computed from this discharge and the full supply area. From these data he developed a formula of the type:

$$V_0 = C\, d^n \qquad (1)$$

which expressed, with reasonable accuracy, the relation between the critical mean velocity, V_0, and the depth, d, as indicated by the results of the measurements. For the Lower Bari Doab Canal, C was 0.84 and n was 0.64. Kennedy expected C to vary with the quality and quantity of silt, but thought n would be nearly constant. On Fig. 1 (with reference to Table 1) is shown a line giving the velocities corresponding to the various depths according to Equation (1). The local conditions influencing these observations and Kennedy's conclusions will be given more in detail subsequently.

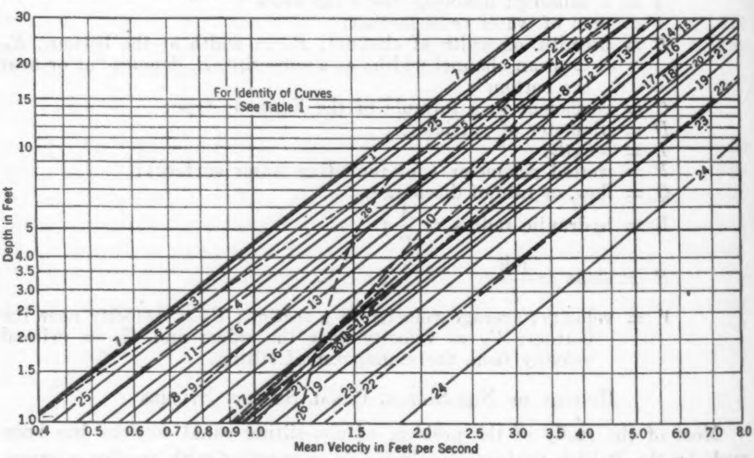

FIG. 1.—CRITICAL VELOCITY FORMULAS FOR NON-SILTING, NON-SCOURING VELOCITIES.

In 1895 Kennedy issued a set of hydraulic diagrams to aid in the design of non-silting channels. In 1904, he gave a rough rule for the relation of width to depth in non-silting canals (5). A second edition of "Hydraulic Diagrams" (6) was issued in 1907, in which Kennedy reprinted the original paper and added an extended discussion to clarify some of the obscure points and to give the results of his experience since the first paper was printed.

[2] For reference to figures in parentheses see "Bibliography."

‡ $V_o = (1.1+)\ 0.095\ d$.

Kennedy's work soon became extensively used throughout India; observations were made on the ditches of other irrigation systems and a number of other equations of the same type as those of Kennedy, were developed, suitable to the various local conditions. One of these was for the Godavari Western Delta and the Kistna Western Delta, in Madras (7). In 1913 a set of hydraulic diagrams for the design of channels was presented by Capt. A. Garrett which deals with non-silting channels (8), and which is used extensively in the United Provinces.

In 1917, Mr. F. W. Woods proposed (2) the use of definite ratios of depth to width, based on an analysis of data from the Lower Chenab Canal System. In 1919, the results of an extensive analysis of canal dimensions of the Lower Chenab Canal, by E. S. Lindley, M. Am. Soc. C. E., was published (3). For these canals, Mr. Lindley found a critical velocity relation such that, in Equation (1), $C = 0.95$ and $n = 0.57$. He also found a relation of bed width to depth of $B_s = 3.8\ d^{1.61}$.

In 1927, Woods (4) proposed a general formula covering velocity, average depth, mean width, and slope, as follows:

$$d_a = B_m^{0.434} \qquad (2)$$

$$V_0 = 1.434 \log_{10} B_m \qquad (3)$$

and,

$$S = \frac{1}{2 \times \log_{10} Q \times 1\,000} \qquad (4)$$

Equations (2), (3), and (4) cover not only the depth and width, but also the discharge and slope. According to them for a given discharge there is a single condition of depth, width, and slope that will produce a stable channel.

In 1928, Mr. W. T. Bottomley (9) advanced the idea that irrigation channels would be non-silting and non-scouring if the slope of the canal was of the same order as that of the parent river, regardless of the relation of width to depth and the shape of the channel. In 1930, an excellent paper on this subject (18) was presented by Mr. Gerald Lacey in which he advanced the proposition that the wetted perimeter of stable channel was a simple function of the square root of the discharge; or,

$$P = 2.668\ Q^{0.5} \qquad (5)$$

and that the shape of the section depended upon the fineness of the silt carried, coarse silt giving rise to wide, shallow sections and fine silt to narrow, deep ones. He developed the formulas,

$$Q\ f^2 = 3.8\ V_0^6 \qquad (6)$$

and,

$$V_0 = 1.17 \sqrt{f\ R} \qquad (7)$$

in which f is a silt factor, related to the diameter of the bed material by the expression:

$$f = 8 \sqrt{D} \qquad (8)$$

In Equation (8) D is in inches. From Equations (6), (7), and (8), knowing the flow, Q, in the ditch, V_0, A, and R can be computed.

Lacey also stated that the shape of a stable channel approximated an ellipse, with its major axis horizontal, the ratio of the major to the minor axis being larger as the silt became coarser. Lacey's ideas have been widely accepted in India, and extensive observations are under way to study the effect of various conditions on his silt factor, f.

The aforementioned authorities have developed their ideas almost entirely from experience in India. The result of experience on canals in Egypt is given by Messrs. Molesworth and Yenidunia (10). They give a general formula in English units:

$$d = (9\,060\ S + 0.725)\ \sqrt{B_B} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

as developed from a careful examination of a large number of recognized good Egyptian canals. As a result of further experience, Mr. A. B. Buckley (11), develops the adjustment of Equation (9) for canals of depths of 1.6 m (5.26 ft) and less, as follows:

$$d = \frac{0.0025\ (100\,000\ S + 8)^2\ B_B}{1.62} \quad \ldots\ldots\ldots\ldots\ldots (10)$$

Equation (10) is in English units. In addition to the general formulas proposed by various investigators, a large number of special formulas of the Kennedy type have been developed. These formulas are listed on Table 1.

Summary of Previous Stable-Channel Formulas

The formulas developed for stable channels fall into two classifications: (*a*) Those giving an expression for velocity; and (*b*) those giving stable channel shapes. Those in the first class are similar to the Kennedy formula, Equation (1). In most of these formulas n has been taken as 0.64, the value developed by Kennedy. In all cases the value of C was constant for a given locality or canal system. Kennedy believed that C would vary with both the size and quantity of silt, but did not emphasize the effect of the quantity of silt as much as the quality, and, as a result, it has been largely lost sight of by other students of the subject. He did not believe that the value of n would change greatly.

A formula of the Kennedy type indicates that the critical velocity increases with the depth, but experience shows that as the depth is increased a velocity is finally reached at which the banks begin to erode. Kennedy believed that the limiting velocity was a matter of experience, and gave limiting values which correspond to depths of about 10 ft. This had the effect of limiting the depths of canals designed according to his rules to these values. No data on this limitation are available for the conditions under which any of the other formulas of the Kennedy type were developed.

Of the formulas of the second type, Lindley gives a relation of critical velocity to depth and bed width, but suggests no modifications for the quality or quantity of silt. Woods gives relations for mean depth, velocity, and slope, but like Lindley makes no suggestion that these relations might be influenced by the quantity or the quality of the silt. Lacey gives channel shapes and velocities. introducing the effect of the size of the silt grain, but does not consider the quantity of material to be transported.

Comparison of Critical Velocities

In order to determine what velocities could be used safely in the All-American Canal, Fig. 1 was prepared, showing the relation of depth to critical

velocity, as determined from all available observations on actual ditches. These show at a glance that for a given depth of flow there is a tremendous variation in critical velocity. The line representing Kennedy's data is shown heavier than the others. The variations range approximately from 46 to 208% of Kennedy's results, or the highest value over 450% of the lowest.

The local conditions under which most of these formulas were developed are not known in detail. In general, however, it is believed that the silt of the Nile River is finer than that of Ravi River, from which water is drawn for the Lower Bari Doab Canal, on which Kennedy's observations were made. The lower velocities found for the Egyptian canals, as compared with those given by Kennedy are, therefore, consistent with the relation of Lacey's formula (Equation (6)), that finer material results in lower critical velocities. It is also known, however, that the silt of the Colorado River and the tributary Imperial Valley canals is finer than that of the Ravi, but the critical velocities are higher in the case of the Imperial Valley canals. This is contrary to the relation given by Lacey.

Comparison of Formulas for Width-Depth Relation

A comparison similar to that of the critical velocity relations was also made of the various formulas for the relation of bed width to depth. The results are shown on Fig. 2, which gives the relation of bed width for the principal formulas and some of the data. The Woods' formula was expressed in terms of mean width, and has been changed to terms of bed width by assuming side

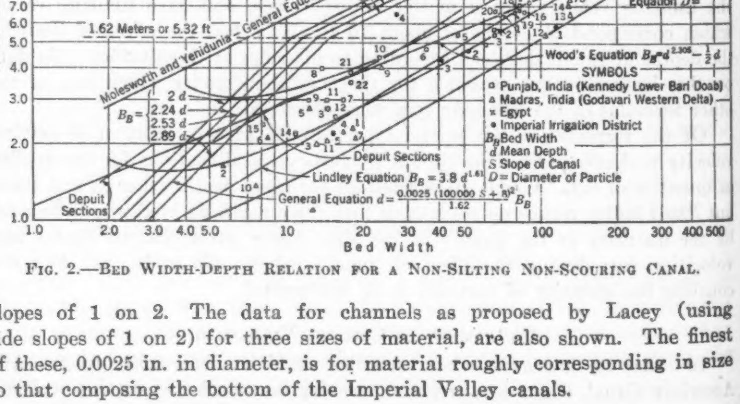

FIG. 2.—BED WIDTH-DEPTH RELATION FOR A NON-SILTING NON-SCOURING CANAL.

slopes of 1 on 2. The data for channels as proposed by Lacey (using side slopes of 1 on 2) for three sizes of material, are also shown. The finest of these, 0.0025 in. in diameter, is for material roughly corresponding in size to that composing the bottom of the Imperial Valley canals.

The Punjab (Kennedy) data are computed from those given by Kennedy for the Lower Bari Doab Canal, using vertical side slopes, as reported by him. Data are also given on canals in the Godavari Western Delta and some values obtained from canals in the Imperial Valley. The data from Egypt were in the form of a general equation by Molesworth and Yenidunia, which is independent of the slope, and an equation which is dependent on the slope, four slopes being given. For depths less than 1.62 m (5.32 ft), a modification of the Molesworth-Yenidunia, formula given by Buckley has been used, based on data which have been collected since the other formula was proposed. The Depuit Section, said to be widely used in Egypt, is also shown.

These data for the bed width-depth relation show even greater variation than the depth critical-velocity relations shown on Fig. 2. For a 5-ft depth, the Molesworth-Yenidunia formula without the slope factor, gives a bed width of 6.4 ft and the Lindley equation gives 50.0 ft, or a ratio of maximum to minimum of 781 per cent. Some of the Imperial Valley data indicate even higher ratios than those given by the Lindley formula. The wide range does not seem to be due to variation in the size of the silt because, although the Egyptian data are believed to be for finer silt than the Indian data of Woods and Lindley, most of the Imperial Valley data, which are also for fine silt, give even higher bed width-depth ratios than those of either Lindley or Wood.

Factors Affecting Stable Channel Shapes

As a result of the wide range of critical velocities and bed width-depth relations found on the canals in the different parts of the world, and the lack of any readily apparent consistency in the variations, it was clear that if the factors controlling this variation could not be determined it would not be safe to adopt any of the relations given by existing formulas for the design of the sections of the All-American Canal. Although these formulas no doubt provide workable relations for the conditions for which they were developed, these conditions have not been delineated sufficiently to enable them to be applied elsewhere. In general, also, they were developed empirically from a very limited range of conditions, and in most cases they omit important factors from consideration.

To develop a rational design for the sections of the All-American Canal, it was necessary, therefore, to attempt to go back to the fundamentals and try to make an analysis of the factors controlling the shape of a stream channel in erodible material, and their relations to each other.

The following is a list of factors that may enter into a determination of stable channel shapes: (*a*) Hydraulic factors (slope, roughness, hydraulic radius or depth, mean velocity, velocity distribution, and temperature); (*b*) channel shape (width, depth, and side slopes); (*c*) nature of material transported (size, shape, specific gravity, dispersion, quantity, and bank and subgrade material); and, (*d*) miscellaneous (alignment, uniformity of flow, and aging).

In arriving at a rational solution of the problem of stable channels it is necessary to consider all these factors, and to determine as accurately as possible which of them are of major importance, and which are minor or negli-

gible. By determining first the relation between major factors, it may be possible later to study the effect of minor factors, but until the major relations are known, the data available are only a collection of miscellaneous facts of limited value.

Of the hydraulic factors, the slope, roughness, hydraulic radius, and mean velocity are interdependent and with reasonable certainty their relation is known quantitatively through the ordinary velocity formulas. It is true that the effect of the movement of material in suspension and by traction upon the roughness is not definitely known and more information on this point is needed, but compared to the uncertainty in other phases of the problem, the relations of these four items is so well known that for the purposes of this study further investigation along these lines was probably unjustified. The relation between these factors and scouring or transportation of solids in channels is not well established and must be studied further.

As will be shown subsequently, it is believed that the velocity distribution, as well as the mean velocity, is of primary importance to the problem and that it, together with the channel shape factors of width and depth, exercise an important influence on stable shapes. The side slopes are relatively unimportant except as regards sloughing.

Temperature has been suggested as having an important effect because it influences the viscosity of the water and, consequently, the rate at which solid particles settle. That temperature might have some effect cannot be questioned, but it is probably small, from the standpoint of stable channel shapes. Most of the data were collected in warm countries, comparable to the locality of the All-American Canal, and the temperature variation although it might cause some difference in settlement rate would not, ordinarily, be enough, when averaged over the year, to cause major effects. For many sizes of silt the effect of temperature on settling rate is small. Moreover, it is possible that the tractive force, which is not appreciably affected by temperature, is the most important factor in stable channel shapes, and, therefore, temperature effects are relatively unimportant. In any event temperature data, which would enable an analysis of its effect to be made, are not available.

Nearly all students of the problem have admitted that the size of the material transported is of major importance. The shape no doubt has an effect, but it is believed to be of secondary importance as laboratory experiments show that angular particles are moved by only slightly higher velocities than rounded ones. In any event, no data on it are available for any of the localities, so that its influence could not be investigated, even if it was desirable to do so. Specific gravity of the transported material also has its effect, but since it rarely varies much from 2.65 it is of secondary importance. No data on this subject would be available, even if it were desirable to study them. The dispersion of the material by virtue of the electrical charges carried by the particles is important in some phases of sedimentation, but it is probably active only in the case of very fine material which is ordinarily not much of a factor in stable channel sections. In this case, again, no data for further study are available.

The quantity of solids in motion is an important factor in the shape of stable channel shapes, and has not received the attention that its importance warrants. Cases illustrating its importance are numerous. For example, it is a common occurrence in some irrigation systems to have the upper section of the ditch fill during periods of high silt content in the streams from which they draw, and for this fill to scour out later during periods of clear-water flow. In other words, the ditch is unstable, at times being unable to transport all the material brought to it, hence filling up, and at other times transporting more material than brought to it, and, therefore, cutting down its bed. Over long periods the ditches are approximately stable because the two actions counteract one another. Another common example is the change from unstable to stable condition which results when an effective sand trap is applied to a ditch that is becoming filled. There are also numerous cases in which the channel of a natural stream is stable but begins to scour severely when a dam is built on it and cuts off the supply of solid material which formerly came down to renew that which was moved forward by the flowing water.

One of the most important factors controlling stable channel shapes is the nature of the material composing the banks and subgrade. If these materials are resistant to scour, higher velocities can be used than if the material is friable. Alignment is another factor to be considered, because bank scour is more likely to occur on curves. If a canal is apt to be operated a large proportion of the time at part capacity, this must also be considered in the design.

Another factor that influences the stability of an irrigation channel is what is commonly termed "aging." After water has run for some time in a channel, the particles composing the bed arrange themselves in such a manner that they are more difficult to move than when the water is first turned in. If the water is silty, this material forms a kind of weak cement which binds the bed material together and makes it more resistant.

In addition to the items listed herein under the heading "Factors Affecting Stable Channel Shapes," another set of relations enters into the selection of the best channel section in any instance; which depends upon the conditions which the canal is designed to meet.

Canals for conveying water for irrigation or power are usually designed to meet one of three sets of conditions. The first type is encountered when it is desired to use the lowest practicable velocity, in order that the slope may be reduced to a minimum. In the case of power canals this is done to obtain the greatest feasible power head, and, in irrigation canals, it is done to enable the ditch to command as much irrigable area as possible for a given length. A second type of conditions is met in both power and irrigation canals where it is desired to reduce the size of the canal to a minimum, in order to make the cost as small as possible without making the slope steeper than necessary. This requires that the velocity be made as great as can be carried without scouring the banks or bed. A third condition is met in irrigation canals where it is desired to carry the ditch on an alignment that has a slope as steep as possible, in order to reduce the cost of drops. The first of these conditions aims at securing the minimum practical velocity within the limitations of cost and silting. The second aims to secure the highest

velocity that the ditch will stand with a shape which will convey the water with a reasonable loss of head. The third aims to dissipate as much head as possible by making the canal wide and shallow, thus reducing the hydraulic radius to a minimum and the slope for a given velocity to a maximum. The group into which any particular canal falls, therefore, indicates limitations which are likely to control the best channel shape, which must not be exceeded while still being subject to the influence of the aforementioned factors.

Conditions Required for Stable Channels

For a channel to be perfectly stable, it must not fill or scour on either the banks or bed. The banks must also be stable against sloughing or sliding. To meet the non-filling requirement, the velocity must be enough to flush away all the solid material brought into the section by the flowing water. To fulfill the non-scouring requirement, the velocity at the bed or at the banks must not be great enough to scour the material of which they are composed. To determine a stable section for a set of conditions it is necessary to determine the various relations which will cause velocities at the banks and along the bed that will bring about these conditions.

The silt carried into a section of canal may be composed entirely of fine material, which is easily moved by the water, or it may be composed entirely of coarse material, which is moved only at relatively high velocities. Usually, however, it has a graded composition varying from coarse to fine. If all the material is very fine, ordinarily it offers little practical difficulty because the velocities required in the ditch to meet conditions of economy are sufficient to keep it in motion. If the material is graded, the fine material moved depends upon the velocity near the bed, to obtain a stable channel the the material is coarse, all of it may be dragged along the bed, and little if any be carried in suspension. Since the quantity of the bed material that can be moved depends upon the velocity near the bed, to obtain a stable channel the velocity along the bed must be greater for larger bed loads. This may require a higher velocity along the bed than the material in which the channel was built would stand from clear water, the entire energy of the water on the bottom being expended in dragging along the bottom the material which has been brought down by the water from above. However, if the velocity along the bottom exceeds that necessary to move the bed load, it will act on the subgrade of the channel. To have a stable channel, the subgrade material must be sufficiently tenacious to resist this scour. Summarizing this relation, it may be stated that the velocity along the bottom of a stable channel must be sufficient to move the quantity of material supplied to it, but not so great as to scour the subgrade.

The material composing the banks of the canal is acted upon by two forces tending to produce motion. One of these is gravity, which tends to make the material roll or slide down the sides of the ditch. The effective gravity force is the component that acts downward along the side siopes of the ditch. The other force acting is that due to the motion of the water through the canal, which tends to drag or to push the material in a down-stream direction. The magnitude of this force depends upon the velocity adjacent to the bank.

The force of gravity and the force of the stream both act together when water is flowing in the canal, and when the resultant of the two forces is sufficient to dislodge material from the sides, it moves in a diagonal direction to the bed of the stream, or if fine enough, is carried off in suspension by the water. The slope of the bank must be sufficiently flat so that the component along it, of the force of gravity, when combined with the force of the water, is insufficient to dislodge the particles. Since flat side slopes cause a smaller component of gravity, therefore, they have less tendency to scour from this cause.

Stable Channels for Clear Water

The simplest cases involving the determination of stable channel sections are those required to convey clear water. When the water carries silt in suspension or drags a load along the bottom, there are added complications. Therefore, the simplest cases, with clear water, will be considered first. When the smallest practical slope is desired, it is usually considered that the cheapest channel is secured when the wetted perimeter is least in proportion to the area. In trapezoidal channels this occurs with a ratio of bed width to depth ranging from 2.0 to 0.472 for side slopes between the vertical and 1 on 2. These values give the most efficient hydraulic section, but since this consideration neglects any excavation above the water line the flattest slope for a given quantity of excavation for a channel in cut is given by cross-sections where the ratio of bed width to depth is less than the foregoing. Thus, maximum economy will result from very low $\frac{B}{d}$-ratios. In earth, however, experience has shown that such channels are not stable.

A stable channel for clear water must have banks with sufficiently flat side slopes to keep the material from sloughing or rolling in, and sufficiently low velocities to keep the banks and bed from scouring. As previously stated, since the material on the banks is acted upon by the force of gravity, as well as that due to the motion of the water, it will not resist as high a force from the motion of the water as the bottom, where gravity does not tend to produce motion.

If the mean velocity in a narrow, deep channel is low enough so that the forces acting on the side material are insufficient to move it, and the sides are stable from sloughing, the channel will be stable. In other words, narrow, deep channels can be used with clear water and low velocities. Ordinarily, however, considerations of cost prevent the use of the large canals necessary to produce low velocities. For such a channel a cross-section must be selected that will give velocities along the bottom which will not move the bottom material, and velocities along the sides which will not move the side material. Since the side material, due to the action of gravity, will move at a lower velocity than that on the bottom, to obtain the maximum possible mean velocity without scour the velocity along the sides must be enough less than that along the bottom to offset the gravity effect. This reduction of side velocity, as compared with bottom velocity, is secured by increasing the ratio of bed width to depth.

In Fig. 3 are shown the velocity distributions in a number of rectangular channels having the same cross-sectional area. Most of these data were secured from the results of the experiments of D'Arcy and Bazin. The velocities are indicated by the "isovels" (also called "isotacks"), or lines of equal velocity expressed in terms of the mean velocity. (These data were obtained with different discharges for many of the examples. Although it is probable that the positions of the isovels would change somewhat with different velocities, such changes would be relatively small and would not change the main relations.) Since the areas of all water cross-sections are equal, the lines giving the same ratio to mean velocity in all the diagrams represent the same

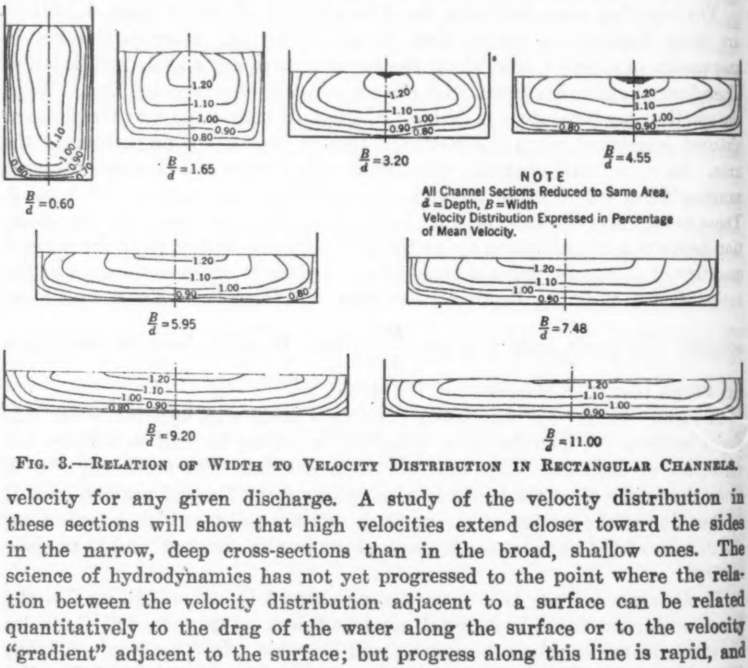

Fig. 3.—Relation of Width to Velocity Distribution in Rectangular Channels.

velocity for any given discharge. A study of the velocity distribution in these sections will show that high velocities extend closer toward the sides in the narrow, deep cross-sections than in the broad, shallow ones. The science of hydrodynamics has not yet progressed to the point where the relation between the velocity distribution adjacent to a surface can be related quantitatively to the drag of the water along the surface or to the velocity "gradient" adjacent to the surface; but progress along this line is rapid, and the near future may bring sufficient advancement in this field to enable more exact analysis to be made. For the present, however, it is sufficient to state that when the high velocities extend close to a surface the pushing or dragging force of water on the surface is greater than if these velocities close to the surface are low.

In a very narrow, deep section, the velocities close to the sides are as high as, or higher than, those close to the bottom. If the velocity in such a channel is increased gradually, due to the added force of gravity on the side material, motion would occur first on the sides.

The design of a channel to convey clear water where it is desired to obtain the smallest practicable slope, therefore, consists, from the hydraulic

standpoint, of securing the smallest ratio of bed width to depth that will not produce scour on the sides, provided such ratio is not less than that which will give the smallest wetted perimeter for a given earthwork quantity. This latter qualification will probably rarely control. The design of a channel for the second type of conditions, where the highest practicable mean velocity is to be secured, is obtained by proportioning the ratio of width to depth so that the forces tending to produce movement, both on the sides and bottom, are the maximum they will stand without motion. For canals in the third class, where it is desired to make the ditch as steep as possible without producing scour, it is customary to make the section wide and shallow in order to reduce the hydraulic radius and thus lower the velocity. For such very wide ditches the scour would be greatest on the bottom, and this condition would control the slope that might be used. Theoretically, there is no limit to the slope a ditch might be given because the velocity could be reduced to any desired value by making it sufficiently wide and shallow. As a practical matter, however, it has been found that when the depth is made very small, the irregularities of construction are such that scour starts in the slightly deeper parts of the channel and enlarges them, causing a progressively greater concentration and scour until the beneficial effect of the widening is lost. This action has been noted in ditches with steep slopes 8 to 10 ft wide and 0.6 to 0.8 ft deep.

Channels Carrying Solids in Suspension

It is quite generally agreed that material can be carried in suspension by a stream because of the vertical currents that occur in flowing water and carry the solid particles upward at a greater rate than the force of gravity causes them to fall. A promising hypothesis for the capacity of a stream to transport material in suspension, therefore, should be that the capacity is proportional to its turbulence, which, in turn, is probably proportional to the energy expended. The concentration of a given quality of solids which a stream could support, therefore, would be proportional to the energy expended per unit of volume of the water. This energy is proportional to the rate of fall of the water, which is equal to the product of the velocity and the slope.

This is a kind of over-all relation, however, and silting may occur in one part of a ditch cross-section while other parts may be scouring. Because the velocity near the edge of a stream flowing in a trapezoidal section is low, in a channel carrying silt in suspension there is a tendency to deposit at that point. This is aided by the growth of vegetation, and usually a berm is formed which creates steeper sides to the section than were originally constructed. This material is quite resistant to scour, and forms more or less evenly even in ditches where there are high velocities. This action is not ordinarily very detrimental, and is often anticipated and allowed for by computing the capacity of the channel with the slopes which it is expected the silt will cause, rather than the slopes to which it is first excavated.

It is probably not feasible to prevent entirely the deposition of suspended material along the edges of channels in earth, although it may be reduced by using higher velocities. The greatest difficulties from suspended matter

occur in ditches where the slopes are so slight that the energy being dissipated in the water is insufficient to prevent deposit. The remedy in these cases is to increase the velocity, or to remove the suspended material in some kind of desilting device.

Channels Carrying Bed Load

Irrigation channels frequently carry considerable solid matter by dragging or pushing it along the bed, with either clear or silt-laden water flowing above. The quantity of material depends upon the velocity near the bottom of the channel. Higher velocity is probably necessary to move the same quantity of coarse material as fine material. If a channel is supplied with a heavy bed load, in order to be stable it must move this load along; otherwise, the channel will become filled. This requires a high velocity along the bottom, as compared with a channel carrying clear water. For a given quality of material in the banks, the velocities that could act on the banks in the two cases would be the same. To be stable, the channel carrying bed loads, therefore, should have a higher velocity along the bed, but the same velocity along the banks, and this could only occur with a wider, shallower section. Heavily loaded channels in easily scoured material therefore, should have high ratios of bed width to depth. If the banks of the loaded channel are of material which is resistant to scour, the ratio of bed width to depth can be less than in friable material without scouring the banks.

Colloids

Colloids carried in the water exercise a considerable effect on the shape of the channel cross-section. They cement the fine particles which collect along the sides of the ditch and are responsible for the vertical or nearly vertical banks which exist in many canals. This colloid cemented material along the sides is more resistant to scour than the size of material would indicate, and thus permits higher velocities along the banks than would otherwise be allowable. To a certain extent also colloids may cement the particles composing the bed and make it more resistant to scour. It is believed, however, that some of the effects ascribed to colloids are really due to the presence of a high silt load. The ability of the canals of the Imperial Valley, which are constructed in fine silt, to carry velocities of 4 or 5 ft per sec without scour has been ascribed to colloids, but the writer believes that a large part of it is due to the presence of the high silt load. When these canals are supplied by the All-American Canal with desilted water, their beds will scour considerably, and this would not be prevented by the colloids.

Recent Conceptions of Flow not Used

To engineers who are familiar with the latest theories of stream mechanics and hydrodynamics, the foregoing analysis of the factors controlling stable channel shapes may seem somewhat crude, and in ignoring the drag theory of bed-load movement and the conception of velocity gradient, it may appear that the writer has not taken advantage of the best available information.

In making the study outlined herein, the most recent pertinent literature in stream mechanics and hydrodynamics has been analyzed to determine all the material that was applicable to the problem. A list of these references is included in the "Bibliography" contained in this paper. Since many engineers are not familiar with recent ideas, however and since a knowledge of them is not necessary to understand the relations developed regarding stable channel shapes, it was believed to be better to explain these relations in terms of conceptions with which all engineers are familiar, rather than to make it unnecessarily confusing to some by adding the other new ideas.

Agreement of Suggested Relations with Observed Data

The relations suggested in this paper seem to agree with the observed data, as shown on Figs. 1 and 2. The critical velocity shown for the Nile River on Fig 1 is much less than that found by Kennedy in India and also less than that for the Imperial Valley canals. The quantity as well as quality of silt is an important factor in these cases. The silt in both the Nile and Colorado Rivers is fine, but the Imperial canals require a much higher velocity than the canals of Egypt because the quantity of silt is much greater in the Imperial canals. The critical velocity for the canals observed by Kennedy is higher than those in Egypt, probably because the particles moved on the bed were larger, and, therefore, required higher velocities to move them. The Imperial canals require more velocity than the canals observed by Kennedy, although the latter have coarser loads, because the velocity required to transport the immense bed load of the fine Imperial Valley sand is greater than that necessary for the lesser quantity of coarser sand of the canals mentioned by Kennedy.

A similar agreement of the relations previously discussed in found in the data on bed width-depth ratios as shown on Fig. 2. In the canals of Egypt the velocities are low and, therefore, the velocities along the sides, although relatively high because the channels are narrow and deep, are still below those that will move the side material. The bed load is fine and small in quantity and, therefore, the low velocities along the bottom are sufficient to move it all.

The Indian canals shown on the diagram (Fig. 2) carry medium loads of rather coarse material and, therefore, require rather wide sections. The Imperial Valley canals carry immense loads of fine sand, which require high velocities to transport. In order that the velocities along the sides may be low enough so that the banks do not scour, the bed width-depth ratio must be high. In three of the four canals on which data are available, this relation is higher than that indicated by the equations of either Woods or Lindley. These had readily erodible sides. The fourth, which had a lower bottom width-depth ratio, had sides composed of material which had considerable resistance. The three sections with easily erodible banks gave widths considerably greater than is indicated by Lacey's formula for the type of silt which they contained. It is believed that Lacey's formula was based on data from canals which carry loads of considerably less magnitude.

Stable Channel Shapes

The only investigator who has attempted a closer definition of the shape of stable channels than the bed width-depth relation is Lacey. He states (18):

> "That natural silt-transporting channels have a tendency to assume a semi-elliptical section is confirmed by an inspection of a large number of channels in final regime and an examination of cross-sections of discharge sites of rivers in well-defined straight reaches of known stability."

He concluded that stable channels would be semi-elliptical, with the major axis horizontal, and with the ratio of the major axis to the semi-minor axis depending on the nature of the silt carried, being greater for coarser silt.

The results of the writer's investigations do not support this conclusion. A convenient way of comparing channel cross-sections is by means of a ratio, which may be called the "form factor," between the area of the channel section, up to the water surface, and the area of the enclosing rectangle. For an ellipse this ratio would be $\frac{\pi}{4} = 0.79$; for a parabola, 0.67; for a triangle, 0.50; and for a rectangle, 1.00. A study of a large number of cross-sections of channels has disclosed ratios from 0.56 to 0.92. The stable channels observed by Kennedy were reported to have practically vertical sides and horizontal bottoms, which would give a form factor of 1.00.

Just what shapes for stable channels are produced by all varieties of conditions has not yet been determined, but the writer has observed that for channels carrying a heavy load of graded silt, ranging from colloids to fine sand, the sections have nearly horizontal beds composed of the fine sand and nearly vertical sides of silts and clays. Such channels have form factors of about 0.90. This is the condition on the canals of the Imperial Valley. This difference between the composition of the bed and bank material has also been observed in India. Similar conditions result in channels carrying considerable bed load and a moderate quantity of fine silt. For a channel carrying water containing a small quantity of silt at high velocity in a material containing a considerable number of cobbles, the cross-section is distinctly saucer-shaped, most of the section being covered with cobbles, but with a small silt berm at each edge. This condition was observed on some of the ditches on the Uncompahgre Project, in Colorado, and in the San Luis Valley, in Colorado. One ditch that was carefully measured, had a form factor of 0.85. It is believed that further study will disclose typical shapes for a number of common conditions and the reasons therefor.

Variation in Discharge

The design of the best section for many canals is complicated by variation in the flow they are to carry. Some canals fill at one time and scour out at another, a substantially stable channel resulting from the balance of scour and fill. Many of the data which can be secured on stable shapes are complicated by this discharge variation. No rules can be given for the treatment of such cases. Until the problem of the simple case of relatively uniform flow is obtained, the more complex case of variable flow can be attacked only

by the application of engineering judgment based on a knowledge of existing conditions and available information regarding shapes required for uniform flow.

Acknowledgments

In the investigation leading to this paper many discussions of the problem were studied and many helpful suggestions were thus secured. With these the writer has combined his own ideas. It is not always possible to state definitely which were original and which were secured from literature. The papers on the subject which have been found most useful have been incorporated in the "Bibliography." To the authors and discussers of those papers the writer is particularly indebted. He is also indebted to C. A. Wright, H. F. Blaney, W. M. Griffith, F. C. Scobey, J. C. Stevens, and S. P. Wing, Members, Am. Soc. C. E., and to the General Board of Irrigation of India, for valuable data and suggestions.

As previously stated, this paper gives the results of studies for the selection of stable channels for the All-American Canal. This canal is being designed by, and constructed under, the direction of the U. S. Bureau of Reclamation.

All designs and investigations of the Bureau of Reclamation are under the direction of J. L. Savage, M. Am. Soc. C. E. All engineering and construction work is under the general direction of R. F. Walter, M. Am. Soc. C. E., and all activities of the Bureau are under Elwood Mead, M. Am. Soc. C. E.[3] The writer wishes to express his appreciation to the authorities of the Bureau of Reclamation for permission to publish these data.

DISCUSSION

R. C. Johnson,[4] M. Am. Soc. C. E. (by letter).—From a practical point of view it seems that the actual design of channels to prevent both erosion and silting must remain for some time to come largely a question of judgment. Although it is generally agreed that Kennedy's formula expresses a general law governing eroding velocities, the coefficient, C, will range through such wide variations for different soil types and other variable conditions, that the formula is of little value for use in the United States. The theoretical considerations, of course, are necessary for the designer as well as for those engaged in research, but such theory cannot supersede judgment based on a knowledge of local conditions.

The writer had the opportunity of observing the erosion and silting in channels constructed by the United States Soil Conservation Service in the Piedmont Section of South Carolina during 1935. These channels were constructed chiefly for the purpose of drainage and have the following general characteristics: (1) The predominating type of soil is Cecil clay high in colloidal content (ranging as high as 46%, as determined by the Bouyoucos hydrometer method); (2) the flows in the waterways vary through wide limits, ranging from no flow to the maximum designed capacity; (3) practically all flows carry large quantities of silt; (4) the depth of flow seldom exceeds 2 ft; and (5) the channels range through a great variety of slopes and shapes. The ratio of width to depth ranges from about 3:1 to 10:1.

It is true that such channels do not come within the same classification as channels of more or less uniform flow; yet their consideration may have some related value. Observations were made repeatedly on a number of these channels, in sufficient numbers to lead to the following conclusions:

(*a*) Kennedy's formula for critical velocity was found to be definitely unsuited for design purposes, especially with a value of C even approximately as low as that recommended for Indian conditions;

(*b*) The roughness of the bottom plays a most important part in influencing bottom erosion for shallow depths of flow;

(*c*) Critical slopes exist beyond which no width-depth ratio will prevent erosion of the bottom, regardless of theoretical calculations. (This may be due chiefly to irregularities in the bottom which cannot possibly be avoided in construction of the channel under field conditions); and,

(*d*) Permissible canal velocities as published by Fred C. Scobey, M. Am. Soc. C. E., and the late Samuel Fortier, M. Am. Soc. C. E.,[5] were found to be much better suited, as a rough guide, for general Piedmont conditions than the critical velocity given by Kennedy's formula.

At present, the problem of stable channels in erodible material is of major importance in soil-erosion control work. The problem is extremely complicated by the fact that the flow is most erratic and by the ever-present danger

[5] "Permissible Canal Velocities", *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 940.

of excessive silting. It is believed, however, that it is possible to place the design on a more rational basis than can be done with existing knowledge of hydrodynamics and soil mechanics. The field for research along this line is practically unlimited.

E. S. Lindley,[6] M. Am. Soc. C. E. (by letter).—Throughout the paper, in the text, and on the diagrams, Kennedy's data are ascribed to the Lower Bari Doab Canal, whereas they were observed on the Bari Doab Canal, which became "Upper" on the construction of another canal many years later. The latter takes off from the same river about 160 miles lower in its course; it was originally designed to Kennedy velocities, but experience has shown that (writing from memory) about 0.80 of these would have been better.

The Garrett diagrams do not offer any additional silt theory, but are only an alternative tool for design with provision for following the Kennedy theory. They originated in the Central Provinces of India, before diversions of rivers for irrigation had been begun there.

As to the writer making "no suggestion that these relations might be influenced by the quantity or quality of silt", there was no need even to "suggest", in 1918, what was so generally known and accepted in Indian irrigation practice. The designing diagram in the writer's paper[7] provides for varying the relation of velocity both as to depth and to width, for local conditions.

Although it has since been superseded by Lacey's later work, the writer would like to refer to a development of his work quoted in the paper; this was published in the *Panjab Irrigation Technical Review* in 1925, and its diagrams (Plates 7 and 8) with a brief explanation, are given also in *Panjab Irrigation Nomograms*.[8] These diagrams increase the widths for very large channels in accordance with data obtained, as the former paper was practically complete. Whereas the former paper dealt mainly with the data examined, the latter considered more the points to be kept in mind in designing.

A fundamental point, now widely accepted in India, but not brought out by Professor Lane, is that a given volume of flowing water carrying a given proportion of a given quality of silt tends to form a channel of which the depth, width, and gradient are all fixed by the said volume and silt. In the writer's papers, attention is called to a number of factors that are likely to operate against this tendency, temporarily, but more powerfully.

This problem is too complicated for rational solution; and it is unlikely that the rational approach will yield more than an occasional "pointer" in the right direction. For example, it may confirm or may contradict Lacey's suggestion that velocity should be correlated with hydraulic mean radius instead of with depth. For effective advance by empirical methods it is almost essential to have a "yardstick" by which to test all obtainable data, and to use these data to improve the yardstick periodically. In India and in

[8] On file for reference in Engineering Societies Library, New York, N. Y.

the irrigating countries in touch with it, such a rule was provided by the Kennedy theory, followed by the others mentioned in the author's paper.

To allow for the considerable volume of data needed to yield any real information, the labor of calculating factors from observed data, and one's weak and sinful human nature, it is further almost essential to put this yardstick into the form of diagrams to facilitate the examination of data and the design of new channels which can be watched. It is highly probable that Kennedy's theory would have been still-born, if he had not also provided diagrams which facilitated work that had to be done in any case.

If the paper conveys the impression that it is now anywhere possible to design a channel precisely to the dimensions which Nature will accept for local conditions, that impression is false. Where "design" is applied to an established channel, and consists of regularizing and accepting actual conditions, this will be accurate as long as the silt-draw of all intakes above, and of all offtakes, does not change materially. Where a new channel is being designed without data for the dimensions demanded by the silt, a value must be judged for the silt factor in the formula in use, and design must err on the side on which error causes the least inconvenience when Nature gives its decision. With designing diagrams available for the different formulas, it is not difficult to calculate a number of channels indicating the range of probability if the silt factors have been wisely chosen. For the choice of silt factors, the only help to experience and judgment is in a suggestion to equate Manning's flow formula and the silt formula, and insert values of observable data taken from the river. This suggestion is due to Mr. F. R. Burkitt, of the Panjab Irrigation Department; it has not been published by him, but is developed for Kennedy's silt formula in *Panjab Irrigation Nomograms* (Plate 6*a*).

The enormous silt charge described in the paper, and also in a paper[9] by the late Carl Ewald Grunsky, Past-President, Am. Soc. C. E., entitled "The Head-Works of the Imperial Canal", is striking: even if all channels are designed to pass it in suspension, it must cause difficulty when it reaches the irrigation ditches and the fields, and so must be reduced to reasonable quantities. This should be feasible if advantage is taken of the experience available in places at which considerable advance has been made in designing offtakes to exclude silt. When that has been done, it will soon be clear whether the channels depart so materially from the dimensions of those studied.

J. C. STEVENS,[10] M. AM. SOC. C. E. (by letter).—The anomalous behaviors noted between Egyptian, Indian, and American canals and rivers in alluvium are probably due to fundamental differences in the character of the alluvium. The author discounts the effect of colloids and thinks their apparent effect may be attributed to the silt load of the stream.

When segregated, colloids appear jelly-like, whereas the cementing effect attributed to them may well be given by coarser material, such as fine clay, that would not fall in the colloid group at all. It is a common observa-

[9] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 262.

[10] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

tion that clay deposits that have had an opportunity to consolidate become highly resistant to erosion as long as the beds remain intact. Once the particles become loosened from the bed by exposure and weathering, however, they are readily moved by very low velocities. Many such examples of this fact may be cited in clear streams and canals of the West.

If the silt carried by a canal contains a considerable quantity of fine clays or colloids it begins to consolidate as soon as it is deposited, and once deposited it requires much higher velocities to dislodge it again than to keep it moving. The writer believes, therefore, that the colloids and fine clays in the alluvium have a great influence on the stability of the streams flowing through it and are among the important reasons for the aforementioned anomalous results. The relations between size of particles and velocities that will move them, given in most textbooks, do not apply even approximately to the case in hand. Moreover, it is not the average velocities near the bed and banks, as given in Fig. 3, that are to be reckoned with. Such "isovels", no doubt, were obtained by current meter and, therefore, represent mean velocities over a certain period of time. If an instantaneous velocity indicator, such as a Pitot tube or a Bentzel velocity tube, had been substituted for the current meter, momentary velocities greatly in excess (often two or three times) of the current meter velocity, would have been observed. For want of a better name the writer has termed them "stray currents." In glass-sided laboratory channels they may be observed in action. They are almost like, and have somewhat the effect of, a whip lash. It is these stray currents that move the bed material, rarely the mean velocity that can be measured with a current meter. These stray currents are induced by the irregularities of the channel bumps, holes, ripples, etc., and are phenomena of turbulence.

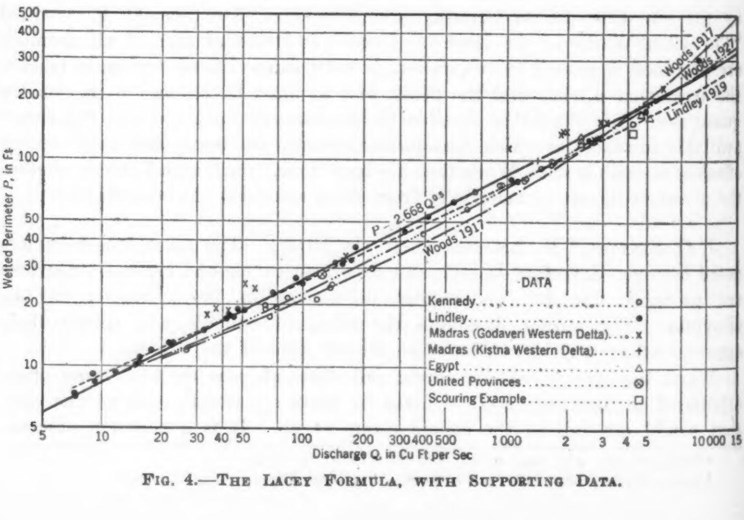

FIG. 4.—THE LACEY FORMULA, WITH SUPPORTING DATA.

If the Lacey formulas cited by the author are quite generally applicable, a stream flowing in its own alluvium would have the following remarkable properties:

(1) The cross-section on straight reaches tends to become semi-elliptical;

(2) The parameter of the ellipse (ratio of the major to one-half the minor axis or surface width to maximum depth) depends solely on the character of the silt as regards fineness;

(3) For a given discharge the wet perimeter is constant and independent of the character of silt; and

(4) The silt factor bears a definite relation to the roughness coefficient in the Kutter and Manning formulas for discharge.

Property (3) is expressed by the author's Equation (5). Fig. 4 is a reproduction of this formula from the Lacey paper[11]. Fig. 5 shows how certain alluvial channels not given by Lacey conform to this formula. The Imperial Valley canals do conform fairly well as credited by the author. The Rio Grande also conforms scatteringly. The Colorado River shows a splendid conformity to another law—not that of Lacey—as is also the case with the Huang-ho River.

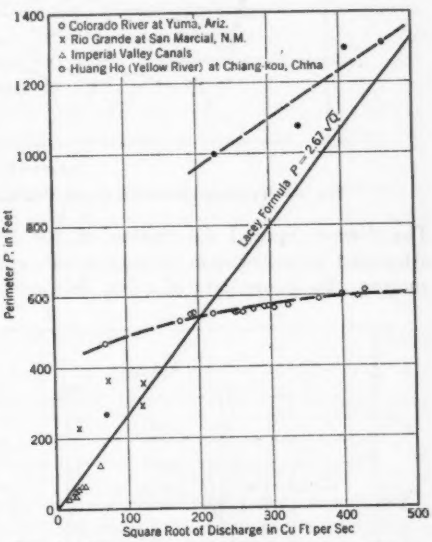

FIG. 5.—RELATION OF PERIMETER TO DISCHARGE, FOR ALLUVIAL STREAMS.

It may be argued that the Lacey formula can only obtain where a given flow persists long enough to establish a stable regimen. The beds of the Colorado River and the Rio Grande respond readily to changes in flow. Figs. 6 and 7 show cross-sections of both streams during 1929. Periods were selected when the discharge was fairly constant.

From data given by the author, particularly the range indicated by his Fig. 1, it is evident that the problem of designing canals in erodible material is an intricate and complex one in which the engineer's judgment and experience must be given a liberal measure of weight.

The writer believes, however, that there is a rational method of approach if the requisite data were in hand. The author could well have added a fourth set of conditions to his list, namely, silt-laden canals requiring hydraulic elements such that silt will be carried through while not scouring the channel—the very condition under discussion.

[11] "Stable Channels in Alluvium", by Gerald Lacey, *Minutes of Proceedings*, Inst. C. E., Vol. 229, p. 259.

Among the thousands of canals throughout the western part of the United States, which carry silt in their alluvial valleys, will be found some that meet this condition, and do carry silt without appreciable deposition or scour.

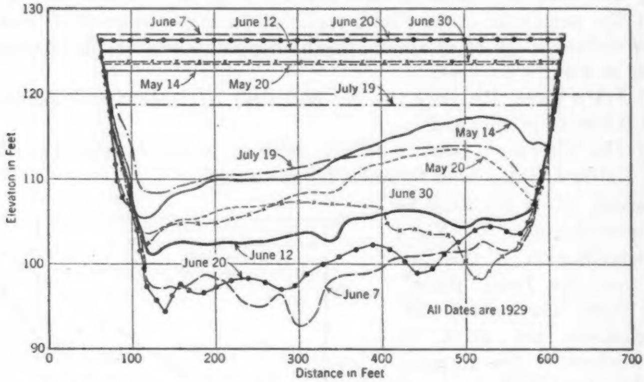

FIG. 6.—TYPICAL CROSS-SECTIONS, COLORADO RIVER AT YUMA, ARIZONA.

The former Special Committee of the Society on Irrigation Hydraulics attempted to gather data on such canals and channels, but with only limited success. To secure data of value, field study and measurements are required

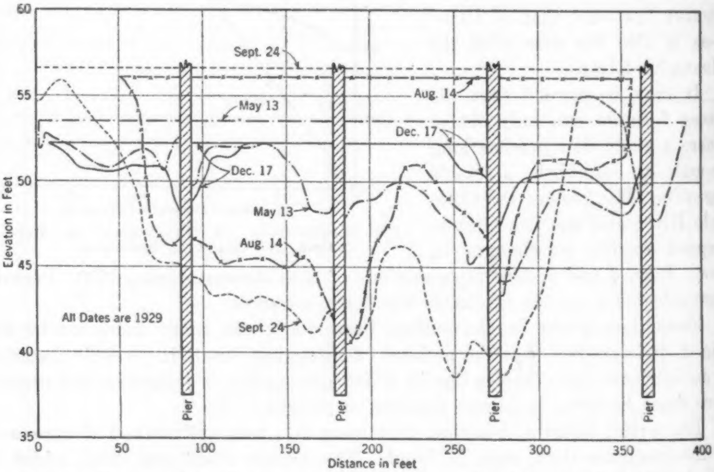

FIG. 7.—TYPICAL CROSS-SECTIONS OF RIO GRANDE, AT SAN MARCIAL, NEW MEXICO.

for which the Committee had no funds. Suppose, however, that complete data were in hand for canals of all sizes and slopes that are known to carry their silt load through, and that complete data were also available as to the mechan-

ical and physical properties of the silts so carried. Each such canal at once becomes an hydraulic model for the design of others to be constructed under similar conditions to which the principles of similitude will apply.

C. R. Pettis,[12] M. Am. Soc. C. E. (by letter).—A clear and interesting discussion of the principles involved in the design of stable channels in erodible material is contained in this paper. Some statement as to the final types adopted for design would have been interesting.

Mr. Gerald Lacey, whose work is cited by Professor Lane, gave[11] certain equations from which the various elements of a stable channel in erodible material can be determined for any given value of discharge, Q; the various elements determined are the velocity, V, the cross-sectional area, A, the hydraulic radius, R, the width of stream, B, and the slope, S. He assumes that the stable channel has a semi-elliptical cross-section. The stable channel in the sense considered is in a straight reach, with uniform and steady flow, and of compact and fairly regular cross-section; if it is a canal it is of sufficient age to have adjusted itself to hydraulic conditions, and it is non-silting and non-scouring. Mr. Lacey's solution is unusually complete and comprehensive.

The writer has proposed an independent solution of the same problem, as applied to rivers[13], which was completed before he knew of Mr. Lacey's work. This solution was derived as a corollary to the width formula for floods: $Q \propto A^{1.25}$; from which $V \propto A^{0.25} \propto Q^{0.2}$. From data on the Miami River it was indicated that the proper value for the velocity in a stable channel is,

$$V = 0.8\, Q^{0.2} \qquad (11)$$

Attention is called to the fact that this is a main channel velocity, and that it is 2.5 times the average velocity of all the flood water, including overflow areas. Since $A = \frac{Q}{V}$,

$$A = 1.25\ Q^{0.8} \qquad (12)$$

From a Kennedy type of formula, assuming $C = 1$ for average conditions in alluvial sections of rivers, the maximum depth, d, of a cross-section will be,

$$d = V^{1.5} = 0.715\ Q^{0.3} \qquad (13)$$

The writer has investigated the shape of a natural stable channel which will best comply with known hydraulic conditions. The evidence indicates that the cross-section must be of the parabolic type indicated by $d\ B^k$; that $\propto$ k is not less than 2 nor more than 3; and that $d \propto B^{2.5}$ is probably the ideal shape for a stable channel. A semi-ellipse is not an ideal shape for the channel of a natural stream. All the writer's formulas were derived from natural streams with drainage areas between 100 and 40 000 sq miles. For such streams (but not for smaller ones) the ratio, $\frac{B}{d}$, will be

[12] Col., Corps. of Engrs., U. S. A., Detroit, Mich.

[13] "Relation of Rainfall to Flood Run-off", *Military Engineer*, March–April, 1936, p. 94.

sufficiently great so that it may be assumed that B is equal to P, the wetted perimeter. Then, $\frac{R}{d}$ will be the author's form factor. The form factor for the parabolic curve, $d \propto B^{2.5}$, is 0.715; for this type of curve, $R = 0.715\ d$. Consequently,

$$R = 0.715\ d = 0.511\ Q^{0.3} \dots\dots (14)$$

$$B = \frac{A}{R} = 2.45\ Q^{0.5} \dots\dots (15)$$

and,

$$\frac{B}{d} = 3.43\ Q^{0.2} \dots\dots (16)$$

Substituting the foregoing values of V and R in the Manning formula, with Kutter's $n = 0.0225$, $S = 0.00036$.

The ideal stable river cross-section is a curve of the type, $d \propto B^{2.5}$. It is a characteristic of rivers that they are subject to very variable flows. No given cross-section can be theoretically perfect for more than one value of Q. A natural channel will adapt its shape to correspond to the bank-full value of Q. Since there is a certain range of stability, such a channel will be safe for a certain amount of overflow. If the overflows are frequent or high, the original shape may be modified slightly to meet this condition. When the water falls below bank-full stage, such a channel will remain within the limits of stability for flows at medium stages. At low stages there will be a tendency to silt along the sides, which may cause some irregularity in flow, and which may be followed by some scouring. These effects will tend to correct themselves with succeeding high stages. The ideal stable channel will remain stable for all ordinary conditions, except for frequent minor and temporary instability near the thalweg.

Considering a given section of a river in connection with a given value of Q, it is evident that V must not be less than a certain minimum value, or silting will occur; and V must not be more than a certain maximum value, or erosion will occur. River channels are carved out of the bed material by erosion, and the writer's solution is based on the maximum value of V beyond which one cannot go and be certain of having a stable channel.

Mr. Lacey's formulas were derived largely from canals. Most of his values of Q were less than any the writer has considered, and his values of V are noticeably less than those of the writer. Mr. Lacey's solution represents the lower limit of safe velocities, which are primarily non-silting; and the writer's solution represents the upper limit of safe velocities, which are primarily non-scouring; and both solutions are necessary to an understanding of the problem as applied to rivers.

On the hypothesis that the Lacey solution and the writer's solution can be combined in the manner indicated, Table 2 gives the limits of stability for the various elements of a cross-section, for a given value of Q; and also intermediate values which are assumed to represent the most stable conditions.

It is assumed that V_0 may vary from $d^{0.67}$ to $d^{0.5}$, or between $d = V^{1.5}$ (non-scouring) and $d = V^{2.0}$ (non-silting). This relationship was used in obtaining a non-silting value of d, since Mr. Lacey did not include d in his solution.

TABLE 2.—ELEMENTS OF STABLE RIVER CHANNELS IN ALLUVIUM

Description	Pettis (non-eroding)	Most stable	Lacey (non-silting)
Velocity, V	$0.8\,Q^{0.2}$	$0.8\,Q^{0.183}$	$0.8\,Q^{0.167}$
Area, A	$1.25\,Q^{0.6}$	$1.25\,Q^{0.617}$	$1.25\,Q^{0.333}$
Depth, d	$0.715\,Q^{0.3}$	$0.683\,Q^{0.317}$	$0.64\,Q^{0.33}$
Hydraulic radius, R	$0.511\,Q^{0.3}$	$0.488\,Q^{0.317}$	$0.468\,Q^{0.33}$
Surface width, B	$2.45\,Q^{0.5}$	$2.56\,Q^{0.5}$	$2.67\,Q^{0.5}$
Kutter's coefficient, n	0.0225	0.0225	0.0225
Slope, S	0.00036	$\dfrac{0.00038}{Q^{0.055}}$	$\dfrac{0.0004}{Q^{0.11}}$
Ratio, $\dfrac{B}{d}$	$3.43\,Q^{0.2}$	$3.75\,Q^{0.183}$	$4.17\,Q^{0.167}$

Table 3 indicates values of the elements corresponding to given values of Q. The values for $Q = 1$ indicates that the Lacey and the writer's solutions are consistent for a terminal condition; $Q = 1\,000$ is fairly representative of the original data used by Mr. Lacey; and $Q = 100\,000$ is representative of the writer's data.

TABLE 3.—ELEMENTS OF STABLE CHANNELS FOR GIVEN VALUES OF Q

Description	$Q = 1$		$Q = 1\,000$		$Q = 100\,000$	
	Pettis	Lacey	Pettis	Lacey	Pettis	Lacey
Velocity, V	0.8	0.8	3.18	2.53	8	5.45
Area, A	1.25	1.25	314	395	12 500	18 340
Depth, d	0.715	0.64	5.7	6.4	22.6	29.7
Hydraulic radius, R	0.511	0.468	4.1	4.7	16.1	21.7
Surface width, B	2.45	2.67	78	84	775	844
Kutter's coefficient, n	0.0225	0.0225	0.0225	0.0225	0.0225	0.0225
Slope, S	0.00036	0.0004	0.00036	0.00019	0.00036	0.00011
Ratio, $\dfrac{B}{d}$	3.43	4.17	13.7	13.2	34.3	28.5

The writer's formulas are a special solution for indicated conditions. Mr. Lacey claims that his formulas are general. The two solutions have been checked with such river data as are available, and the foregoing explanation seems to be the most satisfactory hypothesis under which one can co-ordinate the Lacey assumption that V varies as the sixth root of Q, and the writer's assumption that V varies as the fifth root of Q.

The laws governing velocity distribution in stream cross-sections are not definitely known, but to a certain extent they can be inferred from a study of available diagrams. The following statements appear to be justified: (1) In the stable parabolic cross-section, the bottom velocity will decrease gradually from the thalweg to the top of the banks; (2) the gravity component described by the author will increase gradually from the thalweg to the top of the banks; and (3) the result will be a condition of equilibrium at all points of the cross-section, except at low stages. It is obvious that a semi-elliptical cross-section will not meet the conditions for equilibrium near the top of the banks. The assumption of an elliptical cross-section does not materially affect the solution if the value of d is omitted.

The writer's conclusion is that Mr. Lacey's solution, to which the author refers, is fundamentally sound to the extent indicated, but that his theories should be slightly modified and expanded.

HARRY F. BLANEY,[14] M. AM. SOC. C. E. (by letter).—A problem is analyzed in this paper which has not always been given serious consideration, and the author presents data and conclusions which should prove of great value. Professor Lane has illustrated some of the problems which confront the designer when he attempts to apply formulas by Kennedy and others to conditions in the Southwestern United States.

In connection with silt investigations[15] made some years ago, several efforts were made by the writer and others to co-ordinate the movement of silt in the Lower Colorado River and in canals in Imperial Valley with the laws and formula held to be applicable to the movement of silt in other streams; but although there was agreement in some features, there was disagreement in others, so that, on the whole, few satisfactory conclusions could be drawn, largely because of the character of the silt and the chemical activity of certain salts in the waters of the river. The preponderance of fine silt held in suspension, and the fact that, in its movement downward or parallel to the grade of the channel, it seems to obey physical laws different from those governing bed silt, led to the conclusion that any formula applicable to one kind of silt would not apply to the other. Furthermore, it is not generally feasible to apply two sets of laws or formulas to the same part of a channel, since silt suspended at one time and place may become bed silt elsewhere at another time. Conversely, more or less bed silt may become suspended silt.

It was not difficult to trace the relation between the movement of the finer silt and the velocity of the current. All velocities in excess of about $\frac{2}{3}$ ft per sec transported the finer silt, not only in the river, but also in the canals. The chief difficulty arose in determining the velocities and other hydraulic elements that would cause the transportation of bed silt and the heavier grade of suspended silt.

In the earlier silt investigations, experiments were conducted with the object of applying Kennedy's formula (Equation (1)), to the canals of the Imperial Valley. Kennedy states[16];

"Strictly speaking, a separate value of V_0 should obtain at each season of the year, and for each class of sand carried in each reach of a canal, but this being impossible, the values of V_0 given must be taken as an all-round figure for what may be called the standard sand, found in the river beds near the hills. The question then arises how to define this sand, and a partial reply can be furnished, by taking as the criterion of coarseness, the rate of fall of the grains in still water. Thus, Grade 0.10 would consist entirely of grains which dropped at the rate of 0.10 feet per second; and Class $\frac{0.10}{0.15}$ would include atoms of all coarseness which fell between the rates of 0.10 and 0.15 feet per second."

Attempts to grade the Colorado River silts by Kennedy's method were not very successful as the particles would cling together and produce eddies. However, by making standard sieve analyses by weight and then determining the rate of dropping, in feet per second, for particles of various size, some results were obtained. Compilations for two canals in the Imperial Valley are shown in Table 4(*b*). Although not directly comparable, the results indicate that the silt deposits in the Imperial Canal are somewhat lighter and finer in texture than those of the Sirhind Canal in India.

TABLE 5.—BED WIDTH, DEPTH, AND MEAN, MAXIMUM, AND BED VELOCITIES FOR TYPICAL CANALS, IMPERIAL VALLEY, 1918–1919

Name of cana	Location	Bed width, in feet	Depth, in feet	Bed-width / Depth	Mean velocity, in feet per second	Maximum velocity, in feet per second	Bed velocity*, in feet per second

The author indicates that additional data are desirable on the "bed width-depth ratio." Table 5 has been compiled from original records of the U. S. Bureau of Agricultural Engineering (1918–1919) and may be of use in future studies.

[17] "The Control of Water", by the late Philip A Morley Parker, M. Am. Soc. C. E., Second Edition, p. 758.

SIGURD ELIASSEN,[18] ASSOC. M. AM. SOC. C. E. (by letter).—The subject of stable channels in erodible material is of great interest to engineers in North China, where the silt problem is extremely serious and, consequently, channel stability is difficult to attain. Measurements taken throughout 1934 show that, where the Yellow River enters its diked section, it carried in suspension the stupendous total of 1 500 000 000 cu m, or 2 400 000 000 tons, of silt as this would have been deposited on the plain in a natural dry state. It was more than an average flood-year, but far from an exceptional one. Silt measurements were taken every day throughout the entire year and twice each day during the freshet season, when the silt percentage runs high. The silt load at the place mentioned ran as high as 19% by weight at times, and at places where the river is confined between high banks, such as at Shanchow, in Western Honan, even as high as 38 per cent. On the King Ho, in the Province of Shensi, a tributary to the Wei Ho, which again is a tributary to the Yellow River, or Huang Ho, the writer has personally measured 48% by weight—that is, weight of dried silt over weight of silt plus water. Similar high percentages have been measured on other tributaries of the Yellow River. If the customary procedure for determining silt percentages is used (namely, weight of dried silt over weight of clean water), the percentages can be greater than 100 as the weight of the silt becomes heavier than the weight of the water. It does not seem logical to express it in this manner.

The measurements are dependable enough and have been observed by too many engineers to be doubted. The writer has mixed artificial silt percentages in a gasoline tin and finds that they remain quite fluid, up to 50% by weight. At 56% the "solution" begins to be sticky, and between 58% to 60% it becomes a brick-maker's paste. When fully analyzed, the measurements for 1935 are likely to show similar results as regards silt transportation.

The foregoing comments are offered only to demonstrate that American engineers have a "snap" compared to what confronts engineers in China when it comes to stability of river channels.

The author begins with the Kennedy rule for non-silting channels, $V_0 = C\ d^n$, and then reviews the work of other investigators who have included, also, the relation of width to depth, together with slope and silt character, in their formulas. He mentions that his investigations were prompted by the special conditions of the All-American Canal, for which it is claimed that the Kennedy rule does not apply. At any rate, considering the fine silt which this canal carries, surprisingly large constants have to be used to fit the Kennedy formula. Professor Lane, however, omits the hydraulic features of this canal, and the conclusions arrived at as regards its most satisfactory shape. The writer hopes that the author will include these in his closing discussion and also will show the character of silt in the form of an analysis curve, and the proportional quantity of suspended silt and "geschiebe", or bed load, carried by the canal. Professor Lane thinks that the varying quantity of suspended silt carried by the canal is a reason

[18] Engr.-in-Chg., Survey Dept., The Yellow River Comm., Kaifeng, Honan, China.

why the Kennedy rule does not apply. He also infers that the shape of the channel is a very important consideration when discussing stability.

Although the writer is in hearty agreement that channel shape is a very important factor, nevertheless, he thinks that the quantity and character of the silt transported as bed load is another highly important factor—more so than the varying quantity of the suspended silt, especially if this is fine. He has found that the Wei Pei Main Irrigation Canal, which has a slope of 1:2 330, a bed width of 6 m (19.7 ft), and side slopes of 1:1, carries fine sediment in suspension without silting the canal even when the load fluctuates from 0.1% to 10% by weight. Attempts have been made to use the canal when the silt ratio has been as high as 20 per cent. However, such attempts were discouraged not so much on account of silting of the main canal as the silting of the laterals. The silt is so fine that it all passes a 200-mesh sieve, the largest particles having a diameter of 0.03 mm. No coarse bed load is carried by this canal. It has been in use since 1933 and has not yet been cleaned out. The mean velocities in the canal, when it is running more than half-full, or depths from 1.5 m to 2.0 m (3.9 to 6.6 ft) is from 0.7 m to 1.0 m per sec. (2.3 to 3.3 ft per sec), and the discharge from 8.0 to 16 cu m per sec. (282 to 575 cu ft per sec); thus there is much fluctuation both in silt content and discharge.

From the foregoing it seems that as far as the All-American Canal is concerned there are other factors at work more important than silt variation, when considering the question of non-silting stability. As regards stability against scour the opinions expressed by the author seem very much to the point.

With regard to channel efficiency, a study of the roughness coefficient for the Yellow River shows that Kutter's *n* is fluctuating considerably at the same measuring section. Exactly what causes the fluctuation has not yet been fully discovered. The difficulties of securing good measurements for cross-section, velocity, and slope, under all conditions of flow and silt loads are obstacles to reliable conclusions. On the Yellow River the variation of silt, shape of section, slope, velocity, and discharge are so marked that it ought to be possible to come to definite conclusions in time; but from measurements which have been taken, it is quite evident that *n* is not constant. One of the reasons why it varies, perhaps, is that bottom waves of fine sand pass the measuring station from time to time. During the passage of such sand waves bottom irregularities are set up which increase the frictional resistance and raise the value of *n*. At other times there are no bottom sand waves and the frictional resistance is less with a consequent lowering of *n*. It is difficult to arrive at any conclusion as regards changes in *n*, due to a varying silt percentage.

Scour and re-fill of the bed or cross-sectional changes which proceed so rapidly on the Yellow River are, on the other hand, factors which definitely seem to influence *n*. This leads the writer to think that bed irregularities which slow up the velocity and raise the water level may cause deposits to occur, and he believes that the bed-load movement will create sufficient irregularities to cause deposition especially if the actual velocities under an ideal

canal condition lie close to the silting velocities. On the other hand, under a heavy suspended silt load the coarser bed-load silt grains should be carried along more easily, since they are "buoyed up" by the finer silt particles in suspension, due to the effect of increased specific gravity which mainly affects particles coarser than the average.

With regard to the Kennedy formula the writer wishes to draw attention to feet and metric units. This seems very elementary; but recently he has several times encountered cases in which metric units have been introduced directly into the common form of Kennedy's formula for the Bari Doab System, $V_0 = 0.84\, d^{0.64}$, which is in English units. In metric units, this formula reads, $V_0 = 0.56\, d^{0.64}$.

In logarithmic form, the Kennedy formula reads:

$$\log V_0 = \log C + n \log d \qquad (17)$$

As far as can be judged, Kennedy plotted his results on logarithmic paper. The points fell rather scattered and he drew the best average straight line and obtained his constants from Equation (17). It is interesting to note that the ordinary discharge or velocity formula is also of this form when the gauge height, H, is substituted for the depth, d. Assuming cases in which the Kennedy rule is applicable, the non-silting channel should be one in which the actual velocities and the Kennedy velocities coincide, or better, the actual velocity curve lying a short distance to the right of, but parallel to, the Kennedy curve. In practice, however, the two curves seldom coincide, but cross each other at some definite velocity.

If computed velocity curves are plotted on logarithmic paper for various kinds of sections (such as triangular, trapezoidal, or rectangular sections), it will be found that the slope of the curves varies somewhat with the shapes and dimensions of the sections, especially when these sections are narrow. As the sections widen the curves become parallel. Hence, it is impossible to apply one set of Kennedy coefficients even to one irrigation system.

In order to compare the Kennedy formula with the Chezy-Kutter formula the latter may also be expressed in logarithmic form:

$$\log V = \log C + \frac{1}{2} \log S + \frac{1}{2} \log R \qquad (18)$$

Considering, first, the Chezy-Kutter formula, it seems evident that since the slope is constant for a given section of a canal, $\frac{1}{2} \log S$ becomes a part of the intercept constant. If there is any change in S, the curve will be displaced parallel to itself.

Coefficient C is a function of R and also of the roughness constant, n; but C varies in the same manner throughout a considerable range in R-values for almost any value of n, and the effect on the curve due to a change in n is to displace it nearly parallel to itself. In other words, a change in n has little effect in changing the slope of the velocity curve. For the most part it changes the intercept value of the curve; but since C has also been made a function of R, it too should influence the slope of the curve.

Strictly, Coefficient C should be regarded as being made up of two parts, a constant curve intercept part and a curve slope factor. The constant intercept part, therefore, may be considered as being due to channel roughness, which is fixed within narrow limits, provided there is no bed-load movement and the channel keeps its shape otherwise. The slope factor part of C, for clear water, would then be a cross-section form factor which would change according to the shape of the cross-section. In the Chezy-Kutter formula, C has been made a variable depending to a certain extent upon R and then a general, fixed exponential factor, 0.5, made to represent the remainder of the form factor. To the writer it would have seemed more logical to have given C a fixed value according to the value of n, and then to have had an exponent of R which would change according to the shape of the cross-section. The Manning and Forschheimer formulas involve only n; but they also fix the exponent of R. It is true that form factors for areas of different shapes do not vary much, but it seems obvious that an improvement would result from making the exponent of R vary according to the shape of the section.

In the Kennedy formula, the disturbing element, silt, is introduced. Proceeding through the same line of argument it becomes obvious that the silt composition will affect C, or the intercept constant. Unfortunately, the silt composition is subject to change since floods from different tributaries may bring in different grades of silt. This is very noticeable on rivers in North China. If the silt composition is such that a part is carried as a bed load, this fact is likely to affect the roughness and disturb C still further. It may also affect the shape of the channel and thus change the exponential factor, d^n, which unquestionably can be regarded as a cross-section form factor. If the silt composition does not change much for varying silt percentages, then, up to the point where silting begins, the silt will be carried vertically and longitudinally very much in the same manner throughout the section, even when the water level fluctuates considerably, due to a varying discharge, and the channel is likely to have the same form factor and hence a constant exponent of d. In such cases both C and n can be determined reliably; but the difficulty in applying the Kennedy rule begins when the silt composition changes and a heavy "geschiebe" is introduced. For such cases it may be possible to determine the upper limit for C; but to find a reliable value for n is more difficult since anything may happen to the shape of the section when increasing the velocity to an extent which will make sure that the "geschiebe" is being transported without silting the canal. Most likely, in such cases, there will have to be desilting works. This seems to have been the case with the All-American Canal.

R. E. BALLESTER,[19] Esq. (by letter).—Table 1 of the paper shows a wide variation in values of C and n for Equation (1) applied to non-silting and non-scouring velocities. The formula proposed by the writer (Curve No. 10, in Fig. 1 and Table 1), namely, $V_0 = 1.01\ d^{0.44}$, in English units, has a lower exponent, n, than the other formulas. The writer wishes to present some

[19] Prof. of Applied Hydraulics, Univ. of Buenos Aires, Buenos Aires, Argentine Republic.

additional data, that has confirmed its application to the channel sections in which it was observed (Rio Negro, Argentina).

In a stretch of 10 km (6.2 miles) of the main channel of the irrigation system, of 2.00-m (6.6-ft) depth, 32.75-m (107.4-ft) bottom width, and 45 cu m per sec (1 589 cu ft per sec) of discharge, it was observed in 1926 that the mean velocity was not sufficient to prevent silting and the formula, $V_0 = 1.01\ d^{0.44}$ (English), or, in metric units,

$$V_0 = 0.52\ d^{0.44} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(19)$$

was then graphically established[20], taking this fact into consideration.

The channel silted gradually and, in 1933, the writer advised that the velocity in the channel be increased by widening the notched fall openings at the end of a 10-km stretch, that was causing some back-water. The advice was followed in 1934 and in 1936, after two years, the silting action has disappeared in the last 2 km ($1\frac{1}{4}$ miles) of channel. The mean velocity arrived at is somewhat higher than would be necessary, because some scour has occurred along the bottom of the channel, the slopes being unaffected. The velociti s registered before and after the widening of the fall are shown in Fig. 8, together with the Kennedy and Rio Negro formulas. If the Kennedy formula had been used, the writer is certain that the channel would have scoured seriously.

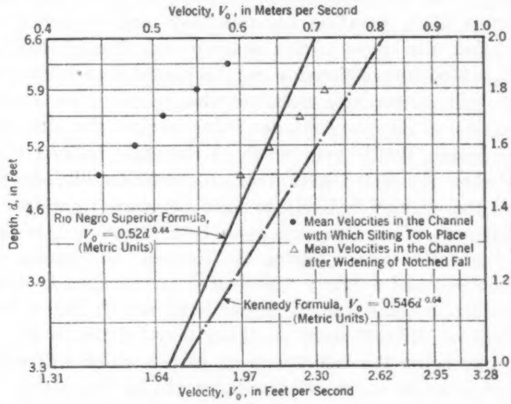

FIG. 8.

The channel cross-section now shows a tendency to scour along the bottom and to assume a semi-elliptical form. The bed-width-depth ratio of 16 for this cross-section is too high for this particular location. In alluvial valleys the soil is far from homogeneous, and there are great changes in the quality of soil, which are difficult to establish from the general topographical survey that precedes the design and alignment of the channel.

[20] "Velocidades y Coeficientes de Aspereza para el Cálculo de Canales en el Rio Negro", Contribuciones al Estudio de Las Ciencias Físicas y Matemáticas, Série Tecnica, Vol. III, Pt. 5, p. 435, Buenos Aires, 1927.

Regarding the composition of soil in the channel of the Rio Negro System, the data in Table 6 may be of interest for comparison with other channels.

TABLE 6.—ANALYSIS OF SILT AND BOTTOM SOIL IN THE MAIN CHANNEL OF THE RIO NEGRO SYSTEM

Sample No.	Station, in kilometers	Depth	Clay contents (percentage)	Sieve Analysis		
				Percentage retained on Sieve No. 100	Percentage retained on Sieve No. 200	Percentage passing Sieve No. 200
1........	18	0.20 m below water	19.4	10.0	23.0	67.0*
2........	16	0.20 m below water	22.2	3.0	7.0	90.0*
3........	12	Bottom of channel	4.6	14.2	49.1	36.7†
4........	12.6	Bottom of channel	2.0	37.7	38.0	24.2†

* Samples of silt deposited on the side slopes.
† Samples of soil forming the channel bed (not silt).

Of course, there are many variables that combine to stabilize the shape of a channel and some of them do not depend on soil condition. In the Rio Negro System there are favorable conditions tending to minimize the troubles due to silting. Irrigation delivery is suspended in winter from the end of May to the middle of August (eighty days on the average), just when the river is in flood, carrying its heavier silt load. At the end of spring (November), there are some small floods, but the intakes are ordered closed during the peak of the flood (not more than a day), because the trouble caused by delaying the delivery of water to the 130 000 acres in the System is less than would be caused by a continuous silting of the distribution system. Special conditions such as these, which are peculiar to each system, may explain the wide variation in the critical velocity formulas in Fig. 1 and Table 1 of the paper.

GERALD LACEY,[21] ESQ. (by letter).—Congratulations are due the author on his very able discussion of the various theories of silt transport extant when his paper was prepared. Engineers in India will immediately be struck by the very different conditions obtaining in Colorado and the great alluvial plains of India. The problem of regime flow is, in general, much simpler in India than on the Colorado River. Kennedy postulated for his channels that they should be flowing in their own self-silted beds and within self-silted side slopes; effectively they were regarded as flowing in an unlimited alluvial plain of the same silt grade as that transported. Recently, the writer has developed, on the same lines, "a general theory of flow applicable to channels flowing uniformly in incoherent alluvium"[22]. If a heavily charged channel is excavated in a medium other than the silt transported, or if the channel is afforded no opportunity of forming a reasonably thick boundary of the material transported, other factors will come into play. In certain circumstances the problem may merge from Gilbert's stream traction into flume traction[23].

[21] Superintending Engr., Irrig. Secretariat, Lucknow, U. P., India.

[23] "The Transportation of Débris by Running Water", by G. K. Gilbert, *Professional Paper No. 86*, U. S. Geological Survey.

In India canal cross-sections flowing within a boundary of silt deposit present an undeniable cup-shaped, curved, cross-section closely approximating a semi-ellipse. Professor Lane has quoted Kennedy's observations that channels carrying a heavy load had practically vertical sides and horizontal bottoms. This condition is prevalent where the channels are in "cut" and the wetted perimeter is less than the discharge can demand, or both. All recent observations have shown that when the channel is in "fill" (that is, formed by artificially constructed embankment) and the wetted perimeter assigned is sufficiently large, the cross-section tends to become semi-elliptical. Engineering practice favors the excavation of channels with horizontal bottoms, and for this reason many large channels with bottoms of stiff clay, or material more tenacious than the silt transported, preserve their horizontal beds to some extent. It may be easier for a limited depth of bed silt to slip and slide over a tenacious sub-stratum, than for the tenacious material to be picked up in the center. The difference between a scouring velocity and a silting velocity may be great. In certain embanked channels in India, with a bottom above ground level no attempt, from motives of economy, was made to raise the bed itself by "filling." It was anticipated that the defect would be corrected in time by silt deposits. It is these channels that now present the characteristic semi-elliptical cross-section. The Kheri Branch of the Sarda Canal in its lower reaches was excavated in fine sand that was almost incoherent. These reaches now present a curved cross-section in many instances of great regularity.

Professor Lane draws attention to the fact that on the Imperial Valley canals the non-silting velocity is considerably greater than the writer's formulas would indicate. The fine heavy silt charge demands a velocity of the same order as that demanded by a smaller charge of coarse silt in India. Equation (8) quoted by Professor Lane can apply only in the case of a regime charge. It was advanced by the writer as "a very rough qualitative formula for the diameter in inches of the predominant type of silt transported" and was intended mainly to assist in computing the critical velocities of natural streams in sand, shingle, or boulders, rather than as a basis of design. The silt factor is proportional to $\frac{V^2}{R}$, and it is this ratio which is required before channels can be designed. Mere measurement of the size of the particle without observations of the local velocity required to transport the charge is of little assistance. The silt charge in the Colorado River appears to be of great importance and abnormal as compared with conditions in India. The writer also feels that there are certain elements of flume traction that cannot be entirely dissociated from channel behavior on some, at least, of the Colorado canals. In channels with flume traction there is no limit to the surcharge that can be forced down provided slope is available and the banks possess some tenacity. In rivers flowing in deep alluvium, the surcharge is thrown down, and the river moves to a flank and picks up a fresh charge which it sweeps forward.

The remark by Professor Lane that the capacity of a stream to transport silt in suspension is probably proportional to its "turbulence" and to the

energy expended, is illuminating. According to Gilbert the prime mode of transportation is saltation rather than suspension, and the difference is important. With flume traction and a heavy surcharge the turbulence necessary to drive the boundary layer forward would also occasion an abnormal suspended charge.

In the writer's view "turbulence" is susceptible of definition, and the ratio, $\frac{V^2}{R}$, for any grade of silt and irrespective of the charge, epitomizes "turbulence." It is thus found that fine silt with a heavy surcharge may well demand the same value of $\frac{V^2}{R}$ as a coarse silt with a smaller charge in another locality. Again, the ratio, $\frac{V^2}{R}$, is intimately connected with the energy concept.

Professor Lane has given a comprehensive list of factors entering into channel behavior, but the writer feels that it is preferable to write them down as dimensioned variables. The Buckingham theory[24] summarizes very conveniently modern practice in dimensional analysis. Briefly, the method consists of writing down all the known independent dimensioned variables, and determining dimensionless arguments therefrom. These arguments are then correlated by ordinary statistical methods. Results obtained in such a manner have the merit of dimensional homogeneity. Mere dimensional homogeneity, however, does not denote accuracy, and a poor degree of correlation may reveal that other important variables remain to be sought.

If the number of independent variables is a, the number of dimensionless arguments is equal to $a-3$. Dealing with the independent variables historically, Chezy selected, effectively, four independent variables which left him with $a - 3$ (equal to one) dimensionless arguments for which it remained only to ascertain the numerical value. Thus, $\frac{i\,R}{\rho\,V^2}$ = the Chezy number, in which, in addition to the notation of the paper, i = energy gradient; R = hydraulic radius; V = mean velocity; and ρ = density of water.

Experience showed that not only was the Chezy number a function of the roughness, but it was also a function of R and possibly, as Kutter thought, of S. An essential variable had been omitted. Attention is drawn to the manner in which the ratio, $\frac{V^2}{R}$, enters the Chezy number, a number that must survive with the addition of other dimensionless arguments as knowledge increases.

Osborne Reynolds added, as a fifth variable, the viscosity of water. This added another dimensionless argument, the classic Reynolds number; thus:

$$\frac{i\,R}{(\rho\,V^2)} = K\left(\frac{R\,V}{\nu}\right)^m \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

[24] "On Physically Similar Systems; Illustration of Use of Dimensional Equations", by E. Buckingham, *Physical Review*, Vol. IV, Series 2, pp. 345–376, 1914; also, "Model Experiments and the Form of Empirical Equations", by E. Buckingham, *Transactions*, A. S. M. E., Vol. 37, pp. 263–296.

in which ν is the kinematic viscosity of water, and $\frac{R\,V}{\nu}$ is the dimensionless Reynolds number. It will be observed that the acceleration due to gravity, g, does not enter as an independent variable in Osborne Reynolds' relation. Osborne Reynolds' experiments were carried out with pipes. The boundaries were rigid and the shape was a constant.

In 1930, the writer suggested that the rugosity, or hydraulic roughness, of regime alluvial stream beds was implicit in the slope and the hydraulic mean depth which they assumed. In open channels, g enters as an independent variable. With the addition of this sixth variable a third dimensionless argument is evolved. This is none other than the Froude number, and,

$$\frac{i\,R}{(\rho\,V^2)} = K' \left(\frac{R\,V}{\nu}\right)^m \left(\frac{V^2}{g\,R}\right)^p \quad \text{.................(21)}$$

Attention is again drawn to the manner in which the ratio, $\frac{V^2}{R}$, enters the Froude number. The silt factor is merely a simple proportion to the ratio, $\frac{V^2}{R}$, and, therefore, as long as dimensional analysis is used as an instrument in hydraulic analysis the ratio, $\frac{V^2}{R}$, must persist as a fundamental element, and with it the silt factor, which more appropriately could have been termed "turbulence." In regime channels, "turbulence" with dimensions, $\frac{L}{T^2}$, would appear to be as real a factor as kinematic viscosity with dimensions, $\frac{L^2}{T}$ (in which T = time).

The writer[23] has shown how these dimensioned arguments can be fitted to empirical relationships defined by him. Thus, substituting for the energy gradient in terms of the geometrical slope, density, and the acceleration due to gravity,

$$\frac{S\,g\,R}{V^2} = K'' \left(\frac{RV}{\nu}\right)^{-\frac{1}{3}} \left(\frac{V^2}{g\,R}\right)^{\frac{2}{3}} \quad \text{.................(22)}$$

If the silt factor is treated as being proportional to $\frac{V^2}{R}$, Equation (22) may be solved and will prove the basis of all the writer's formulas other than those involving the discharge, thus leaving the silt factor in the ratio form, $V \propto g^{\frac{5}{9}}\,\nu^{-\frac{1}{9}}\,R^{\frac{2}{3}}\,S^{\frac{1}{3}}$; and this relationship is true for any regime channel in incoherent alluvium whether fine sand, coarse sand, shingle, or boulders. The very low power of the kinematic viscosity should be noted and the complete disappearance of the "silt factor", which is inherent in the dimensions assumed by the channel.

The formula may be re-cast in the form, $V \propto g^{\frac{5}{8}} \nu^{-\frac{1}{8}} \sqrt{\frac{R}{V}} \sqrt{RS}$, from which it follows if an equation of the Chezy type is required, $V \propto g^{\frac{5}{8}} \nu^{-\frac{1}{8}} f^{-\frac{1}{4}} R^{\frac{2}{3}} S^{\frac{1}{3}}$. The Manning power of $\frac{2}{3}$ becomes $\frac{3}{4}$, and the rugosity coefficient, n, is replaced by $f^{\frac{1}{4}}$.

The introduction of the wetted perimeter, P, as a variable gives the solution, $\frac{P}{R} \propto \left(\frac{RV}{\nu}\right)^{\frac{1}{3}} \left(\frac{V^2}{gR}\right)^{\frac{1}{3}}$, from which $P \propto Q^{\frac{1}{2}}$; and $\frac{P}{R} \propto V$. All the most recent work in India tends to confirm the expression, $P \propto Q^{\frac{1}{2}}$, as fundamental.

Since, by the writer's Equation (5)[23], $P = 2.668\ Q^{\frac{1}{2}}$:

$$P^2 = 7.12\ P\ R\ V \quad \text{(23)}$$

and, dividing through by $P\ R$,

$$\frac{P}{R} = 7.12\ V \quad \text{(24)}$$

This is the writer's empirical shape formula, and it is most unfortunate that so many of the data presented in the past are incomplete in respect of the wetted perimeter. Thus, a diagram showing $\frac{P}{R}$ plotted against V would be more illuminating than Professor Lane's Fig. 2, in which he has used the diameter of the silt as a basis for deriving the shape from the writer's formulas instead of the velocity. It is not clear from Professor Lane's paper whether or not the writer's shape formula is confirmed. The relation between the silt factor and the diameter clearly breaks down when there is a heavy silt charge, the fine silt behaving in the same manner as coarse silt in a normal channel. The writer would be very grateful if Professor Lane would plot the ratio, $\frac{P}{R}$, against V for all the Colorado River data.

Professor Lane states that the velocity along the bed should be sufficient to move all the material brought into the canal and yet not be so high as to cause the sub-grade of the canal to scour. He then goes on to state that the excess of velocity over that sufficient to move the transported material, which will attack the sub-grade, depends upon the material of the sub-grade. This concept clearly involves conditions approximating those of flume traction in which the transported material is pushed forward over a harder, more coherent, and possibly coarser sub-grade. When these conditions obtain, a horizontal bed is readily understandable. The maximum allowable velocity along the banks depends not only upon their material but also largely upon the shape factor. The contours of equal velocity ("isovels") plotted in Fig. 3, proceeding from a central nucleus of maximum velocity, show very clearly what a channel would choose to be, as opposed to what Man makes it. The suggestion of the semi-ellipse is plainly discernible and also the cramping warping effect of the vertical sides. With a tough sub-grade and a heavy surcharge, nearly all the work on the perimeter is done on the bed and little on the sides. The bed would then be nearly horizontal and the sides vertical.

If a channel is too narrow according to Equation (24) it will "kick" at the sides and this is the main reason for bank erosion. Furthermore, if the wetted perimeter is correct, but the bed as constructed is horizontal, the "velocity nucleus" of the isovel diagram will hunt about. With a channel properly constructed to a semi-elliptical trace the greatest velocity will be permanently located over the center of the channel. If a channel is constructed in material similar to that of the silt transported, or is a natural channel flowing in its own alluvium (for example, any sandy river), the central velocity will hammer the bed and curve it. Nature has nothing to say to horizontal beds when a river is flowing in a true alluvial plain.

The writer is of the opinion that a final solution of the problem of silt transport is to be found by investigation on the lines of dimensional analysis outlined by him. In India where the problem is simpler the writer's solution appears to fit a great mass of data. In the Colorado River, where the silt charge is excessive and there are many disturbing factors (notably the merging of stream traction into flume traction), practical design must depend largely on local conditions. The sub-grade as a factor is unknown in India, an unlimited bed of the same material as the silt transported being postulated. These are the conditions governing most great rivers in true alluvium. An examination of the Colorado Delta data should prove interesting.

V. V. Tchikoff,[25] M. Am. Soc. C. E. (by letter)—An excellent analysis of a complex problem is contained in this paper, and the author should be congratulated for his collection of the data accompanying it. The writer approves of most of the propositions suggested in the paper; they appear to be logical and convincing. The special consideration of the stability of the banks and the presentation of the cross-sections with the "isovels" are the most important additions to the study of the problem (see Fig. 3).

Isovels.—The purpose of a number of the rectangular cross-sections with the isovels presented by the author is to show "that high velocities extend closer toward the sides in the narrow, deep cross-sections than in the broad, shallow ones." However, an examination of Fig. 3 indicates that all cross-sections except one ($\frac{B}{d} = 0.60$, which is almost never used in practice), have the same isovel, 0.80, nearest the sides. The author's statement is perhaps more applicable to the bottom velocities, although there is a discrepancy in their distribution. The isovel, 0.80, for instance (shown in the sections with $\frac{B}{d} = 5.95$ and $\frac{B}{d} = 9.20$), disappears at the bottom of the intermediate section in which $\frac{B}{d} = 7.48$; but a more important observation is that both the side and the bottom isovels, being equal to 0.80 in most cases, do not vary much, especially if the section with $\frac{B}{d} = 0.60$ (which is not a very practical one) is disregarded.

[25] Cons. Engr., Washington, D. C.

It is well known that the mean velocity and the corresponding side and bottom velocities vary considerably in stable channels of the various sizes carrying the same sediment. Kennedy's stable sections[26] serve as an example; the mean velocity in the smallest section is 1.31 ft per sec, whereas, in the largest section, the velocity is 2.86 ft per sec. This variation is still more noticeable in Lindley's sections[27], the mean velocities ranging from 1.03 to 3.61 ft per sec, or about 350 per cent. Table 7 further illustrates how the

velocities are augmented with the growing of the width-bed ratio. These changes of velocity are incomparably larger than the rate of variation, if any, of the isovels near the side and bottom in the cross-section presented by the author.

Velocity Gradient.—The approximate value of the velocity gradient for the middle vertical can be calculated by dividing the difference of the two neighboring velocities or isovels by the vertical distance between them. This distance, however, scarcely changes for the low isovels (0.80, 0.90, and 1.00) in the greater part of the sections shown in the paper. There is a minor irregularity in the position of the isovel, 1.10, and a more noticeable one in that of the isovel, 1.20. The maximum velocity gradient is usually found in the low parts of the cross-sections, but it remains practically constant in the cross-sections of the paper.

"Pressure Gradient."—The action of the sides of a channel is mainly typified by the depression of the filament of maximum velocity. This is due to the existence of the transverse current in the flow, which was observed and experimentally demonstrated by Dr. A. H. Gibson[28]. The double-spiral-motion theory and the existence of the cross-currents with the direction of their flow toward, and up along, the sides of a channel could explain, reasonably well, such observed phenomena as the undermining of the low parts of the sides of channels, the rounding up of the angles between the bottom and sides, and the silting of the upper parts of the sides.

[26] "Stable Channels in Alluvium", by Gerald Lacey, p. 286.

[27] *Loc. cit.*, p. 287.

[28] "On the Depression of the Filament of Maximum Velocity in a Stream Flowing Through an Open Channel", by A. H. Gibson, *Proceedings*, Royal Soc. of London, Vol. 82-A, 1909.

The sum of the potential and kinetic energy is constant for all the points of the stream filament that lie on the same horizontal plane. Applying this condition, the "pressure gradient" that causes the transverse current may be expressed by the formula:

$$\frac{V^2_c - V^2_s}{2g\,\frac{B}{2}} = \frac{V^2_c - V^2_s}{g\,B} \qquad (25)$$

in which V_c = a velocity at the center of the cross-section; and V_s = a velocity on the same horizontal plane at the side of a channel. The isovels do not vary much in the cross-section in Fig. 3, but the value of B changes considerably. The broader the channel, the smaller the "pressure gradient" and the transverse currents, and the more stable are its banks. The effect of the sides of a channel is to produce the curvilinear movement of the flow, the cross-sectional profile of the water surface usually being a curve. As a result, the actual vertical pressure differs from the hydrostatic-pressure triangle. This difference depends upon the rate of changes of the pressure heads corresponding to the near-by velocities.

The theoretical equation for the vertical velocity curve is a parabola of the following type:

$$V = a\,y^2 + b\,y + c \qquad (26)$$

The equation for the corresponding pressure heads will be,

$$h_p = \frac{1}{2\,g}\,(a\,y^2 + b\,y + c)^2 \qquad (27)$$

and the rate of the changes of these pressure heads, S_p (= pressure gradient), is,

$$S_p = \frac{h_p}{dy} = \frac{V}{g}\,S_t \qquad (28)$$

in which S_t is the velocity gradient. Due to the combined effect of the isovels and the velocity gradient changes, both leaning in the same direction, the variation of the pressure gradient in Fig. 3 is greater than the change of each component, but even this double effect cannot explain the decidedly different property of the sections in Fig. 3 in regard to their relative stability. The reason for this, in the writer's opinion, is that each individual cross-section will fit a certain set of the hydraulic conditions upon which its stability depends. The condition for stability remaining unchanged, the width-depth ratio is determined according to the discharge of flow. For explanation of this statement, three general hydraulic factors should be considered: The kinetic factor; the coefficient of hydraulic similtude; and the hydraulic number; which have been introduced by the writer elsewhere.

Kinetic Factor.—The kinetic factor[20] is equal to,

$$K = \frac{V^2_m}{g\,R} \qquad (29)$$

[20] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 171, (Equation (73)); also, pp. 852–858.

It is a measure of the kineticity of flow, or turbulence. Equation (29) is similar to Mr. Lacey's formula expressed as Equation (7) in the paper, except that the kinetic factor has a definite physical significance. Equation (29) may be rewritten in the form:

$$V_m = (g\,K)^{0.5}\ R^{0.5} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(30)$$

"Sediment Equivalent."—Lacey correlates his silting factor to the diameter of the bed material by Equation (8) which, expressed in terms of the kinetic factor, is as follows:

$$D = 8.6\ K \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(31)$$

Lacey gave no precise indication of the classification of the sediment; nor has he considered the quantity of the material transported. It should be noted, however, that both Kennedy and Lacey connected their formulas to the sediment taken from the bed of canals or rivers.

By designating the hydraulic value of a particle by ω (the settling velocity in the water) and the concentration of the sediment by η (percentage by weight), the work per second (power) produced by the settlement in the water of a given sample of sediment may be termed the "sediment equivalent" and expressed by:

$$E = \frac{\rho_s - \rho_w}{\rho_s} \sum (\omega\ \eta) \ldots\ldots\ldots\ldots\ldots\ldots\ldots(32)$$

in which ρ_s is the density of the particles; ρ_w is the density of the water; and $\Sigma\,(\omega\eta)$ = the sum of $\omega\eta$ for each class of particles according to mechanical analysis. If ω is measured in feet per second and η in pounds (in 100 lb of water), E is in foot-pound units. For computing E it is convenient to use the mean hydraulic value of a sample, ω_m, which is equal to $\frac{\Sigma\,(\omega\ \eta)}{\eta_t}$, in which η_t is the total concentration. If each class of particles in a mechanical

analysis were indicated by the percentage, ρ, of the total concentration, the mean hydraulic value would be equal to $\frac{\Sigma(\omega\,\rho)}{100}$ (see Table 8). The "sediment equivalent" may be used as a criterion for the comparison of sediments, and it is rightly comparable to the kinetic factor.

Quantity and Quality of Sediment.—If two samples of the sediment, each consisting of only one size of particles of the same density, have the same value, E, the following equation is applicable: $\omega_1\,\eta_1 = \omega_2\,\eta_2$; or,

$$\frac{\eta_1}{\eta_2} = \frac{\omega_2}{\omega_1} \quad\text{(33)}$$

Equation (33) means that the concentration of the sediment varies in reverse proportion to the hydraulic values of the particles. This relation appears to reveal the approximate general law of the transportation of sediment in suspension. The law may be expressed in general terms:

$$\frac{\eta'_t}{\eta''_t} = \frac{\omega''_m}{\omega'_m} \quad\text{(34)}$$

That is, if the "sediment equivalents" are equal, the total concentration of the sediment transported in suspension varies in reverse proportion to the mean hydraulic value of the samples. There is a certain limit for the maximum hydraulic value, $\omega_{max.}$, of the particles that are found in the samples, which have the same value as the "sediment equivalent."

Kinetic Factor and "Sediment Equivalent."—The condition for the transportation of the sedimentary material near the bed in a stable channel in erodible material is of primary importance. The suspended material and bed-load merge into each other near the bed. This is especially true concerning the flow which is heavily charged with fine sediment, as the bed-load differs but little from that carried in suspension. Even if the sand were presented in a noticeable quantity, the same merging effect would occur and the coarse particles are often found at a relatively high distance from the bottom. The kineticity of the flow is directly related to the transportation of the sedimentary material near the bed, especially if this material is not of a coarse nature. Since the kinetic factor is a measure of turbulence and the sediment equivalent serves as a silt criterion, they should be related to each other. On the basis of certain considerations, it appears that their relation may be stated by the following equation:

$$E = a\,K^3 \quad\text{(35)}$$

in which a is a coefficient. The kinetic factor, K, is a dimensionless number, and, therefore, a is in foot-pound units. The determination of a for the two Imperial Valley canals[30] is demonstrated in Table 8. The average hydraulic value for each class of particles (see Table 8), more or less corresponds to

[30] "Silt in the Colorado River and Its Relation to Irrigation", by the late Samuel Fortier, M. Am. Soc. C. E., and Harry F. Blaney, M. Am. Soc. C. E., Tables 55 and 56, p. 75.

the Hazen formula[31]. One-half the hydraulic value of the particles corresponding to the 300-mesh sieve is assumed for the sediment passed through this sieve. Although this class of sediment constitutes a considerable portion of the total concentration, its work during the settlement is relatively small. The silt samples shown in Table 8 are the nearest to the bed of the canals, being in both cases 0.2 ft above the bottom. With the density of the sediment assumed as 2.65, the values of the coefficient, α, are equal to 0.76 and 0.93. The lack of information in regard to the stability, and especially in regard to "degree of concentration" of the sediment, makes it difficult to appreciate these values.

Degree of Concentration.—Three states of the flow carrying the sediment are distinguishable: (*a*) The over-loaded flow; (*b*) the normally loaded flow; and (*c*) the sub-normally loaded flow. The criterion for this general classification is the relation of the sediment load to the kineticity of the flow.

The flow, with a certain kineticity, will only carry the definite sediment load, provided, of course, the necessary quantity of sediment is supplied. This will be a normal sediment-loaded flow. Any increase in the supply of the sediment will over-load the flow with the result that the extra supply will drop. On the contrary, the under-loaded flow tends to pick up the material from the bottom and will scour the channel, depending upon the bed resistance. If the sediment is non-cohesive, there would be a tendency toward the normally loaded flow.

The value of the coefficient, α, depends upon the degree of sediment concentration. For the normally loaded flowing water in a stable channel, it seems possible to suggest that the value of α would be equal approximately to a unit if the sediment at the bottom and the kinetic factor are considered. It is difficult to obtain a representative sample of the sediment transported at the bottom, due to the merging situation. If the sediment from the bottom is considered, the nominal sediment concentration may be computed from Equation (35) on the basis of mechanical analysis of the bed material and under the assumption that $\alpha = 1$.

Sediment Concentration at the Bottom.—Twelve mechanical analyses of bed sediment in the Imperial Valley canals for various stations, at distances of 48 to 104 miles from the river, are given by Messrs. Fortier and Blaney[32]. The result of the calculation of the mean hydraulic values, ω_m, for these samples ranges from 0.023 to 0.047. However, the several highest values of ω_m have been influenced by the local conditions, as the wind-blown sand changes the character of the bed deposit. The average value for all twelve stations is 0.0324, and it is reduced to 0.03 if the three highest values are disregarded. The value of the kinetic factor for the Imperial Valley canals is analyzed in another part of this discussion (see "Stable Canals of Imperial Valley Project"). Its average value is equal to 0.117. Substituting this value into Equation (35) and assuming $\rho_s = 2.65$, the concentration, η, is 0.73 (percentage by weight). This number corresponds to the mean hydraulic value

[31] "Distribution of Silt in Open Channels", by J. E. Christianson, *Transactions*, Am. Geophysical Union, 1935, Pt. II, p. 481.

[32] "Silt in the Colorado River and Its Relation to Irrigation", by the late Samuel Fortier, M. Am. Soc. C. E., and Harry F. Blaney, M. Am. Soc. C. E., Table 49, p. 72.

of 0.03, and the concentration will vary directly with ω_m and K. More information on this point is needed, but the writer believes that the foregoing value is more or less comparable to the concentration of the normally sediment-loaded flow in the Imperial Valley canals. It should be noted that the foregoing consideration refers to the non-silting non-scouring canals.

With reference to the canals of British India, the writer has in his possession[33] the analysis of the sediment from the bed of the Sutlej River which was considered by Kennedy as one of the typical analyses corresponding to his formula,

$$V_0 = 0.84\, d^{0.64} \quad \text{.......................(36)}$$

This analysis is as follows:

Hydraulic value, ω, in feet per second.	Percentage by volume	Hydraulic value, ω, in feet per second.	Percentage by volume
0.00 to 0.05	11	0.20 to 0.30	7
0.05 to 0.10	43	0.30 to 0.40	2
0.10 to 0.15	25	0.40 to 0.50	1
0.15 to 0.20	11		

The mean hydraulic value of this sample is equal to 0.114, or approximately four times larger than the bed sediment of the Imperial Valley canals. Substituting into Equation (35) and taking $K = 0.0415$ (for Equation (36)[34]), $\rho_s = 2.65$ and $a = 1$, the concentration is approximately equal to 0.0242% by weight, or approximately a ratio of 1 to 4 130 by weight. This quantity is comparable to the sediment concentration of the Sirhind Canal which takes its supply from the Sutlej River. The concentration in this canal ranges from 1 in 3 300 to 1 in 9 000 by volume[33]. The highest concentration causes the silting, whereas the scouring was observed at the time of low concentration. Therefore, it may be assumed that the average (approximately 1 to 4 000 by volume) is the normal concentration that is more or less comparable to 1 in 4 130 by weight. The foregoing calculations are approximate, but the purpose of their presentation is to indicate the existence of a quantitative relation between the kinetic factor and the sediment at the bottom of the stable channels. It is also possible to show that the kinetic factor and the "pressure gradient" near the bottom are directly related.

Coefficient of Hydraulic Similitude and Hydraulic Number.—The knowledge of the kinetic factor is not sufficient for determining the dimensions of a stable channel. In addition, one of the two other factors should be known: Either the coefficient of hydraulic similitude, denoted as Y:

$$Y = \frac{Q}{R^3} \quad \text{.......................(37)}$$

or, the hydraulic number, N, related to Y by the equation:

$$Y = N\, K^{0.5} \quad \text{.......................(38)}$$

[33] The data are taken from the writer's publication on "Silting of the Irrigation Canals" (Petrograd, 1915), which was the result of his trip to British India.

[34] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 853.

The coefficient of hydraulic similitude defines the condition that the discharges of similar stable channels are in proportion to their hydraulic radii, raised to the third power. The hydraulic number gives the relation between the other two factors. Representing area of cross-section of a channel by $A = \beta R^2$ and substituting the values of K and Y from Equations (29) and (37), Equation (38) gives:

$$N = g^{0.5} \frac{\beta}{R^{0.5}} \qquad \text{.......................(39)}$$

in which β is a "hydraulic" shape factor. The writer has presented the values of these factors elsewhere[35]. The rectangular cross-sections in this paper furnish an opportunity to examine this type of channel by applying the aforementioned factors. For a stable channel of rectangular form, the relation between depth, hydraulic number, and width-depth ratio, $r = \frac{B}{d}$, is expressed by the following equation:

$$d = \frac{g\,(r + 2)^5}{N^2\, r^3} \qquad \text{.......................(40)}$$

which indicates that the depth in the rectangular non-silting non-scouring channels depends upon only the hydraulic number and the width-depth ratio. Equation (40) is presented by a series of diagrams on Fig. 9. By substituting for r, its equivalent, $\frac{B}{d}$, Equation (40) may be rewritten in a form, giving the direct relation between the depth and the width.

The paper includes two diagrams, Figs. 1 and 2, which give the velocity depth and the bed-width-depth relation for numerous formulas. It is natural that the critical velocity-depth relations (Fig. 1), being contingent on the kinetic factor and the character of the sediment, should vary considerably. The formulas of the type of Equation (1) are analyzed elsewhere in this discussion.

In regard to the equations for width-depth relation (Fig. 2), the author, taking the width corresponding to the 5-ft depth for two formulas, the Molesworth-Yenidunia formula and the Lindley formula, remarks that a ratio of maximum to minimum is of 781 per cent. It is also natural that the bed-width corresponding to the same depth must vary considerably, as it is dependent upon the hydraulic number, as illustrated by Fig. 9.

The width-depth formulas and the velocity-depth equations should be studied together if they were developed for the same conditions. Two previously mentioned formulas, the Molesworth-Yenidunia for $S = 0.00010$ and 0.00007, and the Lindley formula, are drawn on Fig. 9. Their positions are quite consistent with the remainder of the curves. An hydraulic number of about 20 is rather typical of the Egyptian canals, whereas that of the Lindley formula lies between 35 and 45. However, it should be repeated

[35] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), pp. 853–855, Tables 5, 7, and 8.

that the curves in Fig. 9 are for rectangular channels. Their application to other forms of channels, therefore, has some limitations.

Stability of Rectangular Cross-Sections.—Assuming the values of the kinetic factor, the hydraulic number, and the width-depth ratio, the other

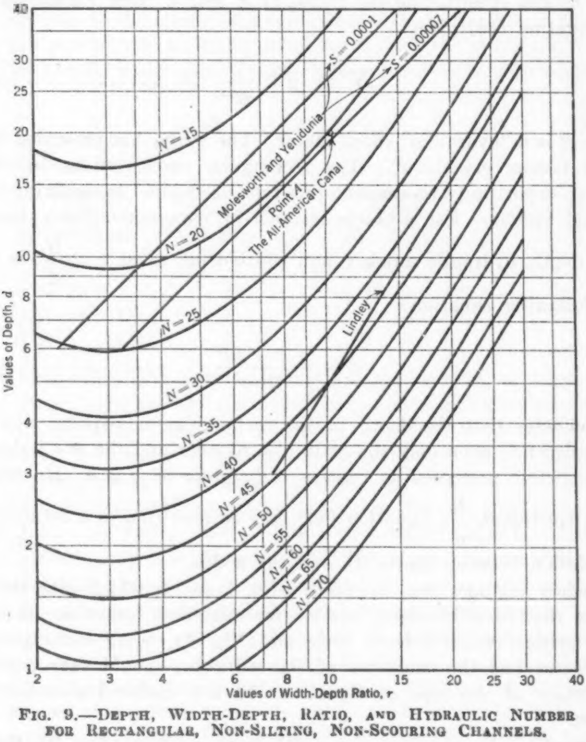

FIG. 9.—DEPTH, WIDTH-DEPTH, RATIO, AND HYDRAULIC NUMBER FOR RECTANGULAR, NON-SILTING, NON-SCOURING CHANNELS.

hydraulic elements can be calculated for the rectangular cross-sections. For the computation of the corresponding discharge, the following formula applies:

$$Q = g^3 \frac{K^{0.5}}{N^6} \left[\frac{(r + 2)^2}{r} \right]^6 \qquad \text{.....................(41)}$$

Table 7 gives the depth and velocity for the various values of K, H, and r. It is obvious from Equation (30) that the velocity changes in proportion to the square root of the kinetic factor. For the same width-bed ratio, the influence of the hydraulic number upon the velocity is that the latter varies in reverse ratio to the hydraulic number.

The width-bed ratio of the cross-sections in Fig. 3 is given in Item Nos. 1, 2, and 3, of Table 7. Considerable variations of the velocity should be noted for the cross-section that has the same width-bed ratio. For example, the

range of velocities in cross-section, $r = 5.95$, is from 1.71 to 6.82 ft per sec, depending upon the values of K and N. The examination of the velocities for the same value of K and N (vertical columns) also shows that they vary considerably They increase with the growing value of the width-depth ratio. There is a practical limit for the increase in the velocity, mainly because of irregularities in the bottom of the canal. However, for a given value of K, N, and Q, the only section of a definite width-depth ratio will be stable, at least theoretically, for the non-cohesive sediment.

For an illustration of the manner in which the foregoing relations could explain the condition of unstable channels, an example is presented. Among Lacey's data[36] there is a cross-section of the Upper Bari Doab Canal, which has "a velocity approximating Kennedy's regime velocity, yet it had scoured its bank for 20 yars past." The actual section of this canal is shown in the solid line on Fig 10. A "normal" section is drawn in dotted lines, and both

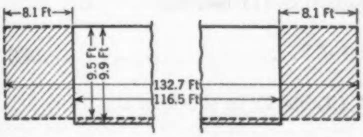

FIG. 10.—ACTUAL AND NORMAL CROSS-SECTIONS, UPPER BARI DOAB CANAL, MAIN BRANCH.

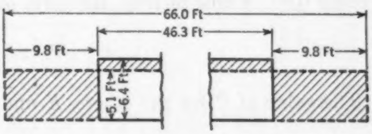

FIG. 11.—VARIATION OF NON-SILTING, NON-SCOURING SECTIONS, EAST HIGHLINE CANAL, AT B HEADING, IMPERIAL VALLEY, CALIFORNIA.

sections are assumed to be of the rectangular form. The "normal" section is determined, using the same discharge and assuming that $K = 0.0415$ and $N = 35.3$, the values that are in Kennedy's formula for this project. Comparing the two sections, the canal scoured to the depth of 9.9 ft instead of the "normal" depth of 9.5 ft, but its "normal" width should be 16.2 ft wider. This condition naturally causes scouring of the banks, which apparently are more resistant than the "normal" ones should be.

Formulas of the Type of Equation (1).—This type of formula has been used extensively for the expression of the relation between the critical velocity and depth, as is well illustrated by Table 1. The same kind of formula, however, can be developed from the data of Table 7. For example, for a velocity and depth corresponding to $K = 0.04$ and $N = 40$, four variations of Equation (1) may be written with two unknowns, C and n. Numbering these equations (A), (B), (C), (D), in the order of the bed-depth ratio values in Table 7, there are six combinations of these equations for finding the unknown value of the exponent, n. The results are as follows:

Combinations of Equations:	Values of n:	Combinations of Equations:	Values of n:
(A) and (B)	0.87	(B) and (C)	0.60
(A) and (C)	0.68	(B) and (D)	0.57
(A) and (D)	0.61	(C) and (D)	0.54

An examination of these and similar data for the other values of K and N, leads to several interesting conclusions.

[36] "Stable Channels in Alluvium", by Gerald Lacey, p. 289.

The exponent, n, is not influenced much by the values of K and N; it depends primarily upon the width-depth ratio. The larger this ratio, the smaller the value of n will be. Its limit is equal to 0.50 for a channel of indefinite width. The range of the width-depth ratio in the canals that have been observed for the development of a specific formula of the type discussed, mainly if not primarily determines the value of n. The more channels with small width-depth ratios that are included, the greater will be the value of n. For instance, the width-depth ratio in the twenty-two cross-sections of the Bari Doab Canal which served for the development of Kennedy's formula, with $n = 0.64$, ranges from 3.5 to 12.7, the group from 3.5 to 5.0 constituting more than 40 per cent. For the data given previously, 0.66 is the average of all six values of n, and this average would be 0.57 if Equation (A) pertaining to the lowest value, $r = 3.20$, is excluded. Assuming 0.57 for the exponent, n, the values of Coefficient C would be as follows: 0.85, 0.92, and 0.93, the mean being 0.90. Consequently, the form of Equation (1) becomes:

$$V_0 = 0.90\ d^{0.57} \quad \ldots\ldots (42)$$

The value of C for the others, K and N (Table 7) in the formulas:

$$V = C\ R^{0.5} \quad \ldots\ldots (43)$$

and

$$V = C\ d^{0.57} \quad \ldots\ldots (44)$$

is given in Table 9.

TABLE 9.—COEFFICIENT, C, IN EQUATIONS FOR VELOCITY IN RECTANGULAR STABLE CHANNELS

Description	Hydraulic Number, $N = 40$		Hydraulic Number, $N = 20$	
	Kinetic factor, $K = 0.04$	Kinetic factor, $K = 0.16$	Kinetic factor, $K = 0.04$	Kinetic factor, $K = 0.16$
Equation (43)..	1.135	2.27	1.135	2.27
Equation (44)..	0.90	1.80	0.82	1.64

It is of interest to mention that Lorenz G. Straub, Assoc. M. Am. Soc. C. E., found the exponent to be equal to 0.56 for the non-silting, non-eroding condition in his study on the bed-sediment transportation.[87]

Unlike the exponent, n, which is practically independent of the kinetic factor and the hydraulic number, the value of the coefficient, C, depends upon both of them. For the same value of n and r (rectangular channels considered), the ratio of the C-values may be expressed by the equation:

$$\frac{C_2}{C_1} = \left(\frac{K_2}{K_1}\right)^{0.50} \left(\frac{N_1}{N_2}\right)^{2n-1} \quad \ldots\ldots (45)$$

[87] "Hydraulic and Sedimentary Characteristics of Rivers", by Lorenz G. Straub, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, April, 1932.

A similar type of equation may be developed by using one-half, or the entire, width of the channels. If d in Equation (1), is equal to $\frac{B}{2}$, the coefficient, C, will change slightly, but the exponent, n, will be noticeably less than in an equation of the usual type.

Stable Canals of Imperial Valley Project.—William T. Collings, Jr., M. Am. Soc. C. E., has published the hydraulic elements for six canals of the Imperial Valley Project[38]. His data have been used by the writer in preparing Table 10,

TABLE 10.—GENERAL HYDRAULIC FACTORS, CANALS IN THE IMPERIAL VALLEY, CALIFORNIA

Item No.	Canal	Location	Discharge, Q, in Cubic Feet per Second, Ranging:		Mean Velocity V_m, in Feet per Second, Ranging:		Hydraulic slope, S	Mean kinetic factor, K_m	Mean coefficient of hydraulic similitude, Y_m	Mean hydraulic number, N_m

giving the general hydraulic factors for these canals. For the first four canals (Items Nos. 1, 2, 3, and 4), all the sections but one have been taken, which are considered by Mr. Collings as non-silting, non-scouring sections. Average values for the kinetic factor, coefficient of hydraulic similitude, and hydraulic number are presented in Columns (8), (9), and (10), of Table 10. These data permit the division of these six canals into two groups.

The first group consists of the four canals (Items Nos. 1, 2, 3, and 4) having practically the same kinetic factor, which ranges from 0.108 to 0.127, the average being 0.117 ± 8 per cent. The two remaining canals (Items Nos. 5 and 6) belong to the second group, having practically the same kinetic factor (0.063), but it appears that both canals are not stable and the material composing their cross-sections differs greatly from that made by the sediments of the Imperial Valley Canal. In regard to Item No. 5, Table 10 (West Side, Main Canal, Boundary Meter Station, California), Mr. Collings made a remark that "the sides and bottom show a hard and tight clay, and an eroded rough surface." The other canal (Item No. 6, Table 10) is called "self-maintaining" by Mr. Collings: "What silting may take place at low heads is relieved when these heads increase, and no cutting of the banks takes place at maximum heads." It should be noted that the hydraulic number is about

[38] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 549.

20 in these two canals, or approximately one-half as much as in the canals of the first group. These values of kinetic factor and hydraulic number are comparable with those that have been found by the writer in eroding drainage channels.[39] Hence, the writer is inclined to believe that the second group belongs rather to the canals scoured in "earth", whereas the first group is typical for the Imperial Valley canals, which are built up, or strongly affected, by the sediment transported by the system. Accepting the kinetic factor, $K = 0.117$, as a typical one for this project, the equation for the mean critical velocity will take the form:

$$V_0 = 1.93\ R^{0.5} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

Equation (46) covers a considerable range of discharges, from 180 to 3 600 cu ft per sec, and of velocities, from 2.9 to 5.0 ft per sec.

Influence of Fine Particles.—For estimating the cohesive force between the particles, Dr. Herbert Chatley suggests the following formula[40]:

$$V_e = \frac{0.02}{D} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

in which D is a diameter of the particle, in centimeters; and V_e is a velocity in centimeters per second, which will just produce the necessary friction force to rupture the molecular bonds; that is, to erode the fine material.

Although the application of Equation (47) is perhaps limited, it offers a concrete idea as to the influence of the fine particles on scouring. This is illustrated by Table 11 in which the velocity, V_e, is computed by Equation (47). There is no definite limit to the size of colloidal particles, but it is generally assumed that particles with a diameter smaller than 0.001 mm (1 micron) are colloidal. For such particles, $V_e = 6.56$ ft per sec. On the other hand, the hydraulic value of a particle represents the gravity action in the water and is equal practically to zero for colloids. The relative values of cohesion and gravity for other sizes of particles are given in Table 11.

TABLE 11.—Eroding Velocity and Hydraulic Value

Class of particle	Diameter D, in millimeters	Eroding Velocity, V_e		Hydraulic value, ω, in feet per second
		In centimeters per second	In feet per second	
Fine gravel to coarse sand	1.00	0.2	0.0066	0.3280
Fine sand to very fine sand	0.10	2.0	0.0656	0.0262
Very fine sand to silt	0.05	4.0	0.1312	0.0095
Silt to clay	0.005	40.0	1.3120	0.0001
Colloids	0.001	200.0	6.5600	0.00004
Clay	0.0001	.....	......	......

There is a large portion of the material in sediment and soils of the Imperial Valley Project, which passed a No. 300 sieve (D = about 0.0043

[39] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 857, Table 8.

[40] "Problems in the Theory of River Engineering", by Herbert Chatley, Lond., 1929, p. 17.

mm), that approximately separates silt and clay. The presence of colloids in this class makes the sedimentary material rather coherent and considerably affects the scouring resistance, especially of the banks of the Imperial Valley canals. The steep banks of the channels in many localities, including the Imperial Valley, are explained by the cohesion forces of the very fine particles.

Silting and Scouring Limits.—There are two critical conditions or limits in a non-silting non-scouring channel. The low limit—the non-silting section—is the point at which the deposition of material stops. The upper limit—the non-scouring section—is the point at which the scouring begins. It has been established that even the sediment recently deposited would not scour again until the velocity was increased to the larger value of the silting velocity. The extent between these two limits might be considerable.

* Sections considered non-silting and non-scouring by William T. Collings, Jr., M. Am. Soc. C. E.

As a demonstrative example in Table 12, Mr. Collings' data for the East Highline Canal, at "B" Heading, are used once more. Among the eleven observations, six are considered by Mr. Collings as non-silting non-scouring cross-sections. It appears that the first of these sections (Item No. 3, Table 12) is for the conditions when the silting stops, and the last observation (Item No. 9) is the upper limit related to the beginning of scouring. Since the kinetic factor in all the six observations is approximately the same, indicating that the conditions at the bottom do not vary much, attention should be directed to the stability of the banks. The widths of cross-sections shown in Table 12 and calculated under the assumption that the channels are of rectangular form, remain constant, their average value being 46.5 ft ± 1 per cent. This fact proves the stability of the banks, although the velocity gradually becomes greater with the diminishing width-bed ratio, both conditions tending to intensify the scouring action of flowing water on the banks. The degree of sediment concentration in flow at the time the measurements were taken, and the character of material composing the banks, are not known to the writer However, an examination of Table 12 as well as con-

sideration of other data, suggests that the value of the hydraulic number is a controlling factor of the stability of banks.

The hydraulic number becomes smaller in all the eleven cross-sections, ranging from 44.4 to 29.9 in the six stable sections. The other three stable canals indicated in Table 10 have the same diminishing tendency in regard to the hydraulic number. The study of canals in British India leads the writer to a suggestion[41] that their average hydraulic number is about 40. The average value of N for the four Imperial Valley canals, cited previously, is 43.5 and exactly 40, if the Alamo Canal is omitted. However, the range of these values is great, being approximately 65 to 30. The variation in flow when it extended beyond the non-silting and non-scouring limits, the large velocities, the difference in resistance of bed and banks, and the influence of original designs and methods of maintenance are probable reasons for such a range in the value of N. The hydraulic number in the two unstable canals of Table 10 has also the same diminishing tendency, approaching the value of 20. A reference has already been made to several erodible drainage canals[42] in which the hydraulic number varies from 15 to 22.50. The tendency for some of the foregoing values to coincide suggests that a hydraulic number equal to about 20 is the average upper limit for stable channels in "earth."

Variations in Discharge.—Examination of Table 12, and the previous remarks in regard to the non-silting and non-scouring limits for a cross-section, seem to indicate a method for the design of a canal with a varied flow. Two sections are drawn on Fig. 11. One section in solid lines is the actual section of Item No. 9, Table 12; that is, the upper limit mentioned previously. Another section in dotted lines is the non-silting section for the same discharge of 1 301.6 cu ft per sec, but the kinetic factor and hydraulic number are of Item No. 3 (Table 12); that is, the low limit. These two sections, or any intermediate section, might be taken for a prototype to compute and design the section corresponding to the given discharge. Each of these sections will be stable. Incidentally, that is one of the principal reasons for the large variation of width-depth ratio in the canals of the Imperial Valley.

If the discharge is variable, the upper limit may be used for the maximum discharge, or the low limit for the minimum discharge. The spread between these two limits will determine the possible variation in the discharges. If the spread could not include the given variation in discharge, it would be impossible to design a stable channel. There remains the possibility of devising a more or less "self-maintaining" channel with an unvarying tendency to silt or scour, the latter usually being preferable for irrigation canals.

All-American Canal.—Among the various factors introduced and discussed, the writer has intended mainly to bring out the importance of two factors, the kinetic factor and the hydraulic number, which, in his opinion, may be used as criteria for the stability of a channel in erodible material. Its bed stability is controlled by the kinetic factor, whereas the hydraulic number is related to the scouring resistance of banks.

[41] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 853, Table 5.

[42] *Loc. cit.*, p. 857, Table 8.

The author presents a study based on the design of the All-American Canal, and it would be of interest to see how the writer's discussion might be applied to the cross-sections adopted for this canal. The hydraulic elements[43] are, as follows, for its largest section: $Q = 15\,155$ cu ft per sec; $A = 4\,041.3$ sq ft; $V = 3.75$ ft per sec; $R = 16.63$ ft; $d = 20.61$ ft; and, by computation, $K = 0.02626$ and $N = 20.33$.

Assuming a rectangular cross-section, the foregoing values of K and N yield values of $d = 19.9$ ft and $r = 10.2$. A point corresponding to this depth and width-depth ratio is shown in Fig. 9 (see Point A, the All-American Canal) near the curves for the Egyptian canals, indicating that conditions in such channels are more or less similar to those assumed for the design of the All-American Canal.

The foregoing kinetic factor in the All-American Canal is not comparable to its prevailing value in the Imperial Valley on account of the proposed desilting works. A proper procedure for checking its value by Equation (35) would be to determine the "sediment equivalent" from a mechanical analysis of silt that is assumed to enter the canal; but such an analysis has not been made as far as the writer is aware. The concentration of the sediment near the bed should be known. Assuming that this concentration would be 10% higher than the average and that the coefficient, α, = 1, the mean hydraulic value computed from Equation (35) is $\omega_m = 0.01$ sec-ft. This hydraulic value corresponds approximately to the 280-mesh sieve, but that gives only a general indication of predomination of the finest particles in the sediment. Further study is required to derive a quantitative expression of the relation between the hydraulic number and the resistance of the material composing the banks. However, it is of considerable interest to note that the hydraulic number in the All-American Canal ($N = 20.33$) coincides with the value of 20, which has been suggested in the discussion as the average hydraulic number for canals in "earth."

Assuming that the proposed cross-section of the All-American Canal would tend to adopt a shape corresponding to the kinetic factor and hydraulic number as calculated previously, its depth should be less, whereas the width should be greater, than in the proposed cross-section. In other words, there might be a slight tendency to scour especially along the low parts of banks. Assuming, furthermore, that the hydraulic number is correct, this tendency to scour would be slight and would occur only at the time of full flow in the canal. The smaller the flow and, consequently, the cross-section, the greater will be the tendency for the silting to develop. These conditions, as the writer understands them, are desirable for the Imperial Valley because the collection of the settling sediment in the main canal is preferable to its conveyance to the distribution system.

W. M. Griffith,[44] Esq. (by letter).—Because it gives no new data, or mathematical reasoning to support or refute theories already advanced on this interesting subject, this paper is disappointing.

---

[43] *Engineering News-Record*, October 17, 1935, p. 539.

[44] Cambridge, England.

Fig. 3 was presented to show that high velocities extend closer toward the sides in the narrow, deep cross-sections than in the broad, shallow ones. This fact in itself would not appear to offer a satisfactory explanation to the well-known phenomenon that channels carrying heavy silt loads tend to adopt broad shallow cross-sections because, for any given discharge and surface slope, channels will be found to carry heavier silt loads if they are given broad shallow cross-sections than if they are given deep narrow ones, even if the sides are protected against erosion by a non-erodible lining.

The author quotes Mr. Kennedy's classic formulas (1) of relationship between velocities and depth of non-silting channels, and a large number of subsequent formulas, based on the same form of analysis of existing canal systems, in many parts of the world, which have values in many cases different from those of the channels cited by Mr. Kennedy. All these equations are in the form, $V_0 = C\ d^n$ (see Equation (1)) in which V_0 is the velocity that gives stability, and d is the depth of the channel section.

He also quotes Mr. Lacey's formula (18) (see Equation (7)), which may also be written in the form,

$$V_o = C\ R^n \qquad (48)$$

and the essential difference between it and those based on Kennedy's studies, is that it claims that the stable velocity is a function of the hydraulic mean depth of the channel, and not of the depth of the channel. It is a more logical formula, in that the principal function, R, is governed by the general shape of the section, whereas d, the depth, is not. In an irregular cross-section it might be difficult to decide what value to take for d; that is, the average depth of the bed, or the maximum depth of the bed.

In consequence, it is not surprising that the values of the indices in these formulas based on Kennedy's studies differ. Kennedy did not claim that his formula was a basic law applicable to all channel sections; it referred to the Lower Bari Doab channel sections, which had approximately the same type of cross-section; namely, side slopes averaging 1 on 0.5 and presumably a bed level across the cross-section.

It has been found that none of these formulas has a universal application, and opinion has been expressed that it is not possible to write formulas for silt transportation and the hydraulic conditions governing a stable section, that have more than a local application.

In a paper entitled "A Theory of Silt and Scour",[45] the writer outlined a theory of silt transportation and the hydraulic conditions governing stable channel sections, which he advanced as the result of experience both in river training work and canal maintenance. This theory was based on the assumption that the power to transport silt depended only on the relative strength of the vertical or resultant vertical eddies, and was independent of that of horizontal eddies or of resultant horizontal eddies.

The main observation on which the theory was based was as follows: At any point in a flowing cross-section heavily charged with silt, if the velocity

[45] *Minutes of Proceedings*, Inst. C. E., Vol. 223 (1927) pp. 243 to 251.

is reduced artificially the depth is found to reduce automatically due to silting, and if the velocity at a point is increased, the depth is found to increase due to scour.

In consequence, the writer was led to the conclusion that Kennedy's relationship between depths and velocities (Equation (1)) was in reality a basic law of silt transportation, not for channel sections considered as a whole, but giving the connection between the silt charge transported and the hydraulic conditions necessary for its transportation at a point.

It follows from this general assumption (that in a flowing section, equilibrium at all points requires that Equation (1) shall be satisfied), and from Chezy's basic law, that if the value of the exponent, n, is equal to 0.5, the section can be in equilibrium whatever its shape. On the other hand if the value of n is less than 0.5 the section must be deep and narrow, for equilibrium, and *vice versa*. As natural sections carrying heavy silt charges are invariably broad and shallow it follows that the value of n must be greater than 0.5.

In the writer's paper[45] referred to, the value of n was assumed to be 0.64. As the examples dealt with were for river beds of shingle and boulders this value was consistent. For sand, however, a lower value of n is indicated. Arguing mathematically from this basic assumption it follows, considering any cross-section, that for equilibrium as a whole, by integrating Equation (1) across the section the condition for equilibrium is that, necessarily,

$$V_m = C\, d^n_m \quad \text{.........................(49)}$$

in which V_m is the mean velocity of the entire cross-section and d_m is the mean depth. In Equation (49), as in Lacey's formulas, the main function governing the critical velocity (that is, the mean depth) is controlled by the shape of the cross-section. On the other hand, while from this theory it follows mathematically that the bed of the cross-section for equilibrium must be level across the section, Lacey postulates a curved bed which, in its true form, he claims to be semi-elliptical.

The difference between Equation (48) and Equation (49) is fundamental because the sum of the eddies created by the friction of the flow is a function of R, the hydraulic mean depth, whereas the sum of the vertical eddies only, or their vertical components, is a function of d_m, the mean depth.

In other words Lacey postulates a semi-elliptical stable cross-section and a law of silt transportation depending on all eddies created by the flowing section, and the writer, a cross-section having a horizontal bed and a law of silt transportation depending on the vertical eddies or the vertical components of the eddies only.

The writer advanced his theory as a general theory of silt transportation, but, in reality, it relates to loose granular material, such as boulders, shingle, and sand, graded down to a size of the order of $\frac{1}{300}$ in. in diameter, but it does not relate to the transportation of a silt charge containing only such light material as is held in suspension and transportable under the action of all eddies.

In practise, normally, a silt charge will contain silt of both classes—heavy and light—but such a case is governed by the law that controls the heavier class only, because if the heavier class is transported, the lighter material will remain in suspension automatically. There are cases, however, in which the silt charge consists of very light material only (such as clay, organic matter, and sand of an extreme order of fineness), and in such cases the theory advanced by the writer[45] does not apply. The two different sets of conditions, perhaps, can best be illustrated by considering a canal or a canal system carrying at its head a heavy silt charge consisting of both classes of material. The sections of the channel or channels near the head will have horizontal beds and the beds will be of pure sand, the great majority of the grains being more than $\frac{1}{300}$ in. in diameter. If the system is a long one, the silt of a heavier order will leave it through the distributing outlets which being situated near the bed level draw off the heavier silt particles. At the tails of this system, then, only light material will be left to be transported and the type of cross-section, if left to form its natural section, will change from a level bed to a curved bed, possibly elliptical in shape as claimed by Lacey.

Now, in such a system the question of designing a non-silting section correctly is usually of importance only in the upper reaches carrying the silt of a heavy order, because the rate of settlement of silt of the lighter order is very small and the material settled on the perimeter at the tail of the system is not pure sand; it has binding properties and is useful for forming the channel banks.

If, therefore, as the writer suggests, there are, in fact, two different conditions of silt transportation, one depending on the ratio, $\frac{V}{d^n_m}$, and the other on $\frac{V}{R^n}$ or $\frac{V}{R^{\frac{1}{2}}}$, it would explain why relationships argued mathematically from the latter formulas would not be applicable to the conditions pertaining in the Imperial Valley Canals, which carry silt of the heavy order.

In Fig. 2 the author has plotted on logarithmic paper the mean depths against bed widths of a number of channels, including those considered to be in regime on different canal systems, apparently, with a view to determining whether any general relationship between bed width and mean depths can be established for non-silting channels. The result shows very clearly that no such relationship exists.

If the general formula, Equation (49), is correct, if B = width at water surface, and Q is the discharge, then as $V_m = \frac{Q}{B\,d_m}$: From Equation (49), $\frac{Q}{B\,d_m} = C\,d^n_m$. Therefore,

$$B = \frac{Q}{C\,d^{1+n}_m} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(50)$$

Equation (50) would indicate that it is not possible to frame a general law of relationship between width and depth irrespective of the discharge or the silt load carried.

Table 1 gives values of C and n (in a general formula of the Kennedy type —Equation (1)) which are found to give values for non-silting channels in different canal systems in different countries.

The differences in C are understandable as the silt load will vary with the conditions of the different rivers feeding the canal systems. The big differences in value of n shown in Table 1, however, are illogical if all beds are of graded sand. In model experiments normal differences in the size of sand are found not to affect the coefficient of roughness. In the case of boulders, or boulders and shingle, where the vertical eddies are materially affected by the obstruction of particles of an entirely different order of size, a different value of n might be expected, but it is not reasonable to expect big differences in silt containing graded sand.

If, however, as the writer claims, Equation (1) is inapplicable to the channel section considered as a whole, and should be of the form of Equation (49), then these differences are explainable.

For example on the assumption of Kennedy's law (Equation (1)), the data of the channels cited by Kennedy are found to conform to the equation,

$$V = 0.84\ d^{0.64} \quad \text{(51)}$$

(Table 1, Curve No. 17) and the Godavari Western Delta, Madras (Table 1, Curve No. 9),

$$V_o = 0.67\ d^{0.55} \quad \text{(52)}$$

This gives a wide difference in values of n. If, however, both sets of data are plotted in terms, not of d, the depth, but of d_m, the mean depth, Kennedy's data are found to conform to the law,

$$V_m = 0.97\ d^{0.57}_m \quad \text{(53)}$$

and the Godavari Western Delta, Madras, to

$$V_m = 0.69\ d^{0.57}_m \quad \text{(54)}$$

and this difference in the values of n has disappeared.[46]

In his research the author is presumably seeking for the most efficient type of cross-section, namely, that relationship of width and depth which will give the channel its greatest silt-carrying capacity for any given discharge and surface slope.

With Equation (49), the maximum silt-carrying capacity is attained when $\frac{V}{d^n_m}$ is a maximum. If B = the width at the water surface,

$$V = \frac{Q}{B\ d_m} \quad \text{(55)}$$

[46] "Stable Channels in Alluvium", *Minutes of Proceedings*, Inst. C. E., Vol. 229 (1930), p. 321.

and, therefore,

$$\frac{V}{d^n_m} = \frac{Q}{B\, d^{1+n}_m} \quad \text{.........................(56)}$$

Consequently, for any given discharge, the maximum silt-carrying capacity is attained for the cross-section in which $B \times d^{1+n}_m$ is a minimum.

Accepting, for sand, the value of n obtained from the data used by both Kennedy and for the Godavari Western Delta, Madras (that is, $n = 0.57$) then the maximum silt is carried when $\frac{V}{d^{0.57}_m}$ has a maximum value, or for any fixed discharge when $B \times d^{1.57}_m$ has a minimum value. If Kennedy's equation is correct the maximum silt-carrying capacity is attained when $\frac{V}{d^{0.64}}$ has a maximum value.

To compare these two different equations of silt-carrying capacity or efficiency, it is necessary to take some particular case as, for example, a channel having a discharge of 100 cu ft per sec, a surface slope of $\frac{1}{4\,000}$, and side slopes of 1 on 0.5, carrying a heavy silt load.

TABLE 13.—HYDRAULIC DATA PERTAINING TO DIFFERENT CHANNEL SECTIONS (Discharge = 100 cu ft per sec; surface slope = $\frac{1}{4\,000}$; side slopes, 1 on 0.5; and discharge is calculated by Kutter's formula for $n = 0.0225$)

In Table 13 are given the calculated hydraulic data of eleven different designs of channel sections giving this discharge, ranging from a 1.5-ft depth, with 54-ft bed width, to 5.7-ft depth and 5.9-ft bed width. Values of $\frac{V}{d^{0.57}_m}$ and $\frac{V}{d^{0.64}}$ are also given.

Fig. 12, for this case, shows that if the silt-carrying capacity is correctly expressed in terms of $\frac{V}{d^{0.64}}$, as Kennedy suggests, the silt-carrying efficiency

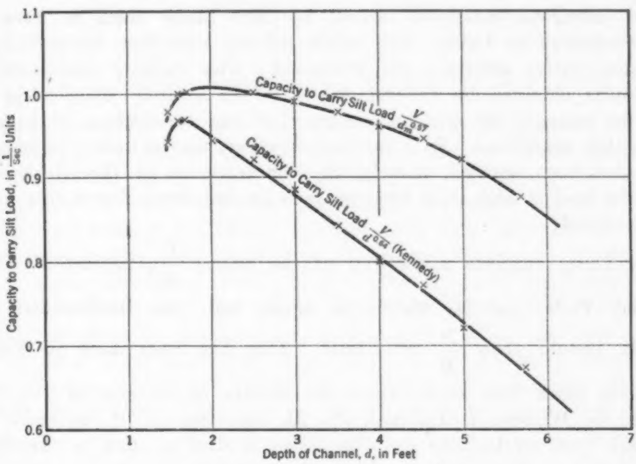

FIG. 12.

will increase uniformly and rapidly from a channel of 6-ft depth to 1.7-ft depth, at which time the maximum efficiency is reached, and a sudden change occurs in the efficiency curve.

If, on the other hand, the correct expression is $\frac{V}{d_m^{0.57}}$, the silt-carrying efficiency at first increases rapidly as depths are reduced from 6 ft downward, but the curve flattens and shows little difference in silt-carrying capacity between a channel of 3-ft depth and one of 2.5-ft depth. The maximum efficiency appears to lie with a channel 2 ft deep.

The writer's experience with channels of this discharge and slope indicates that in practice the expression, $\frac{V}{d_m^{0.57}}$, gives, more correctly, the value of silt-carrying efficiency of the various types of section.

E. W. LANE,[47] M. AM. SOC. C. E. (by letter).—The constructive nature of the discussion of this paper is gratifying, and the writer feels that its value has been materially increased thereby. Although these discussions have shown considerable differences of opinion on minor phases, there seems to be little criticism of the major contentions of the paper, and no points were subject to a general attack. The importance of silt quantity as a factor in stable channel shape and the tendency of heavily silt-laden water to form wide, shallow channels seems to have been generally accepted.

[47] Prof. of Hydr. Eng., State Univ. of Iowa, Iowa City, Iowa.

Since the items of criticism or questions raised by those discussing the paper cover a wide range of ideas and in few cases is the same question raised by more than one person, this closure can best be presented by dealing with the various discussions individually.

The empirical relations derived by Mr. Lacey seem to have been widely accepted in India. The writer believes that they are probably the best quantitative relations yet developed. The striking agreement with the results obtained by Colonel Pettis on an entirely independent basis indicates strongly the general accuracy of the conclusions of both men for average conditions. It is believed, however, that at least one important factor has been omitted, namely, the concentration of the silt load, and when the load is high, this becomes such an important factor that it must be considered.

Mr. Lacey suggests a plotting of the values, $\frac{P}{R}$, against V for the Imperial Valley canals, which, to agree with his fundamental shape formula, should show $\frac{P}{R} = 7.12\,V$. This has been done in Fig. 13. The solid black dots representing the results of sections of the canals reported by William T. Collings, Jr., M. Am. Soc. C. E., as stable[48] and the small open circles give the dimensions of ditches cited by Mr. Blaney

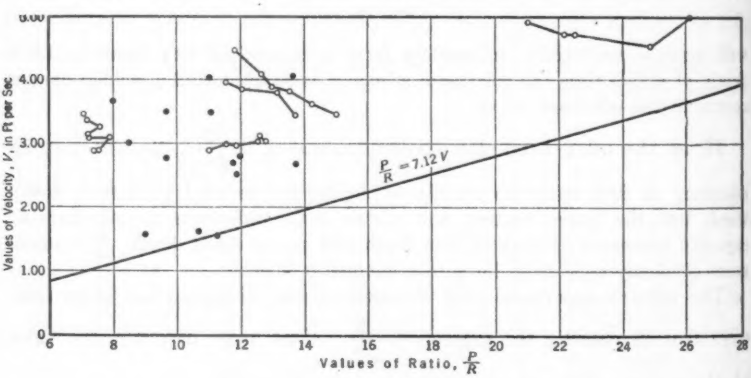

FIG. 13

in Table 5, assuming that the sides are vertical. The values given scatter considerably, even for the same ditch and station, but with one exception, all of them show the ratio, $\frac{P}{R}$, to be less than $7.12\,V$. Although the accuracy of individual observations may be questioned, the data very strongly indicate that the Lacey shape formula does not fit Imperial Valley conditions. This lack of agreement is probably the result of the high silt concentration in these canals.

[48] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 554.

The writer does not believe that the factor, $\frac{V^2}{R}$, empirically derived by Mr. Lacey and also independently by Mr. Tchikoff, has been demonstrated to be a rational measure of turbulence, although it may be a very convenient empirical index of it. Some of the arguments advanced in support of it do not appear to be valid. For example, the fact that the ratio, $\frac{V^2}{R}$, is a valuable criterion in non-uniform flow seems to be pure coincidence and to bear no relation to the phenomena of stable channel shapes. Assuming that all the energy loss due to the friction of the water flowing in a ditch is dissipated by turbulence, the average turbulence of a stream (under conditions of steady, uniform flow), expressed in terms of the energy loss per unit time per unit of volume (occupied by a unit weight), is proportional to the product of the slope and the mean velocity of flow. This follows from the fact that if the water is not accelerating, the energy dissipated per unit of volume per unit of time must be equal to the work represented by the drop of the water in that time, which, in turn, is equal to the mean velocity of the water times the slope. Hence, the criterion of turbulence should be $S\,V$. Although some of the loss, no doubt, occurs in the laminar flow of the boundary layer on the sides and bottom of the ditch, it is believed that under ordinary conditions of an earth channel this is a small part of the total. If the Manning formula is assumed to evaluate, correctly, all the variable factors, this criterion can be transformed as follows:

$$S\,V = \frac{V^3}{\left(\frac{1.486}{n}\right)^2 R^{\frac{4}{3}}} = \left(\frac{n}{1.486}\right)^2 \left(\frac{V^2}{R^{\frac{8}{9}}}\right)^{\frac{3}{2}} \ldots\ldots\ldots\ldots(57)$$

or, in other words, $SV \propto \left(\frac{V^2}{R^{\frac{8}{9}}}\right)^{\frac{3}{2}}$. If the Lacey formula,

$$S = \left(\frac{N_a}{1.3458}\right)^2 \frac{V^2}{R^{\frac{3}{2}}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(58)$$

is used instead of that of Manning, the expression, $S\,V$, becomes $\left(\frac{N_a}{1.3458}\right)^2 \left(\frac{V^2}{R}\right)^{\frac{3}{2}}$. Thus, it will be seen that using the Lacey formula, the empirical Lacey (and Tchikoff) criterion, $\frac{V^2}{R}$, is brought into almost perfect agreement with the criterion, $S\,V$. This probably explains why a criterion, $\frac{V^2}{R}$, gives such good results, especially when used with the Lacey formula instead of the Manning formula.

Mr. Lacey advocates the use of the Buckingham method for future silt studies. This method, unquestionably, is a useful tool, but can only be

used safely if all the important dimensioned variables are known, and it will indicate nothing as to the effect of the dimensionless factors.

It is not believed that the conditions in the Imperial Valley canals approach the condition of flume traction, as suggested by Mr. Lacey. In nearly all cases, the material through which these canals flow is composed of the same kind of silt as is carried by the ditches, since the material was formed by the deposits of the same river, and, therefore, the Imperial Valley canals are flowing in a self-borne alluvium in a manner similar to that of the canals of India. A good description of conditions in the Imperial Valley has been given by H. T. Cory, M. Am. Soc. C. E.[40] The writer's discussion of scour of the sub-grade when the flow in the channel is capable of carrying more material than enters at the head-gate, was included to cover the entire range of cases. It does not apply generally to the canals of the Imperial Valley.

The flow conditions in the Imperial canals are quite different from those found by Gilbert, and saltation is not believed to occur to an important extent. Even the coarser particles of the Imperial Valley material are much smaller than the finest material used by him. Observations were made in the laboratory of the U. S. Bureau of Reclamation on the flow in a long flume with glass panels in the side, using bed material brought from the Colorado River. This showed that at ordinary velocities there was a very slight motion of the material along the bottom as bed load, forming ripples similar to those which appear on the bottom of the Imperial Valley canals, but nothing resembling saltation was observed, and the greater part of the material traveled in suspension. At very high velocities the ripples disappeared and the bottom became smooth, with great quantities of material moving in suspension. This smoothing out of the bottom in Colorado River material at high velocities was also observed by C. A. Wright, M. Am. Soc. C. E.

Mr. Stevens gives an interesting comparison of the sections of several rivers with the Lacey formula, Equation (5), and notes the lack of agreement for the values of the Colorado River at Yuma, Ariz., and the Yellow River, at Chiang-kou, China. The conditions of the Colorado River at the Yuma gaging-station are very unusual, and do not conform to the requirement of banks and bed of alluvium postulated by the Lacey relation. This may account for the lack of agreement. A short distance above the gaging section at Yuma, the Colorado River contracts very suddenly from a wide, meandering stream and passes through a narrow gorge about 400 ft wide, with sides of very resistant material of clay and boulders. At the gaging section, a short distance down stream from this throat, it is about 500 ft wide, and also has very permanent banks, possibly formed of the sandstone rock which outcrops only a short distance away. To pass through the narrow gap during periods of high discharge the water of the river must have a high velocity, which scours the light bed material to a great depth. When the discharge falls, the channel refills. The

[40] "Irrigation and River Control in the Colorado River Delta," *Transactions*, Am. Soc. C. E. Vol. LXXVI (1913), p. 1204.

writer does not believe that this is typical of the Colorado River as a whole, as soundings in an unconfined section made elsewhere show no change of the mean bed elevation with high or low water. Moreover, for such scour to occur along the entire river during high water would require the transportation by the river of much larger quantities of silt than are shown by any measurement. The conditions at the Yuma gaging station, therefore, are a very special case, and conclusions based upon what happens there, if generally applied, will be very misleading.

The measurements on the Yellow River given by Mr. Stevens seem to be those recorded by the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E.[60] At this section there was a rock ledge on the right bank and rock also appeared on the left bank some distance back from the river. It is doubtful, therefore, whether this station is in the class for which Mr. Lacey claims his relations to hold.

Mr. Stevens is probably correct in his opinion that it is the momentary "stray currents" which are most effective in moving bed material, and the same probably applies also to the movement of the material at the sides of the ditch. The writer does not believe that it is the difference in the velocity of the adjacent filaments of water which in itself causes the movement of the material, but that in those parts of the cross-section of a ditch where the isovels are close together the velocity differences within a small distance are great and, therefore, the turbulence is large. The spacing of the isovels, therefore, is an indication of turbulence, close spacing indicating high, and wide spacing indicating low, turbulence. Although this relation is believed to be true for the ordinary conditions of ditch flow where the turbulence is introduced by friction, it does not necessarily hold where the turbulence is the result, for example, of a hydraulic jump.

The data on the silt-carrying ability of the Wei Pei Main Canal which Mr. Eliassen presents, and that of Mr. Ballester for the Rio Negro Canals, are very valuable. Very little complete data of that kind are available and until it is collected, the carrying capacity of channels for solids will be only imperfectly known.

Mr. Eliassen's description of the heavy silt loads of the Chinese rivers is interesting. Unquestionably, he is correct in his remarks that a silt percentage should be a ratio of silt weight to the weight of silt plus water. In most conditions the silt concentrations are so small that to omit the silt weight from the silt-plus-water weight makes a negligible difference, but with the concentrations mentioned by Mr. Eliassen such a procedure leads to important errors.

The writer is not inclined to share with Mr. Eliassen the belief that bed load is an important factor in streams that carry a heavy suspended silt load. Measurements were made in the Colorado River on the crest of Laguna Dam where many years ago the river had filled the storage space with silt to the crest level, and, therefore, where the load measured was

[60] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1437, Fig. 16.

the combined bed and suspended loads. At the same time, measurements were made in a section five miles up stream, where only the suspended load was sampled. A comparison of the results over a considerable period of time showed very little difference,[51] indicating a relatively small bed load. That this is the case is confirmed by the observations in the flume previously mentioned. No bed-load measurements have been made for material comparable in size with that of the Colorado River, but the formulas derived for coarser material were extrapolated by Samuel Shulits, Assoc. M. Am. Soc. C. E., to the size of the Colorado River material, and the loads computed were found to be large, but in comparison with the very large suspended load, are relatively small. Still another reason for believing that the bed is not, to any great extent, in motion is that when sounded with a rod it is surprisingly hard, and does not have the much softer feeling which characterizes coarser material moving as bed load. As a result of these four independent lines of approach all of which are in agreement, the writer believes that in streams carrying high concentrations of fine material in suspension, the bed load, although perhaps of considerable absolute magnitude, is a small part of the total load.

The changes of roughness of the Yellow River channel mentioned by Mr. Eliassen may be due to the elimination of the ripples on the bottom observed at high velocities in the flume, as previously described. Such changes occur also in the Mississippi. In this case they are probably due to bed-load movement, as Mr. Eliassen suggested, as waves reaching more than 30 ft in height have been observed in the Mississippi River which, compared with the Colorado and Yellow Rivers carries a very small concentration of suspended material. For reasons previously stated, however, the writer does not believe that such waves form in rivers carrying heavy loads of suspended material.

Mr. Lindley objects to the writer's statement that he did not mention the quantity of silt as a factor in stable channel shape, explaining that the effect of the quantity of silt was so well known in India as to need no mention. There is no doubt that, in the literature from India, accessible to the writer when his paper was written, occasional mention was made of the fact that the quantity of silt was a factor, but in no place had he found any one who gave it the important place to which he believed it was entitled. The writer's emphasis of this phase was largely due to the fact that the Lacey relations, which were gaining wide acceptance in India, made no mention of the effect of the concentration of the silt load as a factor. Since preparing his paper the writer has secured a copy of the *Punjab Irrigation Technical Review* of 1925, and finds there a statement by Mr. Lindley (as well as others by Messrs. W. G. Quinton, A. R. Murray, and A. M. R. Montagu) that both quantity and quality are factors in determining the channel shape. Except for this publication (which is relatively inaccessible to American engineers) in no recent

[51] "Why Desilting Works for the All-American Canal", by C. P. Vetter, M. Am. Soc. C. E., *Engineering News-Record*, Vol. 118, March 4, 1937, p. 322.

publication from India or elsewhere at the time this paper was written had the writer found the effect of silt concentration mentioned as an important factor.

Mr. Griffith states that it was well known that channels carrying heavy silt loads adopt broad shallow cross-sections. At this distance from India, it is possible for an American engineer to learn what was known there only from their written literature. From a very thorough study of extensive literature from India and other countries the writer found, as late as November, 1935, not a single mention of this phenomenon, and has found since only casual mention of it by Messrs. F. W. Woods and W. G. Quinton in the relatively inaccessible publication previously mentioned. Under these circumstances no apology for discussing it seems to be required.

Mr. Lindley suggests that the writer should have emphasized the fact that a given volume of flowing water carrying a given proportion of a given quality of silt tends to form a channel of which the depth, width, and gradient are all fixed by the said discharge and silt load. The writer's discussion suggested that a given discharge with a given quality and quantity of silt did fix a definite cross-section of channel The gradient would follow from these by the ordinary laws of flow in open channels and, therefore, could not be considered an independent variable. Fixing the shape of the cross-section for a given discharge, therefore, fixes the gradient which would be stable, and it is not necessary to discuss it separately.

Not much benefit will result from arguments over the relative merits of the mean depth and the hydraulic radius as the hydraulic property to which the critical velocity is related. Mr. Griffith plots the available data on the basis of mean depth and finds it follows, reasonably well, an exponential relation to the critical velocity. Mr. Lacey uses the same data and finds an equally good agreement using the hydraulic radius. Both claim this as important evidence of the correctness of their formulas. The facts probably are that, within the range of channel conditions ordinarily encountered, the ratio of the mean depth to the hydraulic radius varies so little that the discrepancy is much less than that due to other factors.

The writer was seeking to obtain the form of cross-section which would be stable for the various conditions of discharge and silt characteristics, not necessarily the depth-width relation which would give the channel its greatest silt-carrying capacity for a given discharge and surface slope, as Mr. Griffith concluded. His determination of the depth of channel that would give the greatest silt-carrying capacity for a given condition may have value, but it seems to rest entirely upon his assertion that the capacity is a maximum when the ratio, $\frac{V}{dm^n}$, reaches its highest value, since no proof to support this assertion was submitted.

Mr. Tchikoff's proposition of "sediment equivalent" is a very ingenious one which merits thorough experimental investigation and testing by

comparison with observed data in natural streams. It has the advantage of reducing the very complex relation of the quantity and quality of the silt present in a stream at a given time, to a single number. It is unfortunate that more quantitative data are not available to check this and the other interesting hypotheses suggested by Mr. Tchikoff. The collection of quantitative data seems to be one of the greatest needs in this field of science, for until hypotheses can be adequately checked against observed relations it is unsafe to build upon them.

Referring to Mr. Tchikoff's criticism of the position of the isovels in the cross-section given in the paper, the fact that the isovel, 0.80, is nearest the sides does not mean that the isovels of the lower values were non-existent but merely that they could not be plotted because of the lack of space. These velocity distribution charts were drawn from data which were not taken originally to investigate the point under discussion. They are the result of a number of different experiments and, therefore, are not perfectly consistent. It is believed, however, that they do in general illustrate the fact that in narrow channels the high velocities come closer to the sides.

The writer is unable to accept Mr. Tchikoff's arguments regarding the velocity gradient. He states: "The sum of the potential and kinetic energy is constant for all the points of the stream filament that lie on the same horizontal plane." This would only be true in a frictionless channel. Where friction is present, the water particles near the sides of the channel are more retarded by friction and more of their energy is converted into heat, than those near the center. On a given horizontal plane, therefore, the sum of the potential and kinetic energy of the water at the sides of the channel may be less than near the center. This is demonstrated by measurements made in a chute near Montrose, Colo.[53] A velocity of 34.8 ft per sec was observed 0.4 ft below the surface near the center of the channel, and, at the same depth at the sides, velocities of 23.3 and 26.9 ft per sec were observed.

The water surface was level, and, hence, the pressure at the three points was the same. The kinetic energy, expressed in velocity head, at the sides was 10.4 and 7.6 ft, respectively, less than at the center. At another section of the same chute (not described in the paper cited[53]), float measurements showed a velocity of 20 ft per sec at the center and about 9 ft per sec as close to the sides as could be observed. The water surface was shown by measurements to be level, and the pressure was the same (atmospheric), but the sum of the potential and kinetic energies was 5 ft of head greater at the center than near the sides. By observations at a large number of cross-sections the water surface was shown to be level across the flume (except at the entrance where contraction effects entered), but the water in the center was obviously moving much more rapidly than near the edges and, therefore, the sum of the potential and

[53] "Recent Studies on Flow Conditions in Steep Chutes," *Engineering News-Record*, Vol. 116, January 2, 1936, p. 5.

kinetic energies at the center was greater than at the sides. The error in Mr. Tchikoff's statement arises from not considering the friction term in the Bernoulli theorem.

Mr. Blaney has called attention to the difficulties found in his investigations of the Lower Colorado River, in analyzing the data, because of the widely different size of silt particles carried. In the writer's studies made for the U. S. Bureau of Reclamation in 1934 and 1935, on the silt carried in the Colorado River, a discovery was made which is believed to be of great significance in understanding the transportation of silt in suspension. It has long been known that, in many rivers (including the Colorado) carrying heavy silt charges, there is no close relation between the discharge and the total silt load. In these studies analysis was made not only of the quantity but of the size range of the particles carried in the Colorado River, by means of bi-weekly samples taken over a period of more than a year. It was found that although there was no relation between the quantity of fine silt and the discharge there was a very definite relation between the load of coarser particles and the discharge. Some of the results of this study have been published.[51] The size range of the particles the load of which bore a definite relation to the discharge was the same as the range of sizes found in the bed material. The reason for this condition is believed to be the fact that the river, in general, always carries as great a load as it is able, of the material which is available in large quantities in its bed. Because of the eddies which impinge on the river bottom, particles from the bottom are thrown into suspension. At the same time, other particles from suspension are settling down again on the river bed. When the same number of particles are picked up as settle back to the bottom the load is as great as the river can carry. When fewer are picked up than fall back, the bed is being filled and when more are picked up the bed is being scoured. With a given size of material on the river bed, the river will pick up sufficient material to produce a condition in which the rate of re-depositing on the bottom is equal to the rate at which the material is picked up from the bottom. The load of very fine silt which the river is capable of carrying seems usually to be much greater than the supply available, which is limited by the quantity of fine material that is brought into the stream by its tributaries. The load of fine material, therefore, is dependent entirely on the load brought to the stream by the tributaries and, hence, is independent of the discharge carried by the stream. The stream picks up from the river bed all the fine material available, but is not able to obtain from this source sufficient material to saturate it with the finer particles. It is believed that many other of the phenomena of the transportation of silt in suspension may be cleared up as a result of this discovery, and that it can form the basis of a quantitative science in this field.

The dimensions adopted for the All-American Canal have been requested and are given in Table 14.[53]

[53] Specifications 573 and 621, U. S. Bureau of Reclamation.

In selecting these sections several factors were unusually important. One was the great depth of cut in which much of the canal was built, which reached a maximum of more than 100 ft and for long stretches was more than 75 ft. Another was the fact that considerable time may elapse before the demand reaches the design capacity. Both these factors justify the use of narrower widths and higher velocities than would otherwise be the case. In comparing this canal with the Imperial Valley canals it should

be kept in mind that the material traversed by them is not the same. The Imperial canals, in general, flow through a Colorado River deposit of very fine material, whereas the All-American Canal is nearly all located on higher land in coarser "mesa material" which seems to be an outwash deposit from the surrounding high land.

In the acknowledgments accompanying the author's paper he inadvertently omitted mention of his indebtedness to Mr. W. M. Griffith, to H. F. Blaney, and F. C. Scobey, Members, Am. Soc. C. E., and to the Central Board of Irrigation of India, for valuable data and suggestions.

TRUSS DEFLECTIONS: THE PANEL DEFLECTION METHOD

By Louis H. Shoemaker[1], M. Am. Soc. C. E.

With Discussion by Messrs. David B. Hall, E. Mirabelli, William Bertwell, Robert H. Hurlbutt, A. A. Eremin, T. P. Noe, Jr., David A. Molitor, Glenn L. Enke, Fang-Yin Tsai, A. W. Fischer, L. E. Grinter, and Louis H. Shoemaker.

Synopsis

The purpose of this paper is to describe a new method for computing the deflections of trusses. In principle, the method is similar to that of computing the deflections of beams, use being made of the distortions of the individual panels. In this manner, the deflections of all the panel points of a truss can be computed with a considerable saving in work over other analytical methods. Therefore, it offers material advantages in computing the reactions of statically indeterminate structures.

Application of the Method

To compute the deflection of a point of a beam of constant moment of inertia with reference to a tangent to the elastic curve of that beam, the sum is taken of the products of the angular change of every vertical section, multiplied by its distance from the point. If the moment of inertia of the beam is not constant, it is necessary to divide the beam into longitudinal sections of lengths corresponding to the different moments of inertia. In this case, the deflection of the point is computed by taking the sum of the vertical distortions of the different longtitudinal sections, plus the sum of the products of the angular distortion of each section, multiplied by the distance of the section from the point. It is evident that the same method can be used to compute the deflections of a truss by utilizing the distortions of the individual panels of the truss.

Note.—Published in November, 1935, *Proceedings*.

[1] Santa Monica, Calif.

To apply the method to a truss, a convenient point is selected as the origin, from which all deflections are measured. The vertical and horizontal deflections and angular distortion of every panel are computed. In Fig. 1, $ABCD$ represents any panel of a truss. The origin of deflections is considered as being at some panel point to the right. The point, A, and the side, AB, are taken as reference point and direction from which panel distortions are measured. The triangle, ABC, will be called the deflection triangle, and C, the deflection point. The point, D, will be called the secondary point. The vertical and horizontal deflections of C are caused by the changes of length of the members of the triangle, ABC. The vertical deflection at D is the vertical deflection at C plus or minus the change of length of CD, which is also a member of the deflection triangle of the panel to the left. The angular distortion of the panel is the angular rotation of CD, due to

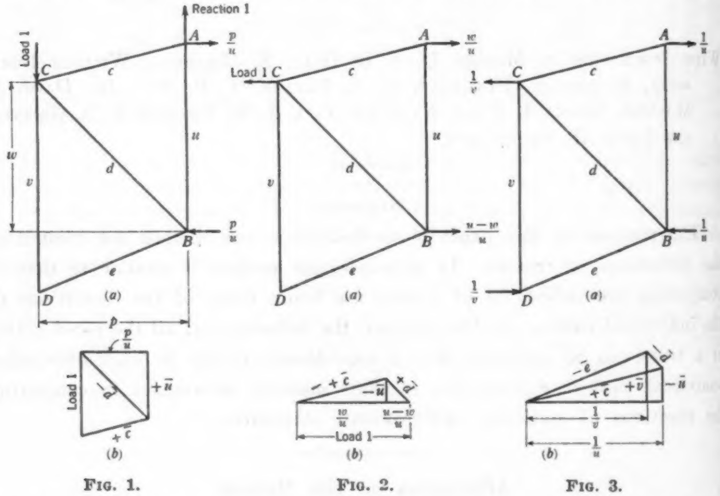

FIG. 1. FIG. 2. FIG. 3.

the horizontal deflections of C and D. The total vertical deflection of any deflection point is the sum of the vertical deflections of all the deflection points taken from the origin to and including the point in question plus the sum of the products of the angular distortion of each panel multiplied by its distance from the point in question taken in the same way. The total deflection of any secondary point is the deflection of the corresponding deflection point plus or minus the change of length of the connecting vertical.

NOTATION

The following notation is introduced in this paper:

c = length of a chord member of a deflection triangle; c' = change in length, $+ c'$, denoting an increase and $- c'$, denoting a decrease; $\bar{c}$ = the stress in Member c resulting from a load of 1, or a bending moment of 1, applied to the panel;

d = length of a diagonal member of a deflection triangle; d' = a change in length, $+ d'$ denoting an increase and $- d'$ denoting a decrease; $\overline{d}$ = the stress in Member d resulting from a load of 1, or a bending moment of 1, applied to the panel;

e = length of a chord member at a secondary point; e' = a change in length, $+ e'$ denoting increase and $- e'$ denoting decrease;

n = number of panels, counted from the origin;

p = length of a panel;

u = length of a vertical member of a deflection triangle; u' = change in length, $+ u'$ denoting an increase and $- u'$ denoting a decrease; $\overline{u}$ = the stress in Member u resulting from a load of 1, or a bending moment of 1, applied at the panel;

v = length of a vertical member between a deflection point and a secondary point; v' = change in length, $- v'$ denoting a decrease, and $+ v'$ denoting an increase, in length;

w = length of a vertical projection of a diagonal member;

x = number of panels from the origin to any deflection point or secondary point between the origin and the nth panel point;

y = vertical distance of any panel point n panels from the origin above or below a deflection point x panels from the origin, $+ y$ denoting distance downward and $- y$ distance upward from the xth panel point.

A = cross-section area;

E = modulus of elasticity;

H_1 = horizontal deflection of Deflection Point C with respect to Point A; H_T = total horizontal deflection of a deflection point or a secondary point, distant n panels from the origin;

L = length of a member:

R = angular distortion of a panel with reference to Member AB;

S = total axial stress applied to a member;

T = a subscript denoting "total";

Δ_1 = vertical deflection of Deflection Point C with reference to Point A; $\Delta_2 = \Delta_1 - (\pm u')$ = vertical deflection of Deflection Point C with reference to Point B; $\Delta_3 = \Delta_1 + (\pm v')$ = vertical deflection of Secondary Point D with reference to Point A; $\Delta_4 = \Delta_1 + (\pm v') - (\pm u')$ = vertical deflection of Secondary Point D with reference to Point B;

δ = change in length, c', d', etc.

General Formulas for Panel Distortions

In developing formulas for panel distortions, the method of internal work will be utilized. To derive the formula for the vertical deflection at Point C, refer to Fig. 1, thus: by proportion, $\pm \overline{c} : 1 :: c : u$; $- \overline{d} : 1 :: d : u$; and $+ \overline{u} : 1 :: w : u$. Therefore, $\overline{c} = \frac{c}{u}$; $\overline{d} = - \frac{d}{u}$; and, $\overline{u} = \frac{w}{u}$, respectively, and:

$$\Delta_1 = \frac{c}{u}(\pm c') - \frac{d}{u}(\pm d') + \frac{w}{u}(\pm u') = \frac{(\pm c'c) - (\pm d'd) + (\pm wu')}{u} \quad \ldots (1)$$

The horizontal deflection at C is derived by reference to Fig. 2, thus: $\overline{c} : \frac{w}{u} :: c : p$; $\overline{d} : \frac{u - w}{u} :: d : p$; and, $- \overline{u} : \frac{w}{u} :: u - w : p$. Therefore,

$\overline{c} = \frac{c\,w}{p\,u}$; $\overline{d} = \frac{d\,(u - w)}{p\,u}$; and, $\overline{u} = -\frac{w\,(u - w)}{p\,u}$, respectively, and,

$$H_1 = \frac{[(\pm c'\,c) - (\pm d'\,d) + (\pm\,w\,u')]\,w}{p\,u}$$

$$+ \frac{(\pm\,d'\,d)}{p} - \frac{(\pm\,w\,u')}{p} = \frac{w\cdot\Delta_1}{p} + \frac{(\pm\,d'\,d) - (\pm\,w\,u')}{p} \quad \text{........(2)}$$

The angular distortion of Member CD is derived by reference to Fig. 3, thus:

$\overline{c} : \frac{1}{u} :: c : p$; $-\overline{e} : \frac{1}{v} :: e : p$; $-\overline{u} : \frac{1}{u} :: u - w : p$; $\overline{v} : \frac{1}{v} :: v - w : p$,

and, $-\overline{d} : \frac{1}{u} - \frac{1}{v} :: d : p$. Therefore, $\overline{c} = \frac{c}{p\,u}$; $\overline{e} = -\frac{e}{p\,v}$; $\overline{u} = -\frac{u - w}{p\,u}$;

$\overline{v} = \frac{v - w}{p\,v}$; and, $\overline{d} = -\frac{d\,(v - u)}{p\,u\,v}$, respectively, and:

$$R = \frac{c}{p\,u}(\pm\,c') - \frac{e}{p\,v}(\pm\,e') - \frac{u - w}{p\,u}(\pm\,u') + \frac{v - w}{p\,v}(\pm\,v') - \frac{d\,(v - u)}{p\,u\,v}(\pm\,d')$$

$$= \frac{1}{p}\left[\frac{(\pm\,c'c) - (\pm\,d'd) + (\pm\,w\,u')}{u} + \frac{(\pm\,d'd) + (v - w)\,(\pm\,v') - (\pm\,e'e)}{v} - (\pm\,u')\right]$$

$$= \frac{1}{p}\left[\Delta_1 + \frac{(\pm\,d'd) - (\pm\,e'e) - (\pm\,w\,v')}{v} + (\pm\,v') - (\pm\,u')\right] \quad \text{....(3)}$$

The total deflections are expressed, as follows:

$$\Delta_T = \sum_{x=0}^{x=n}\left[\Delta + R\,p\,(n - x)\right] \quad \text{..................(4)}$$

and,

$$H_T = \sum_{x=0}^{x=n}\left[H - R\,(\pm\,y)\right] \quad \text{..................(5)}$$

It is evident from the manner in which Equations (1) to (5) have been derived that the resultant signs of Δ, H, and R, have the following significance: $+\,\Delta$ indicates deflection inward and $-\,\Delta$, deflection outward with respect to the truss; $+\,H$ indicates deflection away from the reference point and $-\,H$, toward the reference point; and, $+\,R$ indicates left-handed rotation if acting to the left of the reference side and right-handed rotation if acting to the right of the reference side, and $-\,R$ is the reverse.

The formulas for panel distortions are very simple in form and composition. There are five terms involved for each panel, the products, $c'c$, $d'd$, etc. When these terms have been computed, the evaluation of the formulas to determine the total deflections, is a simple matter. Two short examples are offered to illustrate the application of the method. The loads indicated are in kips, 1 kip being equal to 1 000 lb.

Example 1.—Deflections of a Simple Truss.—In Table 1 the deflections for the 180-ft truss shown in Fig. 4 are calculated. The deflection points are 0, 1, and 3. The values of Δ are the deflections upward of 0 from 2, 1 from 3, and 3 from 5. The deflection of Point 2 is obtained by adding algebraically the change of length of Member 1-2 to the deflection of Point 1. The signs of Δ for 1 and 3 are minus as the deflections are outward, and

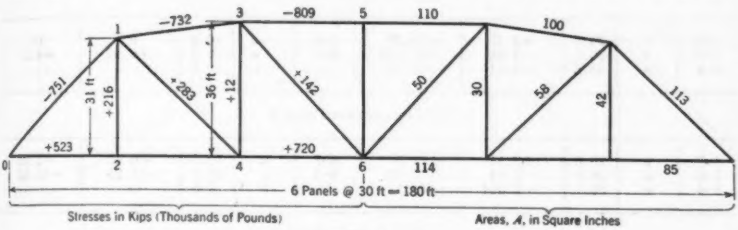

FIG. 4.

that of 0 is plus for an inward deflection. In computing the changes of length, the formula,

$$\delta = \frac{S\,L}{1\,000\,A} \qquad \text{.........................(6)}$$

has been used, this being the variable factor. The constant factor, $\frac{12}{30\,000}$, is applied in the final calculations. The calculated deflections are upward from Panel Point 5. These are transposed in the last two columns to give deflections downward from Point 0, in inches.

has been used in computing the changes of length. The deflection points are 1, 3, 5, and 7. The values of Δ are the deflections downward of 1 from 3, 3 from 5, etc. The deflection of Point 0 is obtained by adding the elongation of Member 0-1 to the deflection of Point 1. The horizontal deflection of Point 0 is obtained by applying Equation (5). The calculated deflections downward from Panel Point 9 are transposed to give upward deflections from Point 0.

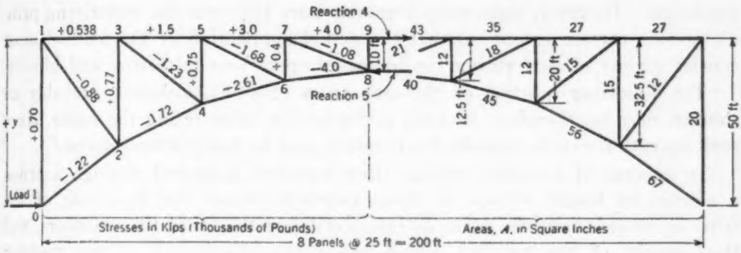

FIG. 5.

CONCLUSION

The "panel deflection method" solves the problem of truss deflections in a simpler and more direct manner than other analytical methods. It has the advantage of effecting a large saving in the work of computation.

The principal distortions are expressed by means of formulas, which makes the computation easy and accurate. Two short examples have been given to illustrate the practical application of the method. It was not considered necessary to include the extended calculations of a large structure. The writer, however, has applied the method to the solution of most of the problems of indeterminate structures and to the computation of the stresses in a very large structure.

DISCUSSION

David B. Hall,[2] Assoc. M. Am. Soc. C. E. (by letter).—By well-chosen formulas, Mr. Shoemaker has unquestionably eliminated most of the superfluous operations and reduced the labor of calculating truss deflections to a minimum. However, these same formulas have obscured the underlying principles to a certain extent, so that the actual application of the method must consist mainly of performing the indicated operations faithfully and blindly.

The following solution of the arch truss (Fig. 5), although probably no shorter, may be, therefore, of some assistance in interpreting the paper, since each operation can be explained separately, and in fairly simple terms.[3]

In general, if a section cutting three members is passed through a truss, a change in length of one of these members causes the free side of the truss to rotate about the point of intersection of the other two members, and the amount of the rotation equals the change in length of the member divided by the perpendicular distance from the center of rotation to the member. Shortening Member 4–6 in this manner causes the left portion of the truss to pivot about Point 5, and the stretch in Member 4–5 causes it to rotate about the point where Member 4–6 (prolonged) intersects the top chord.

For chord members, since the center of rotation is at a panel point, the work is very simple and obvious. Thus, when Member 5–7 (Fig. 6) stretches 2.14 units, the deflection one panel length from Point 6 (the hinge for this member) is $2.14 \times \dfrac{25.0}{12.5} = 4.28$ units, and at more remote panels is a multiple of this value. In the case of lower chords, the lever arms of which are not given directly, it will be noted that the lever arm is equal to the height of the panel times the cosine of the chord inclination, and that the cosine of the chord inclination equals the panel length divided by the chord length. From this it readily follows that substitution of the chord length for the panel length is the only additional step necessary. Thus, the deflection factor for Member 2–4, for instance, is $\dfrac{27.9}{32.5}$, as given in Table 4.

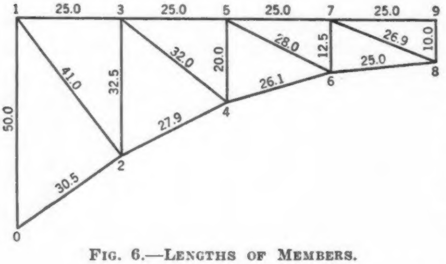

Fig. 6.—Lengths of Members.

To avoid the inconvenience resulting from the imaginary centers of rotation for web members the following procedure appears to be the simplest to explain. The deflection at the end of a vertical web member is

[2] Asst. Engr., State Dept. of Public Works, Albany, N. Y.

[3] For a similar method see letter by William Bertwell, Assoc. M. Am. Soc. C. E., *Engineering New-Record*, November 1, 1934, p. 565.

equal to the change in length of the member. For a diagonal, the change in length must be multiplied by the length of the diagonal divided by the height of the panel on the stationary side.

* Lower panel points.

The following proof of this rule may be found easier to remember than the rule itself. In Fig. 7, if Member *BC* (or *a*) changes in length an amount, Δa, while Side *b* remains fixed, Side *c* will rotate about Point *A*. The rotation

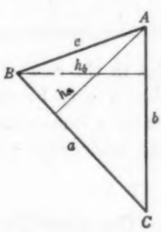

FIG. 7.—WEB MEMBERS.

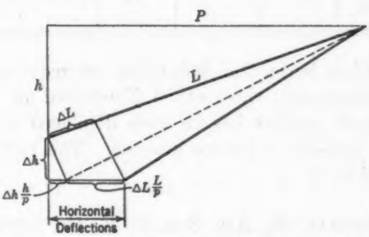

FIG. 8.—HORIZONTAL DEFLECTIONS.

will be $\frac{\Delta a}{h_a}$, and the vertical movement at Point *B* will be $\Delta a \frac{h_b}{h_a}$. Now, $\frac{h_b}{h_a} = \frac{a}{b}$, since $b \frac{h_b}{2} = a \frac{h_a}{2}$ = area of triangle (also because $\frac{h_b}{a} = \frac{h_a}{b} = \sin C$). Therefore, the deflection at Point $B = \Delta a \frac{a}{b}$. Thus, the deflection at

Point 5 for Member 5–6 is $2.61 \times \frac{28.0}{12.5} = 5.85$. Since the deflections at other points are proportional to their distances from the center of rotation, and since, in this case, the distances of Points 5 and 7 are in the same ratio as the panel heights at Points 5 and 7, it is seen that the difference per panel may be obtained by multiplying the deflection at Point 5 by $\frac{(20 - 12.5)}{20}$, making the panel increment equal to $2.61 \times \frac{28.0}{12.5} \times \frac{7.5}{20} = 2.19$. Thus, the deflection at Points 2 and 3 contributed by Member 5–6 is $5.85 + 2.19 = 8.04$, etc.

For a single horizontal deflection at the support as in this problem, a very simple method is available. The multiplying factor for each member of the truss is the stress due to a unit load at the support. These factors are already known, and the calculations are shown in the last two columns of Table 4. The remainder of the work, transposing the deflections and calculating the horizontal reactions, is the same as in the original paper and has not been repeated. For algebraic signs it is sufficient to examine the picture and note whether a given deformation deflects the truss up or down.

TABLE 5.—HORIZONTAL DEFLECTIONS, BOTTOM CHORD PANEL POINTS

Point	Δ h-CONTRIBUTION				ΔL-CONTRIBUTION			Combined increment	Horizontal deflection
	Vertical deflection	Difference, Δ h	Factor	Increment	ΔL	Factor	Increment		
8	0								0
		9.96	2.5÷25	1.00	2.51	1	2.51	3.51	
6	9.96								3.51

2	61.18								27.04
		31.25	17.5÷25	21.87	0.555	30.5÷25	0.68	22.55	
0	92.43								49.59

If complete horizontal deflections are required (as in the case of secondary stress calculations), the method illustrated in Table 5 may be used. Each bottom chord member has its ends displaced vertically a known amount and its length changed a known amount. The resulting horizontal movement is shown in Fig. 8.

E. MIRABELLI,[4] M. AM. SOC. C. E. (by letter).—The numerical examples chosen by the author to illustrate the application of the panel deflection method involve symmetrical loadings and symmetrical structures with vertical members at mid-span. In dealing with such cases it is possible to use the center vertical as a reference bar and thus to obtain deflections directly. When there is lack of symmetry it is necessary to apply corrections for rotation of the structure for the same reason that corrections are necessary when a Williot diagram is used. The necessity for such corrections when dealing

[4] Asst. Prof., Structural Eng., Mass. Inst. Tech., Cambridge, Mass.

with vertical deflections may be avoided by combining the panel deflection method with a method of elastic weights.

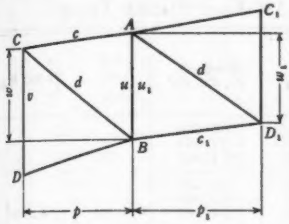

FIG. 9.

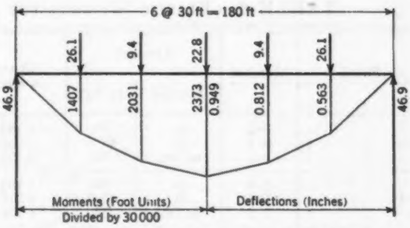

FIG. 10.—DEFLECTIONS OF A 180-FOOT SIMPLE TRUSS.

Referring to Fig. 9 which shows two adjacent panels of a truss, the elastic weight to be applied at Panel Point B may be expressed by the equation developed by Müller-Breslau[5]. In the notation used by the author, the elastic weight is:

$$W_B = -\frac{\Delta_D}{p} - \frac{\Delta_{D1}}{p_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

in which, Δ_D = downward deflection of Point D with respect to Point B; and, Δ_{D1} = downward deflection of Point D_1 with respect to Point B.

From the author's development (under the heading "General Formulas for Panel Distortions"):

$$\Delta_D = \frac{c'\,c - d'\,d + w\,u'}{u} + v' - u' \quad \ldots\ldots\ldots\ldots\ldots (9)$$

and,

$$\Delta_{D1} = -\frac{c'_1\,c_1 - d'_1\,d_1 + w_1\,u'_1}{u_1} \quad \ldots\ldots\ldots\ldots\ldots (10)$$

Equations (9) and (10) may be combined with Equation (8) to determine the elastic weight for any panel point of the truss. The deflections of the bottom chord panel points are then found by the usual method of calculating the bending moments in an auxiliary end-supported beam on which the elastic weights are applied as loads. It should be noted that Equation (9) is used for panels in which the diagonal is attached to the lower panel point, B, and Equation (10) is used for panels in which the diagonal is attached to the upper panel point, A.

The data from the author's Example 1 are used to illustrate the application of this method. The elastic weights are computed as shown in Table 6. The application of elastic weights to the auxiliary beam and the determination of bottom chord deflections are shown in Fig. 10.

It appears to the writer that the panel deflection method may lose some of its simplicity when applied to truss panels which differ from the typical one shown in the author's Fig. 1. For example, if the web system has no

[5] "Die graphische Statik der Baukonstruktionen", by H. Müller-Breslau, Fifth Edition, Vol. 2, Pt. 1, Stuttgart, 1922, p. 95, Equation (2).

vertical members at the panel points it is necessary to insert phantom vertical bars at such points unless entirely different deflection equations are to be

developed. For a truss with a K-web system, application of the method would seem to be even more difficult.

WILLIAM BERTWELL,[6] ASSOC. M. AM. SOC. C. E. (by letter).—In calling attention to the process of computing truss deflections as the cumulative effect of movements of the component parts of the truss, this paper is interesting and valuable. The author states that the "'panel deflection method' solves the problem of truss deflections in a simpler and more direct manner than other analytical methods." By the use of set formulas, however, the writer believes that the simplicity of the process is somewhat lessened.

By treating a single member at a time, rather than an entire panel, there results what may be termed the "geometric" method.[7] The computations for the author's Examples 1 and 2, presented in Tables 7 and 8, respectively, demonstrate that this basis of analysis is simpler.

The basis of the geometric method is: Assuming the part of the structure to the right of the member under consideration fixed in position, any change in length of the given member causes the part of the structure to the left to rotate about the center of moments for the given member. It remains only to determine the angular movement caused by the member, a geometric problem.

The writer believes that this one fundamental relationship is sufficient to solve all such problems simply and directly. Reducing the principle to a group of equations, or introducing supplementary derivations of one sort or another, inevitably diminishes understanding of the physical action of the structure. Keeping this one principle in mind, a glance at the line diagram

Every step of the geometric method appears in Tables 7 and 8; no formulas need be kept in mind. The figures for the chord members are obvious. The

effect of each diagonal web member has been determined by finding the vertical component of motion at the left end of the member and dividing this by the horizontal distance to the center of moments. The vertical component is equal to the change in length of the diagonal multiplied by the ratio of its length to the height of the truss at its right end.

ROBERT H. HURLBUTT,[8] JUN. AM. SOC. C. E. (by letter).—The method described in this interesting paper is based upon the area-moment principle as applied to a beam of varying moment of inertia. The same relation between the panel distortions and panel-point deflections of a truss may also be derived through inspection, as follows.

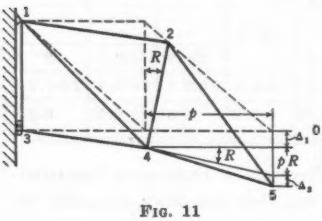

FIG. 11

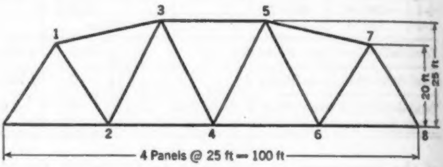

FIG. 12

In Fig. 11, a cantilever truss shown in a distorted position, the total deflection of Panel Point 5 is the sum of Δ_1, the vertical distortion of the first panel, plus R, the angular distortion of the first panel, multiplied by p, the length of the second panel, plus the vertical distortion, Δ_2, of the second panel.

The panel-deflection method has advantages over the Maxwell-Mohr method for trusses with rectangular panels. The application is simple and direct, each step is easily visualized, and, most important, the deflections of all points are found from one set of calculations, as by the Williot diagram. However, a rotational correction corresponding to that provided by the Mohr rotation diagram, is necessary when dealing with a truss in which every member changes its line of action when the truss deflects.

Table 9 gives the calculations for Δ in a problem of this type, an unsymmetrically loaded Warren truss. Assuming that Member 0–1, Fig. 12, does not rotate, all deflections are found upward from Point 0. The distorted truss is then rotated downward to produce the effect of the rotation of Member 0-1. Thus, referring to Table 9 for values of Δ and R:

$$30\,000\; V_8 = 811 + 2\,026 + 3\,155$$

$$- 3\,590 - 300\;(3 \times 1.824 + 2 \times 5.0 + 9.705) = -5\,151$$

$$V_2 = \frac{1}{30\,000}\left(811 + \frac{5\,151}{4}\right) = +\;0.070 \text{ in.}$$

$$V_4 = \frac{1}{30\,000}\left(811 + 2\,026 - 300 \times 1.824 + \frac{5\,151}{2}\right) = +\;0.162 \text{ in.}$$

[8] Junior Engr., War Dept., U. S. Engr. Office, Rock Island, Ill.

and,

$$V_6 = \frac{1}{30\,000}\left[811 + 2\,026 + 3\,155 - 300\,(2 \times 1.824 + 5.0) + \frac{3 \times 5\,151}{4}\right] = +\,0.242 \text{ in.}$$

Δ_8						−3 590		

The advantages of the panel-deflection method for the solution of this problem are not particularly great, due to the increased work involved in applying the unit forces and couples to the irregularly shaped panels.

A. A. EREMIN,[9] ASSOC. M. AM. SOC. C. E. (by letter).—Equations for computing truss panel deflections have been developed by Mr. Shoemaker in this paper. His method is more direct than the least work method with unit loading at each panel joint. However, the panel deflections may also be computed in one operation by means of elastic weights.[10] For example, at some chord joint of a truss, such as Point N, Fig. 13, the elastic weight is expressed by:

$$W_n = \delta\,\alpha_n + \frac{s_{n1}}{E}\tan\phi_{n1} + \frac{s_{n2}}{E}\tan\phi_{n2} \quad \text{..............(11)}$$

in which, $\delta\alpha_n$ = the deformation of a chord angle at Joint N; ϕ_{n1}, ϕ_{n2} = angles between the chord and a horizontal line to the left and to the right of a

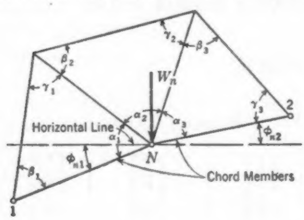

FIG. 13.—ELASTIC WEIGHT OF TRUSS CHORD JOINT.

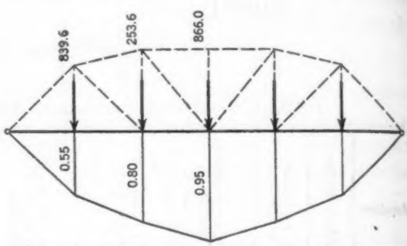

FIG. 14.—DEFLECTION OF TRUSS LOWER CHORD.

joint; s_{n1}, s_{n2} = unit stresses in the chord members to the left and to the right of Joint N; and E = modulus of elasticity of the chord in tension and compression.

If the chord is horizontal the angles, $\phi_{n1} = \phi_{n2} = 0$. Therefore, the elastic weight is equal to:

$$W_n = \delta\alpha_n \quad \text{.........................} \quad (12)$$

The angular deformation of the chord at Point N is computed from deformations of the angles formed by members converging at that point. The deformation of an angle such as α_2 in Fig. 13, is expressed as,[11]

$$E\,\delta\alpha_2 = (s_3 - s_2)\cot\beta_2 + (s_3 - s_1)\cot\gamma_2 \quad \text{..........} \quad (13)$$

in which β_2 and γ_2 are angles in the triangular panel opposite Joint N.

The elastic weights are considered as vertical forces at the chord joints. The force polygon of the elastic weights constructed through the end joints of a truss represents a deflection polygon of chord panels. The force polygon may be determined either graphically, or analytically, as the bending moment diagram of a beam sustaining the elastic weights at the spaces corresponding to the horizontal projections of the joints (see Fig. 14).

In Example 1 of the paper the elastic weights at the lower chord computed with Equation (12) are: $W_2 = 839.6$; $W_4 = 253.6$; and $W_6 = 866.0$.

Deflections at the lower chord panels determined as ordinates of the bending moment diagram in terms of $\dfrac{12}{30\,000}$ are: $\Delta_2 = 0.55$; $\Delta_4 = 0.80$; and, $\Delta_6 = 0.95$. These deflections are closely in agreement with those computed by the author (see Table 1). The elastic weights and deflections were computed with a standard 10-in. slide-rule. Various simplifications in the elastic weight method have been developed by Professor Müller-Breslau.[10,12]

The advantage of the elastic weight method over that introduced by Mr. Shoemaker is in the simplicity of the conventional rules for determining signs,

[11] "Modern Framed Structures", by J. B. Johnson, C. W. Bryan, and F. E. Turneaure. 1917, p. 427.

[12] "Graphische Statik", Bd. II.

which are the same as those for the stresses in the members of a truss. In the elastic weight method it is necessary to remember only two formulas (Equations (11) and (13)). Furthermore, the deformations of panel angles, computed in the elastic weight method may also be used for computing the secondary stresses in the truss.

T. P. Noe,[13] Jr., Jun. Am. Soc. C. E. (by letter).—A clearer conception of the panel deflection method as described by Mr. Shoemaker is gained by developing the basic equations by means of the Williot diagram. C. A. Ellis, M. Am. Soc. C. E., has pointed out in two papers[14] that the geometrical relationships established by a Williot diagram may be expressed in the form of algebraic equations which will yield an algebraic solution for those values previously obtained graphically from a Williot diagram drawn only for known changes in length of the truss members. The writer has had several occasions to make use of such an algebraic solution of the Williot diagram, notably in the determination of secondary stresses, but heretofore has not developed any standard expressions for typical truss panels. However, there is much merit in doing so. For unusual cases, however, the writer believes that the Williot diagram offers the best solution.

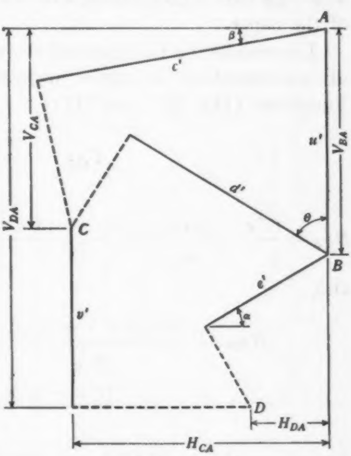

Fig. 15.

In Fig. 15 is shown the Williot diagram drawn for the typical panel considered by the author This diagram is constructed on the basis of the assumptions made in the paper, namely, that Point A is fixed in position, Member AB is fixed in direction, and the change in length of each member is considered as a lengthening. From the geometry of Fig. 15 the following relations may be developed, Angles α, β, and θ referring to the slopes of the inclined members as indicated:

The vertical deflection of Point C relative to Point A equals,

$$V_{CA} = \frac{c' \sin\theta + u' \cos\beta \cos\theta - d' \cos\beta}{\sin\beta \sin\theta + \cos\beta \cos\theta} \quad \text{............(14)}$$

the horizontal deflection of Point C relative to Point A equals,

$$H_{CA} = \frac{c' \cos\theta - u' \sin\beta \cos\theta + d' \sin\beta}{\sin\beta \sin\theta + \cos\beta \cos\theta} \quad \text{............(15)}$$

[13] Checker, Carolina Steel & Iron Co., Greensboro, N. C.

[14] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 580; also *Engineering News-Record*, Vol. 112, April 26, 1934, p. 534.

the vertical deflection of Point D relative to Point A equals,

$$V_{DA} = V_{CA} + v' \quad \text{.......................(16)}$$

the horizontal deflection of Point D relative to Point A equals,

$$H_{DA} = (e' \sec \alpha - v' \tan \alpha) - \frac{(c' \sin \theta - u' \sin \theta \sin \beta - d' \cos \beta) \tan \alpha}{\sin \beta \sin \theta + \cos \beta \cos \theta} \text{.(17)}$$

and the rotation of Member CD relative to Member AB equals,

$$R_{CD} = \frac{H_{CA} - H_{DA}}{\overline{C\,D}} = \frac{H_{CA} - H_{DA}}{v} \quad \text{.............(18)}$$

The sign convention and notation for change in length of a member are those of the paper.

Expressing the functions of the angles, α, β, and θ, in terms of the lengths of the members or their projections, and substituting these values in Equations (14), (15) and (17):

$$V_{CA} = \frac{c'\,c + u'\,w - d'\,d}{u} \quad \text{..................(19)}$$

$$H_{CA} = \frac{(c'\,c - d'\,d + u'\,w)\,w}{u\,p} + \frac{(d'\,d - u'\,w)}{p} = \left(\frac{w}{p}\right)(V_{CA}) + \frac{(d'\,d - u'\,w)}{p} \text{..(20)}$$

and,

$$H_{DA} = \frac{(e'\,e - v'\,v + v'\,w)}{p} + \frac{(c'\,c - d'\,d + u'\,w)\,w}{u\,p} - \frac{u'\,w}{p} - \frac{(c'\,c - u'\,u + u'\,w - d'\,d)\,v}{u\,p} \quad \text{..................(21)}$$

Equations (19) and (20) are identical with Equations (1) and (2) of the paper.

Substituting the values of H_{CA} and H_{DA} given by Equations (20) and (21) into Equation (18):

$$R_{CD} = \left(\frac{1}{p}\right)\left(V_{CA} + \frac{d'\,d - e'\,e - v'\,w}{v} + v' - u'\right) \quad \text{.......(22)}$$

Equation (22) is identical with Equation (3) of the paper.

It is evident that each of the panel points, C, D, and B, will undergo an additional deflection, both horizontally and vertically, if the reference member, AB, rotates through some small angle denoted by R_{AB}. These rotational displacements are similar in nature to those given by a Mohr diagram. It is easily seen that for the case considered these additional deflections are given by the following expressions:

$$V'_{CA} = (c\,R_{AB}) \cos \beta = p\,R_{AB} \quad \text{.................(23)}$$

$$H'_{CA} = (c\, R_{AB}) \sin \beta = (u - w)\, R_{AB} \ldots\ldots\ldots\ldots\ldots (24)$$

$$V'_{DA} = (\overline{A\,D}\, R_{AB}) \left(\frac{p}{\overline{A\,D}}\right) = p\, R_{AB} \ldots\ldots\ldots\ldots\ldots (25)$$

and,

$$H'_{DA} = (\overline{AD}\, R_{AB}) \frac{(u - w + v)}{\overline{A\,D}} = (u - w + v)\, R_{AB} \ldots\ldots (26)$$

In order to illustrate the application of the panel deflection method to the case of an unsymmetrically loaded truss, the writer has computed the vertical deflections of a truss having the same dimensions and cross-sectional areas as that of the author's Example 1, but with an unsymmetrical loading. The values of the stresses in the members due to the assumed loading are

* 1 kip denotes "kilo-pounds," or 1 000 lb.

recorded in Table 10. Panel points on the right of Member 5–6 are denoted by the corresponding panel point numbers appearing on the left with the prime attached.

Since the writer has modified the author's arrangement of the computations a brief summary of the procedure used will be given. To save space the individual products entering into the solution of the basic equations have not been recorded in Table 10.

In Column (5) are recorded the values of the vertical deflections of the panel reference points as computed by Equation (19). It should be noted that the deflections of Points O and O' are referred to Points 2 and 2', respectively. In Column (6) are recorded the values of the rotations of each reference member due to the distortion of the given panel, as computed by Equation (22). Column (7) gives the total rotation of each reference member referred to Member 5–6. Column (8) gives the vertical deflection of each reference point due to rotation of the panel reference member. This value is given by Equation (23). The values in Column (9) represent the vertical deflection of each point relative to Point 5, assuming that Member 5–6 does not rotate. For example, the deflection of Panel Point 1 equals the deflection of Point 1 relative to Point 3, plus the deflection of Point 3 relative to Point 5, plus the deflection of Point 1 due to the rotation of the panel reference Member 3–4. This sum is given by $(-278.4 - 144.3 - 367.2) = -789.9$. Column (10) gives the values of the transposed deflections referred to Point O. It is seen from Column (10) that the deflection of Point O' relative to Point O is not zero, due to the assumption that Member 5–6 does not rotate. This means that the truss as a whole must be rotated clockwise about Point O through such an angle as to make the deflection of Point O' zero. This rotation is identical to that assumed in the Mohr diagram. The vertical deflection of each point for such a rotation will be given by the product of the horizontal distance of the point in question from Point O, multiplied by the rotation angle (in this case $\frac{171.8}{180}$). Column (12) gives the true deflection of each point, which is the sum of the values in Columns (10) and (11). In Column (13) the final values are converted to inches.

It is the writer's opinion that the foregoing procedure for applying the basic equations is easier to follow than that given by the author.

David A. Molitor,[15] M. Am. Soc. C. E. (by letter).—The method proposed by the author should scarcely be classified under such a broad title, because of its limited application to very simple truss forms.

In point of labor and clarity of presentation, the method of elastic weights affords equally simple solutions for the same cases, but with the advantage of being universally applicable to all kinds of structures, even to solid web beams. The complications encountered in odd-shaped triangular truss systems without vertical members, are due to the more involved geometric relations, for which the new method becomes quite "out of bounds."

An exhaustive treatment of the method of elastic weights, based on Professor Otto Mohr's (1875) statement of the relation between deflection

[15] Structural Engr., Public Buildings Branch, U. S. Treasury Dept., Washington, D. C.

polygons and equilibrium polygons for simultaneous cases of loading, was presented by the writer in 1911.[16]

There is a decided danger that those who do not appraise the distinct limitations of this paper may misapply it, in view of the author's broad conclusion that the method "solves the problem of truss deflections in a simpler and more direct manner than other analytical methods."

Glenn L. Enke,[17] Jun. Am. Soc. C. E. (by letter).—The analytical method for solving for truss deflections presented by Mr. Shoemaker is an interesting one. It appears much superior to what is referred to in most textbooks as the "method of internal work" wherein individual computations are made for any one panel point.

The writer prefers a graphical method utilizing Williot-Mohr diagrams to arrive at the vertical and horizontal displacement of all panel points simultaneously. An unsymmetrical or continuous structure is handled as easily as a symmetrical layout and throughout the process a rough idea of what is happening to any joint can be visualized; a valuable factor in eliminating blunders. By means of a drafting-machine, large-scale diagrams of sufficient accuracy are quickly prepared.

The writer's purpose in discussing this paper, however, is not to extol the merits of any particular method, but to point out the necessity of correctly applying results obtained by any method to the case in hand. Consideration of the various types of structures will be restricted to the modern types of highway and railway bridges.

Resident engineers on bridge construction from the writer's office have found, without exception, that actual truss deflections are uniformly less than the theoretical by 40 to 50%, and in setting header-boards for concrete surface finishing, they take this fact into consideration. Upon the accuracy of their estimate depends how level a roadway surface is obtained. This effect is a very common one, and is based upon a number of factors to be discussed subsequently. A specific instance is quoted: The Bridge Department of the State of California in 1935 completed a vertical lift structure over the Sacramento River, known as the M Street Bridge. The lift span is a symmetrical 202-ft, riveted, through truss span, 56.5 ft from center to center of trusses, with two unsymmetrical approach spans of 167.5 ft and 192.5 ft, respectively. A concrete deck with curbs 52 ft apart, over which four lanes of highway traffic and a single-track railroad pass, is supported by the usual system of floor-beams and stringers framed into each other and riveted throughout. Deflection diagrams were prepared for various conditions of dead load for each span. In erecting these trusses and pouring the concrete roadway slab, the resident engineer correctly estimated the deflection at about one-half the theoretical and set his grade line accordingly. A highly satisfactory profile was obtained, to the credit of the resident engineer. Many factors enter into a result such as the foregoing, as, for example: (1) Joint rigidity; (2) joint

[16] "Kinetic Theory of Engineering Structures", by David A. Molitor, Chapter VII, 1911.

[17] Associate Bridge Designing Engr., Highway Div., State Dept. of Public Works, Sacramento, Calif.

"slippage"; (3) direct stress taken by lateral bracing and steel floor systems; (4) using gross section to compute total elongation; and (5) reduced strains due to heavy lacing-bars, stay-plates and long gusset-plates.

Factor (1).—Probably the most important cause of reduced truss deflection is joint rigidity. In a completely riveted truss, every member is practically fixed at the ends (end restraint is not unknown in pin-connected members), and the secondary stresses set up by a nominal amount of deflection will produce a certain degree of resistance to further deflection in addition to a resistance already created by direct stresses. Analysis for secondary stresses can be made, and from these a set of panel-point deflections secured. The work involved, however, is very laborious, and the assumptions made are even broader than those used in the original computations. For purposes of analysis, the distance between intersections of gravity axes is considered as effective length. With this assumption, the moment of inertia of an individual member is decidedly not uniform throughout its length, although it is ordinarily considered so for convenience.

Factor (2).—Another kind of distortion brought about by joint rigidity and the resulting end moments induced in every member can be termed, "joint slippage", wherein the outer rivets in any connection deform laterally under secondary stress and permit a slight end rotation of the member. This effect is usually slight, and acts to relieve secondary stress.

Factor (3).—Despite every effort to avoid it, lateral bracing and steel floor systems do take a part of the direct stress originally intended by analysis for the chord members only, the percentage taken by each being nearly proportional to the relative areas, positions, and stiffness of connections. In a narrow structure with heavy wind-bracing and relatively light main members, a considerable portion of the direct stress can be resisted by lower chord-bracing.

Distribution of stress among chord members and floor systems is very uncertain. The writer recently conducted a few strain-gauge measurements on a lower chord of the lift span of the M Street Bridge. Available loading consisted of two electric freight engines, which, theoretically, would stress this lower chord in tension to 2 400 lb per sq in. Within the range of accuracy of the measuring equipment, this lower chord was stressed almost to this value. The live load was symmetrically placed, longitudinally and laterally, to avoid any eccentric loading. Strain-gauge readings were also taken on the lower flange of a roadway stringer parallel to, but a considerable distance away from, the railroad stringers directly supporting the live load, and, theoretically, not subject to railroad loading. This stringer is framed between floor-beams by means of light connection angles, but is rigidly attached to the concrete deck because of the field welding of the main slab reinforcement directly to the top flange of all roadway stringers. Longitudinal continuity of the slab across floor-beams is prevented by the presence of a cold joint along the center line of floor-beams; yet, under the same live load, it was able to register a tensile stress of about 500 lb per sq in. Although no definite conclusions can be drawn from this brief investigation, it is of interest to

note the presence of direct stress in members distinctly not a part of the lower chord, nor directly connected thereto.

Factor (4).—A designer usually considers the gross section of all members in arriving at the total elongation, or strain. Actually, this is somewhat in error for built-up tension members, as directly across a line of rivets, the unit strain is greater than across a line between rivets. A more accurate method is to use a "weighted" cross-section wherein the rivet pitch and percentage of holes out, are taken into consideration.

Factor (5).—Another important effect is the presence of much detail material on the member, such as heavy lacing-bars, stay-plates, long gusset-plates, and portal and sway-frame gussets, all of considerable cross-section, which materially reduce the unit strain wherever they occur. This effect becomes most pronounced at the joints themselves. A haphazard allowance for these variables is impossible. A scientific analysis may be attempted for every truss member throughout its length to determine the variation in unit strain, but the numerous assumptions made while doing it scarcely warrant any high regard for the result.

In consideration of these variables, the writer wishes to conclude his discussion by warning against too much accuracy in determining truss deflections by any method, however excellent it may be, if the actual structure under consideration will behave quite differently from a theoretically pin-connected truss. As the majority of highway and railway structures to-day are completely riveted throughout, in addition to being well braced and comparatively rigid, the aforementioned facts deserve full consideration when applying truss deflections in the field.

Undoubtedly, the author is well aware of these limitations, but there are many who need a gentle reminder from time to time to prevent their interest in the mathematics of a solution from obliterating other, and often more important, phases of a problem.

FANG-YIN TSAI,[18] ASSOC. M. AM. SOC. C. E. (by letter).—The method for computing truss deflections presented in this paper is certainly somewhat simpler and more convenient than the elastic weight methods of either the bar changes developed by Professors O. Mohr[19] and H. Müller-Breslau[20], or the angle changes (also known as bar-chain method) developed by Professor R. Land[21], which, as far as the writer knows, have been the only analytical methods available to date for computing the truss deflections for all the panel points in any chord by a continuous operation. The author is to be commended for his ingenuity.

[18] Prof. of Structural Eng., Dept. of Civ. Eng., National Tsing Hua Univ., Peiping, China.

[19] "Beitrag zur Theorie des Fachwerks", *Zeitschrift* des Architekten- und Ingenieur-Vereines zu Hannover, 1875, p. 17.

[20] "Beitrag zur Theorie des Fachwerks", *Zeitschrift* des Architekten- und Ingenieur-Vereines zu Hannover, 1885, p. 418.

[21] "Beitrag zur Ermittelung der Biegungslinien ebener und elastischer Stabwerke", *Zivilingenieur,* 1889. This method has been presented in the United States in the following three books and papers only: (1) "Kinetic Theory of Engineering Structures", by D. A. Molitor, M. Am. Soc. C. E., McGraw-Hill Book Co., New York, 1911, p. 107; (2) "Truss Deflections Accurately Determined by Angle Changes and Elastic Weights", by D. B. Steinman, M. Am. Soc. C. E., *Engineering Record,* May 13, 1916, p. 644; and (3) "Structural Theory", by H. Sutherland and H. L. Bowman, Members, Am. Soc. C. E., Second Edition, John Wiley & Sons, New York, 1935, p. 178.

It is regrettable, however, that the derivation of Equations (4) and (5) was not included in order to clarify their application and their limitation. These formulas are valid only for trusses having vertical web members and equal panel lengths. It is possible to modify the method, expressing it in a more general form, so as to make it applicable to trusses of any type.

Fig. 16 shows an intermediate oblique panel, $MN\,mn$, of a truss, with M and N denoting the upper panel points and m and n the corresponding lower panel points. The dimensions of the panel are designated by P, p, Y, y, h, and k, which will be considered as positive when measured upward from, or to the right of, a certain reference point (say, M, Fig. 16) and otherwise negative. The lengths of the five bars of the panel are designated, respectively, by L_{MN}, L_{mn}, L_{Mm}, L_{Nn}, and L_{Nm}. Let ΣR be the sum of the rotations of all the deformed panels to the left of this panel, ΣR being considered as positive when it is clockwise and negative when counter-clockwise. Considering the panel point, M, as the reference point (that is, considering M as fixed in position after it has been deflected by all the deformed panels to its left), the panel, as a fixed frame, will first be rotated about M through the angle, ΣR. Thus, the panel points N, n, and m, are deflected, respectively, to the positions of N', n', and m'. The deflection, NN', is evidently equal to $L_{MN}\,\Sigma R$, which may be resolved into the vertical component, $P\,\Sigma R$, and the horizontal component, $Y\,\Sigma R$. The deflection, nn', may be resolved into the two components, $L_{mn}\,\Sigma R$ and $L_{Mm}\,\Sigma R$, which again may be resolved, respectively, into the two vertical components, $p\,\Sigma R$ and $k\,\Sigma R$, and the two horizontal components, $y\,\Sigma R$ and $h\,\Sigma R$. All the deflections will be considered as positive when they are downward from, or to the right of, the original position of the panel point.

Assume the bar deformations, ΔL_{MN}, ΔL_{Mm}, and ΔL_{Nn}, to be the increases in length, and ΔL_{Nm} and ΔL_{mn}, the decreases. Considering M as a fixed reference point and, in addition, $M\,m'$ as a reference bar, fixed in direction, the deflected panel points, N', n' and m', due to those bar deformations, will be further deflected, respectively, to the positions of N'', n'', and m'', which are located by the Williot construction as shown in Fig. 16. Let V'_{NM}, H'_{NM}, and V'_{nM}, and H'_{nM} be the vertical and horizontal components of the deflections, $N'\,N''$ and $n'\,n''$, respectively, which are the panel deflections due to the bar deformations of the panel alone, and let V_{NM}, H_{NM}, V_{nM}, and H_{nM} be the vertical and horizontal components of the deflections, $N\,N''$ and nn'', respectively, which are the panel deflections due to both the bar deformations of the panel and the total rotation of all the deformed panels to the left of this panel. In the foregoing notation for deflections, the first subscript denotes the deflected panel points, whereas the second subscript denotes the reference point. From Fig. 16 the following relations are evident:

$$V_{NM} = V'_{NM} + P\,\Sigma R \qquad (27)$$

$$H_{NM} = H'_{NM} + Y\,\Sigma R \qquad (28)$$

$$V_{nM} = V'_{nM} + (p + k)\,\Sigma R \qquad (29)$$

and,

$$H_{nM} = H'_{nM} + (y + h)\,\Sigma R \qquad (30)$$

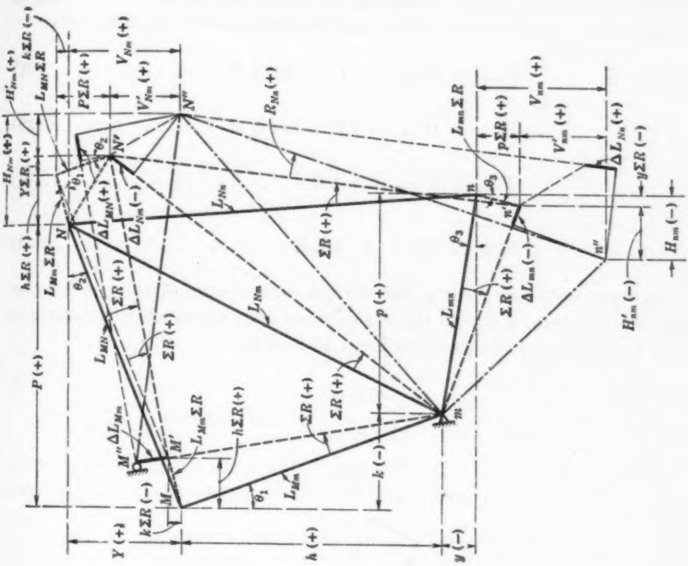

FIG. 17.—PANEL DEFLECTION DIAGRAM WITH LOWER PANEL POINT *m* AS THE REFERENCE POINT.

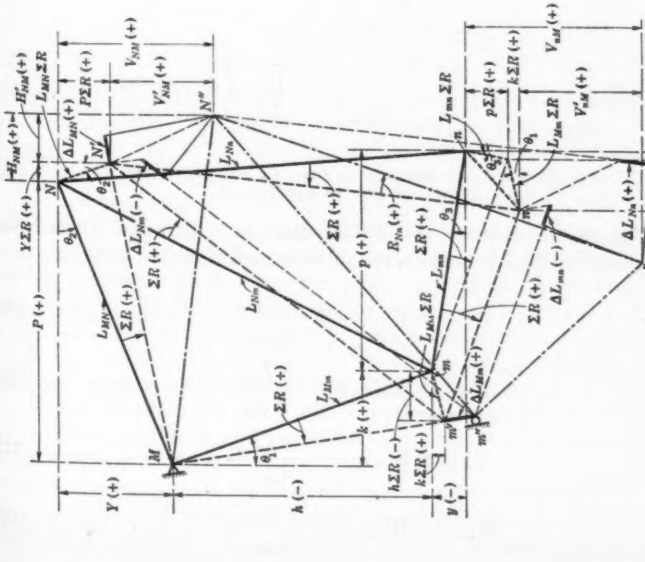

FIG. 16.—PANEL DEFLECTION DIAGRAM WITH UPPER PANEL POINT *M* AS THE REFERENCE POINT.

If the lower panel point, m, is considered as the reference point, as shown in Fig. 17, the various components of the panel deflections will be as follows:

$$V_{Nm} = V'_{Nm} + (P + k) \Sigma R \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

$$H_{Nm} = H'_{Nm} + (Y + h) \Sigma R \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

$$V_{nm} = V'_{nm} + p \Sigma R \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

and,

$$H_{nm} = H'_{nm} + y \Sigma R \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

In order to represent, very clearly, the various components of the panel deflections, the total rotation, ΣR, and the bar deformations are much exaggerated in proportion to the size of the panel in Figs. 16 and 17.

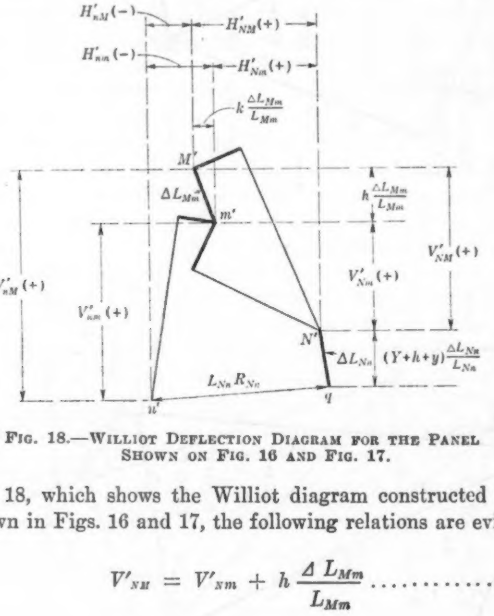

FIG. 18.—WILLIOT DEFLECTION DIAGRAM FOR THE PANEL SHOWN ON FIG. 16 AND FIG. 17.

From Fig. 18, which shows the Williot diagram constructed for both the two cases shown in Figs. 16 and 17, the following relations are evident:

$$V'_{NM} = V'_{Nm} + h \frac{\Delta L_{Mm}}{L_{Mm}} \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

$$V'_{nM} = V'_{nm} + h \frac{\Delta L_{Mm}}{L_{Mm}} \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

$$H'_{NM} = H'_{Nm} + k \frac{\Delta L_{Mm}}{L_{Mm}} \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

$$H'_{nM} = H'_{nm} + k \frac{\Delta L_{Mm}}{L_{Mm}} \ldots\ldots\ldots\ldots\ldots\ldots (38)$$

$$V'_{nM} = V'_{NM} + (Y + h + y) \frac{\Delta L_{Nn}}{L_{Nn}} \qquad (39)$$

and,

$$V'_{nm} = V'_{Nm} + (Y + h + y) \frac{\Delta L_{Nn}}{L_{Nn}} \qquad (40)$$

In Equations (35) to (40), the dimensions, h, k, Y, and y, have numerical values only, and ΔL_{Mm} and ΔL_{Nn} will be positive when they are increased in length and negative when decreased. In the case of a rectangular panel, with vertical members, $Y = y = k = 0$, $P = p$, and $h = L_{Mm} = L_{Nn}$, Equations (27) to (40) will be much simplified. These formulas will suffice to indicate the fact that the values of the panel deflections, V, H, V', and H', may be altogether different in accordance with the reference point chosen and, for the sake of clearness, the latter should be preferably indicated in computing the former.

In Fig. 18, note also that $n'q = L_{Nn} R_{Nn}$, or $R_{Nn} = \frac{n'q}{L_{Nn}}$, which is the rotation of the panel due to its bar deformations, with Mm as the reference bar. If Bar Nn is a vertical member, the rotation, R_{Nn}, will be,

$$R_{Nn} = \frac{H'_{NM} - H'_{nM}}{L_{Nn}} = \frac{H'_{Nm} - H'_{nm}}{L_{Nn}} \qquad (41)$$

When both Nn and Mm are vertical, $H'_{NM} = H'_{Nm}$; and $H'_{nM} = H'_{nm}$, then,

$$R_{Nn} = \frac{H'_{NM} - H'_{nm}}{L_{Nn}} \qquad (42)$$

Since the total rotation, ΣR, and the bar deformations, are always very small in comparison with the dimensions of the panel, the computation of the panel deflections, V' and H', due to its bar deformations may be made without including the effect of ΣR.

For the computation of the panel deflections, V', H' (which correspond to the author's V_1 and H_1), and the rotation, R, the author has presented Equations (1), (2), and (3), respectively, which are valid only for a panel with vertical members. It seems to the writer that those formulas are likely to cause confusion in their application, and this is indicated by the fact that a special column is provided in Tables 1 and 2 of the paper to "symbolize" each bar in applying the author's formulas, even to the simple examples. Therefore, for such computations, the writer would prefer the method of work, or even the Williot diagram, the latter being particularly expedient for the oblique panel shown in Figs. 16 and 17. With the construction of the simple Williot diagram shown in Fig. 18, all the eight panel deflections, V' and H', and the rotation, R, of the panel are obtained at once. It has been universally recognized that the Williot diagram is the best method when the deflections of all the panel points of a truss are desired, the only disadvantage being that the

diagram increases in size, rapidly, as more panels are included in the construction, and, consequently, it is somewhat difficult to obtain the results with a high degree of precision. However, if applied to one panel only, the Williot diagram will have no disadvantage. By combining the Williot diagram for computing V', H', and R, and the author's method for summing up the panel deflections to obtain the deflection of the truss, a semi-analytical method is evolved which, perhaps, will be the best method of all.

With the panel deflections known, it will be very simple to compute the total deflections of the truss. Fig. 19 shows a non-deformed truss, with its deformed position, the end panel point, a, being a reference point and the bar, ab, a reference member, fixed in direction. The total deflection for any panel point is designated by the second subscript, a, which indicates the reference point; thus, V_{Da} is the total vertical deflection of the Panel Point D with Panel Point a as a reference point. From Fig. 19 it is evident that the total deflection of any panel point in any chord is the algebraic sum of the panel deflections of all the panel points to the left of, and including, the panel point in question.

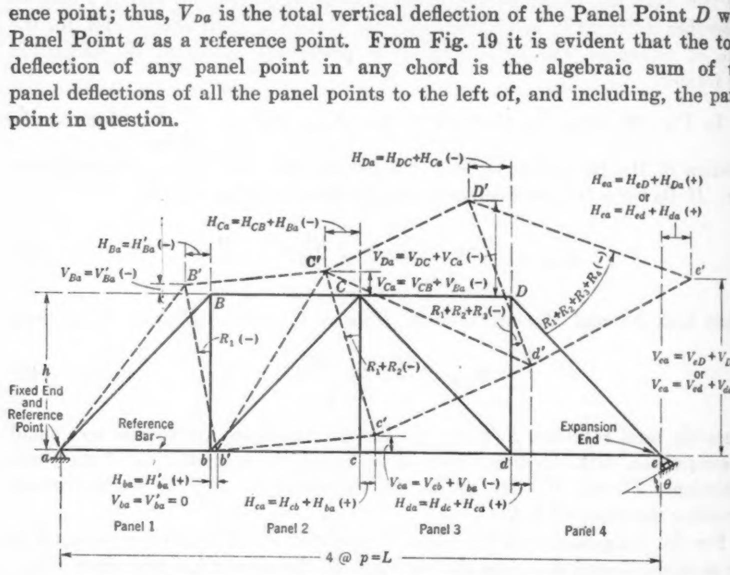

FIG. 19.—RELATIONS OF TOTAL DEFLECTIONS WITH PANEL DEFLECTIONS.

The correctness of this statement may be proved by the following example, considering Panel Point C. Since V_{CB} is the vertical panel deflection of C, with B as the reference point, and if Panel Point B also has its own vertical deflection, V_{Ba}, with a as the reference point, the algebraic sum, $V_{CB} + V_{Ba} = V_{Ca}$, must be the total vertical deflection of C with a as the reference point. Of course, all these deflections are computed with the bar, ab, as the reference bar. It should be observed that in summing up the panel deflections, care must be taken regarding their reference points and, by using panel deflections with different reference points, the total deflection of any panel point may be obtained in various ways. Thus, the total vertical

deflection, V_{da}, of the panel point, d, may be obtained in any of the following four ways:

$$V_{da} = V_{dC} + V_{CB} + V_{Ba} \qquad (43)$$

$$V_{da} = V_{dc} + V_{cb} + V_{ba} \qquad (44)$$

$$V_{da} = V_{dc} + V_{Cb} + V_{ba} \qquad (45)$$

or,

$$V_{da} = V_{dc} + V_{cB} + V_{Ba} \qquad (46)$$

The significance of Equations (43) to (46) is evident from Fig. 20, which shows the various panel deflections for different reference points and also the total deflections (shown barred; thus, $\overline{V_{ca}}$) with a as the reference point, for all the panel points of the truss in Fig. 19.

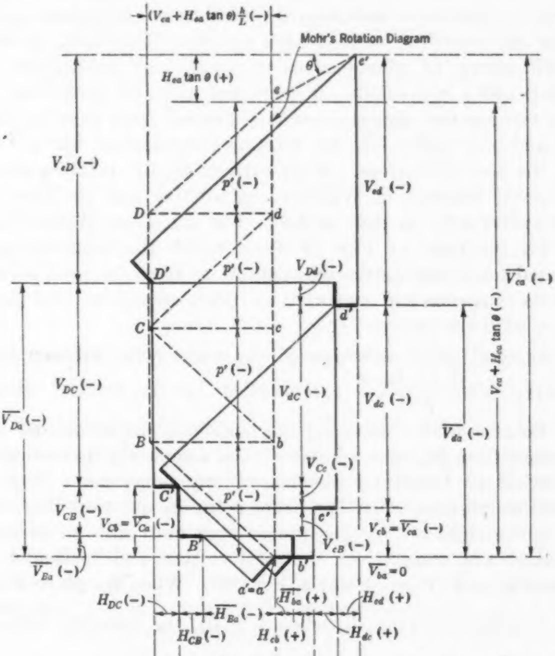

FIG. 20.—WILLIOT-MOHR DIAGRAMS SHOWING THE VARIOUS DEFLECTION COMPONENTS WITH DIFFERENT REFERENCE POINTS FOR THE TRUSS OF FIG. 19.

Since the computation of the total deflections is merely a matter of summation as soon as the panel deflections are known and since the summation may be somewhat varied according to the choice of the reference points on the basis of which the panel deflections are computed, it seems to the writer that formulas for computing the total deflections such as Equations (4) and (5) of the paper are not only unnecessary, but also undesirable.

The author has presented two numerical examples, in which both the trusses and their deformations are symmetrical with respect to the center lines. In computing the panel deflections, the center panel point and the center bar are taken as references (that is, they are assumed to be fixed) and, by so doing, the true deflections can be obtained by merely transposing the reference point from the center panel point to the end panel point, which is actually fixed. This procedure is certainly advantageous in these symmetrical cases. However, in cases in which either the truss or its deformations are asymmetrical, such a procedure will require corrections both for transposing the reference point and rotating the reference bar in order to obtain the true deflections from the total deflections, and the computations might become seriously complicated in an analytical method such as this. Therefore, in asymmetrical cases, it will always be advantageous to use the end panel point, (preferably the left end) and a convenient bar connected to it, for reference.

In this manner the computations may proceed from panel to panel toward the right, and only corrections for rotating the reference bar will be required to obtain the true deflections. Such corrections for rotation are similar to Mohr's rotation diagram in Williot's construction and are also very simple if applied analytically to this method. Fig. 20 shows Williot's and Mohr's diagrams for the truss of Fig. 19, from which the following general rule may be stated for obtaining the true deflections from the total deflections in a truss with its expansion end supported by rollers on any inclined plane, making an angle, θ, with the horizontal:

From the total panel deflection of any panel point subtract algebraically the quantity, $\frac{V_{ea} + H_{ea} \tan \theta}{L}$, multiplied by its vertical distance from Reference Point a when computing the horizontal deflection and by its horizontal distance from Reference Point a when computing its vertical deflection.

The vertical or horizontal distance of any panel point from Reference Point a will be positive when the panel point in question lies, respectively, above, or to the right of, a. The proper sign must also be assigned to V_{ea} and H_{ea}, which are, respectively, the total vertical and horizontal deflections of the expansion end (Panel Point e, Fig. 19). When the plane that supports the rollers is horizontal (that is, when $\theta = 0$), the quantity, $\frac{V_{ea} + H_{ea} \tan \theta}{L}$, is reduced to $\frac{V_{ea}}{L}$. Applying the foregoing general rule to the example of Figs. 19 and 20, it is noted that: (1) The horizontal deflections of all the lower panel points require no corrections; (2) for the horizontal deflections of all the upper panel points, the quantity, $(V_{ea} + H_{ea} \tan \theta) \frac{h}{L}$, must be subtracted

algebraically from the respective total horizontal deflection; and (3) for the vertical deflections of all the upper and lower panel points, the quantity, $(V_{ea} + H_{ea} \tan \theta) \frac{p}{L}$, multiplied by n, the number of panels which the panel point in question is away from Reference Point a, must be subtracted algebraically from the respective total vertical deflection.

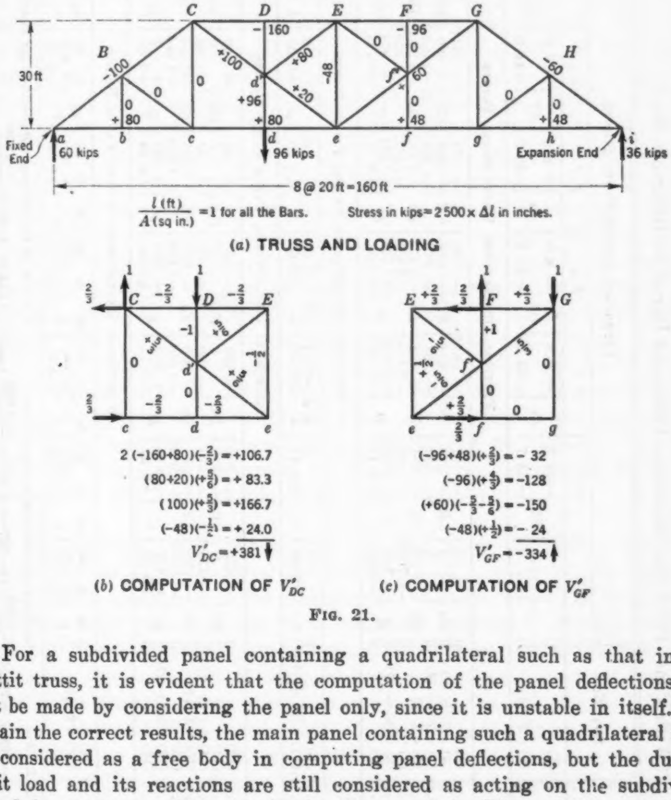

FIG. 21.

For a subdivided panel containing a quadrilateral such as that in the Pettit truss, it is evident that the computation of the panel deflections can not be made by considering the panel only, since it is unstable in itself. To obtain the correct results, the main panel containing such a quadrilateral must be considered as a free body in computing panel deflections, but the dummy unit load and its reactions are still considered as acting on the subdivided panel in question. This is clearly illustrated in Figs. 21(b) and 21(c).

In this case, again, it is noted that, for computing the panel deflections, V' and H', formulas of limited applicability, such as Equations (1) and (2) of the paper, will be of little value and it will also be futile to attempt devising such equations in a generally valid form.

In applying a method of this nature, systematic tabulation of computations and consistent convention for signs are both of the utmost importance; otherwise, confusions and errors are likely to occur. Even for the very simple example given in the paper, the writer experienced some difficulty at first

in following Tables 1 and 2. For instance, the author has not indicated the reference points for the vertical deflections in Table 1, Column (7), so it is somewhat difficult to understand how they can be added in Column (11). The value, 1 355, in Column (11) is evidently the numerical sum of the values, −354, −267, and +734 in Column (7), indicating, obviously, that the signs of the latter have been disregarded.

In order to illustrate the application of the method to an asymmetrically deformed truss with subdivided panels, and also to show the method of tabulating the computations without using Equations (4) and (5) (as the writer prefers), the example[22] shown in Fig. 21(*a*) is completely developed and tabulated systematically in Table 11. The deflections, V' (Step No. (3)), for all the panel points in the upper chord, and H' (Steps Nos. (12) and (19)), for all the panel points in both the chords are first computed and tabulated, most of the latter being merely the bar deformations of the chord members. The rotations, R, are computed by Equation (41) or Equation (42). With those values known, the remaining computations are merely a matter of arithmetic, the operations for obtaining the results in every row being also indicated. It may be noted that the true vertical deflection of any lower panel point (Step No. (11)) is equal to the algebraic sum of the same deflection of its corresponding upper panel point (Step No. (9)) and the bar deformation of the vertical member connecting the two panel points (Step No. (10)). This relation is always valid for trusses having vertical members, irrespective of the shape of the chords and the arrangement of the diagonals. The exact agreement between the values (+ 0.21 in.) of the true horizontal deflection of Panel Point i computed from both the upper and the lower chords serves as a check.

A. W. Fischer,[23] Esq. (by letter).—In this paper the author has added another method for calculating the deflections of a truss by the analytical method, which is stated to solve "the problem of truss deflections in a simpler and more direct manner than other analytical methods." To the writer it seems that there are several analytical methods for trusses of a certain type, that are as simple as that of the author, which is based upon set formulas. One solution which is very simple for computing the deflections of Warren trusses is the "method of elastic weights"; another is the "geometric method"; and still another (which is a very flexible method for solving the vertical and horizontal deflections of any shape truss) is the method of "relative deflections"[24].

To determine the deflections of panel points in the author's Example 1, for instance, relative to Member 5–6, assume the truss supported at Panel Points 6 and 5 instead of at the left and right ends, being hinged at Point 6 and supported horizontally at Point 5.

[22] The example is taken from "Structural Theory", by H. Sutherland and H. L. Bowman, Members, Am. Soc. C. E., John Wiley & Sons, New York, Second Edition, 1935, p. 173, Figs. 7-12.

g_{mn} represents the quantity, $\frac{S\,L}{A\,E}\,u_m$, for Member mn.

Table 12 gives the values of u for the members for unit vertical load at various panel points. This table is not absolutely necessary, in the method of relative deflections, but is presented for a better understanding of certain values given in Table 13.

Using Example 1 and the elongations given by Mr. Shoemaker it is easy to enter the values as given in Table 13 from which the deflections can be computed. All the values given in Table 13 are readily determined and once the method is mastered it is easy to calculate the vertical deflections of a truss. Furthermore, the method of relative deflections may be readily applied to a truss bridge with inclined top and bottom chords and with unequal panel lengths, p.

The paper is based on analytical methods, but for solving the secondary stresses in a truss by the slope-deflection method or by distributing fixed-end moments, the relative vertical and horizontal deflections are only required for the value of Δ for each member, Δ being the displacement, at right angles to the axis of the member of one end with respect to the other end, and to get these values of Δ the analytical method is not as flexible as the simple Williot diagram. In the author's closure it might be well for him to demonstrate the calculation of the horizontal deflections for his Example 1 and then show how he would calculate the values of Δ (that is, the displacement at right angles to the axis of the member, of one end with respect to the other end) and compare the time against that required by using a Williot diagram.

In conclusion, the writer will state that he sees no particular advantage in using the "panel deflection" method for the solution of certain types of trusses. There are certain other types in which the method is satisfactory, but as certain set formulas must be available for use, it loses its simplicity against other analytical methods.

L. E. Grinter,[25] Assoc. M. Am. Soc. C. E. (by letter).—The summation process of deflection computation has long been used in the study of truss deflections. The innovation proposed by Mr. Shoemaker is that the contributions of the several panels, rather than the individual contributions of the separate members, be added to obtain the deflection. However, since the effect of each panel must be evaluated by considering the individual changes in lengths of the separate members, it is evident that the amount of computations involved in the two procedures must be about the same. If the method proposed by the author seems simpler than the procedure of summing, directly, the effects of the individual members, it is merely because the standard textbook treatment of the latter method (elastic or angle weights) is unnecessarily cumbersome. When the method of angle weights is reduced to its fundamental conceptions, it will be found to be essentially the same as the method suggested by Mr. Shoemaker.

There are two basic conceptions involved in the method of angle weights. First, the physical picture that deflection can be computed by summing the products of angle changes and lever arms; and, second, the conjugate-beam

[25] Dept. of Civ. Eng., Armour Inst. of Technology, Chicago, Ill.

conception which cares for the effect of dissymmetry. The author has considered only symmetrical structures with symmetrical loading; and, accordingly, he has neglected consideration of the conjugate beam. Hence, his procedure for determining the deflection of a symmetrical truss is to find the upward deflection of the end relative to a fixed center-vertical member or relative to a fixed central-chord member. One notices at once the similarity to the use of the Williot diagram for those cases in which the use of the Mohr rotation diagram can be avoided.

When the author discusses the correspondence of his method with the method of computing beam deflections in the following passage, "to compute the deflection of a point of a beam of constant moment of inertia with reference to a tangent to the elastic curve of that beam, the sum is taken of the products of the angular change of every vertical section, multiplied by its distance from the point", he is referring to relative and not to absolute deflections. If this method of computing relative deflections is to be used to compute the maximum deflection of a beam that is unsymmetrically loaded, the procedure illustrated by Fig. 22 becomes necessary. The deflection, Δ_1, is obtained as the statical moment of the $\dfrac{M}{EI}$ - area from A to B about the point, B, where the deflection, Δ_1, exists. Then, the value of θ_1 is Δ_1 divided by L, the span of the beam. The point of maximum deflection, or D, is located such that the area of the $\dfrac{M}{EI}$ - diagram from A to D is equal to θ_1. Then, finally, the maximum deflection Δ_2, is computed as Δ_3, the deflection of the beam at A from a tangent drawn to the elastic curve at D.

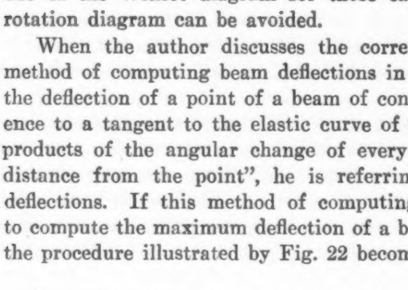

Fig. 22.—Computation of the Maximum Deflection.

The foregoing procedure, or a similar one, would be involved in the use of the author's method for the study of an unsymmetrical truss. Evidently, the difficulties involved would make the use of the method of panel deflections rather cumbersome for such trusses. The study of dissymmetry by the use of elastic weights (which involves the conjugate beam) would be much more satisfactory. The Williot-Mohr diagram is also a convenient method of determining the deflection of an unsymmetrical structure.

In the selection of a method for computing deflections, one should make a distinction between those methods that give a single deflection and those that give rise to the entire deflected load line. The author's procedure belongs to the second classification along with the method of elastic weights and the Williot-Mohr diagram. Castigliano's theorem and the method of virtual work give a single deflection for each separate computation. Hence, the determination of a single deflection or the calculation of a reaction (indeterminate structure) for fixed loads follows more simply by the use of these tools.

On the other hand, a method that develops the entire elastic curve (deflected load line) is more satisfactory for the determination of an influence line as the shape of the deflected load line.

In summarizing, the writer feels that the panel-deflection method is an interesting and useful conception that in practice should be limited to the field of symmetry. It bears the same relation to the method of elastic weights that the moment-area method (statical moments of moment areas) bears to the conjugate-beam method. One should not lose sight of the fact that the deflections obtained are relative to a fixed tangent. The panel-deflection method belongs to the classification of methods that develop the entire elastic line. No known procedure can compete with the method of virtual work for the computation of a single truss deflection. The author has performed a service in calling this interesting procedure to the attention of engineers and educators.

LOUIS H. SHOEMAKER,[38] M. AM. SOC. C. E. (by letter).—A number of interesting suggestions have been made by discussers of this paper. Several have proposed, and explained in some detail, methods of calculation in which the effect of the deformation of each truss member is treated separately. Others have proposed special ways of treating certain problems which they appear to consider as offering difficulties if a solution is sought by the method under discussion. These methods, as well as the Williot diagram and the method of "elastic moments," are claimed to offer material advantages, especially as regards the work of computation and avoidance of the use of formulas.

The question of the comparative amount of work required by different methods of computation can only be decided by experience; and in this case there is no doubt as to the result. Formulas, as the name implies, provide a form for the computations to take and, consequently, expedite the work and contribute to its accuracy; and, although these formulas will not be memorized, the manner in which they are developed and applied is easily remembered. Other methods, although not requiring the use of formulas, are much more complicated in their application.

The "panel deflection method" treats the deflections of a truss in exactly the way in which they occur. There is no question but that the panel is the unit of deflection and the equations express the panel deflections in the simplest form.

It is evident that the typical form of panel used applies to all single braced panels with parallel sides, the deflections being taken in the direction of the sides. This type is used in practically all engineering structures.

In the case of sub-divided panels, the deflections of the main panel points are obtained from the deformations of the members of the main panel and the deflections of the sub-panel points from the deformations of the members of the triangle forming the sub-panel construction. In trusses having web systems composed of diagonals only, temporary verticals can be considered as applied at the panel points. As these verticals have no stress, the terms

[38] Santa Monica, Calif.

in the formulas involving their changes in length disappear. Formulas for the K-type of panel are easily developed by the method described in the paper.

Mr. Noe has made an excellent contribution to this discussion by developing the deflection formulas by the use of Williot equations. By applying the formulas to the deflections of an unsymmetrically loaded truss, he has answered the objection that has been raised, that the procedure in this case would necessarily be very complicated.

Mr. Molitor advances the statement, without offering supporting facts, that the method under discussion applies only to very simple truss forms. He refers to "odd-shaped triangular truss systems without vertical members" and complications "due to the more involved geometric relations, for which the new method becomes quite 'out of bounds'." Other than to disagree completely with Mr. Molitor's conclusions in so far as they are definite, it seems unnecessary to reply. However, it is confidently expected that thoughtful and discerning members, who study the facts as published, will conclude that the method offered has the advantages claimed for it.

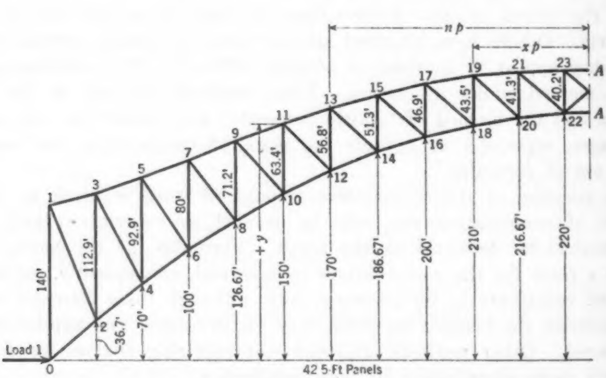

FIG. 23.—ELEVATION OF HALF ARCH, OVER HELL GATE, NEW YORK, N. Y.

An analysis of the steel arch bridge over Hell Gate, in New York City, (see Fig. 23) will serve to answer various criticisms offered in discussion. The computations for the reactions are given in Tables 14 and 15. The preliminary data (that is, changes of length and length of members) were taken from a paper[27] by O. H. Ammann, M. Am. Soc. C. E., published in 1918. Table 14 gives the results of the computations of the products $c' c$, $d' d$, etc., which are the terms composing the formulas. In Table 15 the final results are given. In computing the total deflection of a point Equation (4) gives the total deflection of each point from the origin. Another method of making these computations is to compute the deflection of each point with reference to the preceding point.

[27] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 852.

Professor Tsai has developed equations for the deflections of an irregularly shaped panel by Williot diagrams. The writer appreciates his interesting contribution to this discussion. In developing the "panel deflection method,"

the writer had in mind its application to engineering structures, and derived the necessary formulas for that purpose in the most direct manner. A complete explanation of the data in Table 1 was included in Example 1 of the paper. Professor Tsai is in error in thinking this method does not apply to trusses with sub-divided panels. The writer believes that his explanation, given previously in this discussion, fully answers this question.

Professor Grinter has misinterpreted the description of the method under discussion. The writer's reference to the deflections of a beam was for the purpose of calling attention to similarity of methods. A careful study of

the paper will reveal the fact that deflections are computed with reference to a point called the origin of deflections and a line through this point called the axis of deflections. The deflection of a single point of a structure, furthermore, can be computed as easily by the "panel deflection method" as by the method of virtual work.

The deflection of the nth panel point with reference to the $(n-1)$th panel point is,

$$\Delta_n = \Delta_1 + \sum_{x=0}^{x=n-1} (R\ p) \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots (47$$

and,

$$\Delta_T = \Delta_T + \Delta_n \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

This method of computing Δ_T enables the results to be tabulated in more compact form. In Table 15, Δ and R are given together in Column (2), Δ on the upper line and R on the lower line of the panel space. In the same manner $\Sigma\ (R\ p)$ and $\Delta + \Sigma\ (R\ p)$ are given in Column (3) and y and $R\ y$ in Column (5). In obtaining the values of Δ_T, the value of $\Delta + \Sigma\ (Rp)$ on the bottom line of a given panel space is added to the value of Δ_T in the panel space above, and the result is the value of Δ_T for the given panel. The computations for horizontal deflections of Point O are written at the bottom of the table. It is believed that a comparison of Tables 14 and 15 with the tables of computations, made by Mohr's method of elastic moments,[27] is a sufficient answer to the various claims and criticisms that have appeared in this discussion.

LATERAL PILE-LOADING TESTS

By Lawrence B. Feagin[1], M. Am. Soc. C. E.

With Discussion by Messrs. A. E. Cummings, J. C. Meem, T. Kennard Thomson, August E. Niederhoff, Lazarus White, Y. L. Chang, D. P. Krynine, and Lawrence B. Feagin.

Synopsis

Tests conducted at Lock and Dam No. 26, Alton, Ill., to determine the resistance under lateral loads of timber and concrete piles, driven in Mississippi River sand, are described in this paper. The work includes descriptions of tests on single piles with heads not fixed, and on groups of four, twelve, and twenty piles with heads fixed in concrete test monoliths. The field data are presented in tabular or graphical form, and the results discussed. In view of the fact that these tests were conducted in only one type of soil, and in view of the many variables involved, no mathematical analysis is included. It is hoped, however, that the results of tests conducted by others may be presented in the discussion.

Introduction

Lock and Dam No. 26 on the Mississippi River, at Alton, Ill., is the farthest down stream of the twenty-six locks and dams included in the general program of canalization of the Upper Mississippi River. It is situated 23 miles up stream from St. Louis, Mo., 8 miles above the mouth of the Missouri River, and 15 miles below the mouth of the Illinois River. In addition to being a part of the 9-ft canalization of the 650-mile section of river below the "Twin Cities"—St. Paul and Minneapolis, Minn.—the pool above Lock and Dam No. 26 will also form a part of the waterway from the Great Lakes to the Gulf of Mexico.

The designs of twenty-two of the twenty-six locks and dams are entirely, or in part, on piles, driven in most cases in river sand of varying degrees

Note.—Published in November 1935, *Proceedings*.
[1] Senior Engr., U. S. Engr. Office, St. Louis, Mo.

of coarseness. Lock and Dam No. 26 is founded entirely on piles, and its designed lift at extreme low water of 25.2 ft is nearly double that of any of the other projects founded on piles. Under the twin locks there are about 14 200 timber piles and nearly 5 000 concrete piles, and under the dam, about 13 100 timber piles. Although many vertical pile-loading tests have been made in various soils, it appears that comparatively few field tests have been made of the resistance of piles to movement under lateral loads; such, for example, as those resulting from back-fill behind the land-wall of a lock, or from water pressure on dams. It is hoped, however, that lateral loading tests made by others will be fully described in discussion of this paper.

Purpose of Tests

The general purpose of the tests herein described was to secure data on the movement of timber and concrete piles in groups of various sizes when subjected to lateral loads. In as much as the design lateral load assumed under certain conditions, for the piles beneath the river wall of the auxiliary lock, is 6.5 tons per pile (which, in general, may be regarded as rather high), it was particularly desirable, furthermore, to determine the degree of safety of this assumption. Information was also desired for use in designing the foundations for the piers of Dam No. 26, and for designing future locks and dams on similar foundations.

Test Monoliths

In order to simulate, as nearly as practicable, the actual loading conditions that will occur in the completed structures, six concrete monoliths were constructed on timber and concrete piles driven along the toe of the

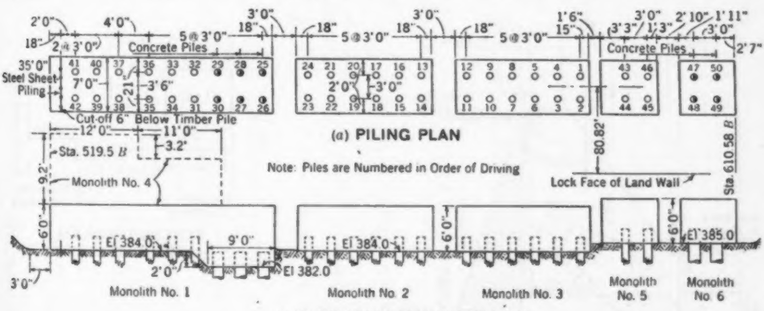

Fig. 1.—Plan and Elevation of Test Monoliths.

slope of the Illinois shore behind the land-wall of the main lock, as shown in Figs. 1 and 2. The heads of the piles were fixed, as in the lock-walls, by being embedded 2 ft in the concrete. The cross-section of Monolith No. 1 was typical of the foundation pour of the river wall of the auxiliary lock between gate-bays. The section includes two rows of nine piles each and a 7-ft width of 35-ft, steel sheet-piling. There are six concrete, and

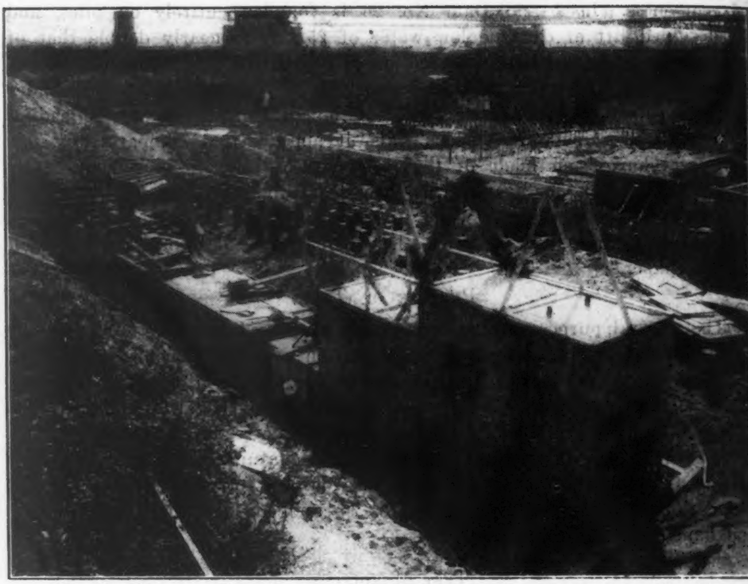

FIG. 2.—VIEW OF TEST MONOLITHS, UPPER MISSISSIPPI RIVER, LOCK NO. 26.

twelve timber, piles. Monolith No. 4 was superimposed on Monolith No. 1 to provide a vertical load approximately equal to that of the river wall under the eccentric loading that occurs when the auxiliary lock is filled

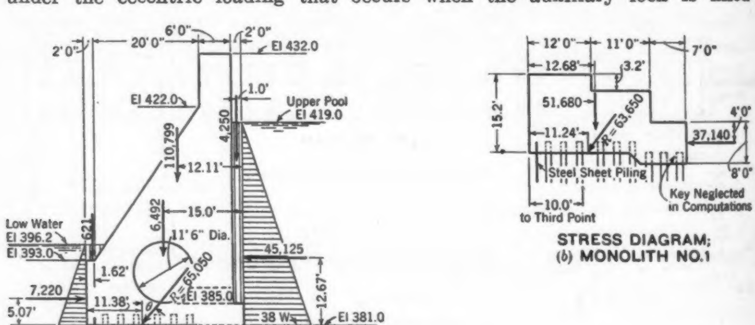

FIG. 3.—LOAD AND STRESS DIAGRAMS.

and the river below the dam is at extreme low water. A comparison of the loading conditions is shown in Fig. 3. Monoliths Nos. 2 and 3 are each on two rows of six timber piles each, or twelve piles to the monolith. Monolith No. 5 is supported by four timber piles and Monolith No. 6 by four concrete piles. Thus, provision was made for comparing the movement of monoliths on groups of four, twelve, and twenty piles, assuming the steel sheet-piling under Monolith No. 1 as equivalent to two piles. In addition to supplying the means of making lateral load tests, the monoliths were used for making studies of relative volume changes, heats of hydration, etc., with various types of cement and methods of curing.

Single Piles

In order to compare the movement of groups of piles with heads fixed in the concrete to that of a single pile with head not fixed, lateral tests were also made on a single timber pile and on a concrete pile driven as a part of the foundation of the land-wall of the locks.

Driving and Physical Data

Table 1 contains pile-driving and physical data for each pile under the test monoliths, and Fig. 4, supported by Table 2, shows corresponding data for the single concrete and timber piles tested.

* Measured stroke of ram, 35 in.; weight of ram, 5 000 lb; and jet pressure, 100 lb. All timber piles were oak, principally white oak.

† Concrete pile.

Foundation Conditions

A log of a hole, *O*, bored in the vicinity of Monolith No. 1, is shown in Fig. 5. It will be noted that the foundation consists of medium sand. The samples, of which sieve analyses are given in Fig. 5, were taken by jetting a 2-in. pipe about 3 ft below a 3-in. casing, stopping the jet, and permitting sand to enter the 2-in. pipe through side openings, and then

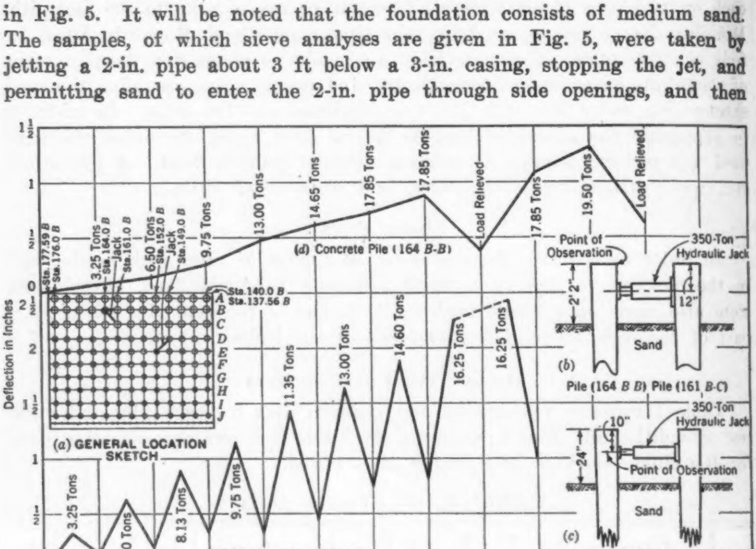

Fig. 4.—Deflections of a Single Concrete Pile.

withdrawing the pipe. Although this method affords a reasonably representative sample, the sample tends to be somewhat coarser than the material from which it is taken, due to the fact that some of the fines are washed

away prior to stopping the jet. A small open pit dug during the progress of the tests indicated that the line of saturation was at Elevation 381.7, or approximately 2.33 ft below the base of Monoliths Nos. 2 and 3. A surcharge

was created at each end of the group of monoliths by sand back-fill. At the up-stream end of Monolith No. 1, however, the back-fill above its base was removed for a distance of 3 ft, and at the down-stream end of Monolith No. 6, approximately 5 ft. In view of the small movement of the monoliths during the tests, and the fact that there was no perceptible

upheaval of the sand between the monoliths and the toe of the slope of the back-fill, it is believed that the movement of the monoliths under test was not materially affected by the surcharge.

EQUIPMENT

The tests under lateral load were made by placing a hand-operated hydraulic jack of 350 tons rated capacity between two monoliths and jacking them apart. The loads were determined from an accurately calibrated gauge. The jacking equipment is shown in Figs. 6 and 7. In order to secure sufficient resistance to move Monolith No. 1, heavy oak struts were placed between Monoliths Nos. 2, 3, 5, and 6. The point of application of the lateral load was 2.5 ft above the base of the monoliths for the test on Monoliths Nos. 5 and 6, and 2.0 ft above the base for the tests on Monoliths Nos. 1, 2, and 3. Thus, the point of application was at the general level of the tops of the piles.

OBSERVATIONS

Observations were taken by reading with a transit a rule held over the jack with its end against a point on the center line of the monolith and 2.25 ft below the top. Readings were taken to the nearest $\frac{1}{32}$ in. Additional observations were taken at the top and sides of each monolith to determine whether or not there was twisting or tilting of the monoliths. In general, however, it was found that there was no appreciable twisting or tilting. The movement of the single piles in the foundation of the land-wall was taken by jacking two piles apart and observing their spread.

SEQUENCE OF TESTS

The first tests, which were somewhat of a preliminary nature, were made on the single timber and concrete piles of the foundation of the land-wall, with butts not fixed. Details are shown in Figs. 4 (*b*) and 4 (*c*). The first test on the monoliths (see Fig. 8 (*a*)) was made by jacking

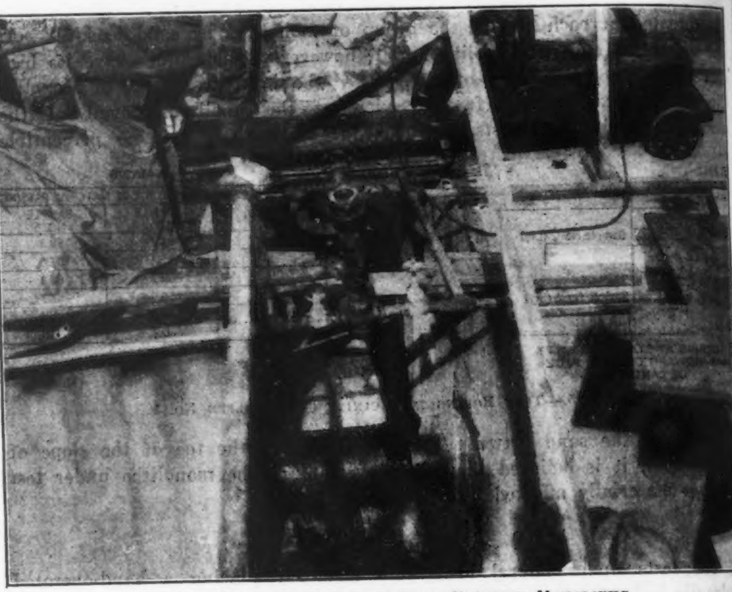

FIG. 6.—HORIZONTAL LOADING TEST BETWEEN MONOLITHS.

FIG. 7.—LATERAL LOADING TEST BETWEEN TIMBER FOUNDATION PILES, (152 *B-E*) AND (149 *B-D*). (SEE FIG. 4(*a*)).

Monoliths Nos. 5 and 6 apart. The load was increased in increments of 1 ton per pile until a load of 5 tons per pile was reached. This load was maintained overnight, after which it was increased to 30 tons per pile.

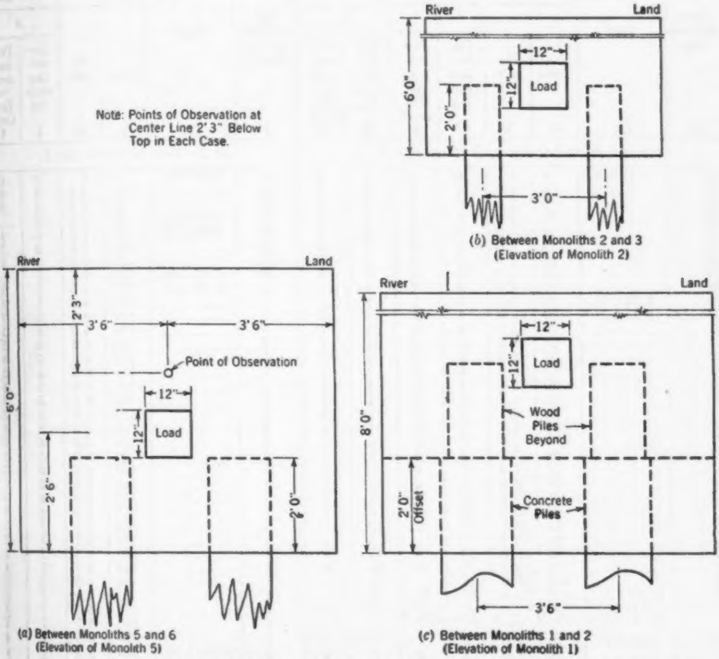

FIG. 8.—POSITION OF 350-TON, MANUALLY-OPERATED HYDRAULIC JACK IN LATERAL PILE-LOADING TESTS.

The results of this test are shown in Table 3 (*a*) and Fig. 9 (*a*). (It is to be noted that, in Fig. 9, the loads are in tons per pile. Each cycle comprises a variation from no load to the indicated load and back to no load.)

The second test was made by jacking Monoliths Nos. 2 and 3 apart, each of which is supported by twelve timber piles. The load (see Fig. 8 (*b*)) was increased in increments of 1 ton per pile until a load of 10 tons per pile was reached, which was then maintained overnight, after which it was increased to 20 tons per pile. Following each increment the load was released and the permanent deflection observed. The results of this test are shown in Table 3 (*b*) and Fig. 9 (*b*).

The third test was made by placing the jack between Monoliths Nos. 1 and 2 (see Fig. 8 (*c*)) and placing oak struts between Monoliths Nos. 2, 3, 5, and 6. A load of 4 tons per pile, assuming the steel sheet-piling as the equivalent of two piles, was maintained overnight. This load was then increased to 6.5 tons per pile (the design load of the river wall of the auxiliary lock) and maintained over the week-end. The load was then

* Load of 5 tons per pile sustained overnight. † Five cycles of load. ‡ 25 cycles of load.
¶ Permanent deflection is deflection observed after indicated load was removed.

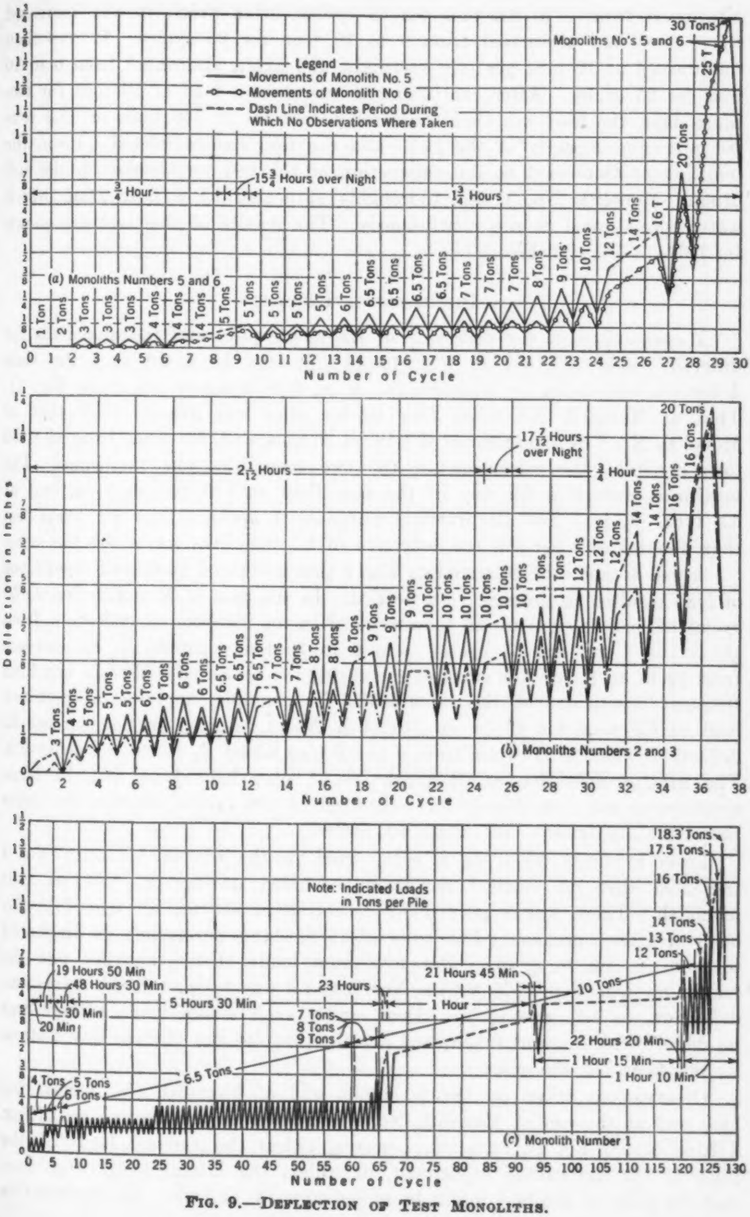

FIG. 9.—DEFLECTION OF TEST MONOLITHS.

alternated from 0 to 6.5 tons for 53 cycles, after which it was increased to 10 tons and alternated from 0 to 10 tons for 25 cycles. It was then maintained at 10 tons per pile overnight and again alternated from 0 to 10 tons for 25 cycles. After continuing to maintain a load of 10 tons for two more days, the load was then increased to a total of 366 tons, or 18.3 tons per pile—the capacity of the jack—and the test was completed. From the morning of October 1 to the completion of the test on October 4, the soil around Monolith No. 1 was thoroughly saturated by a hose from which water was allowed to run continuously. The results of this test are shown in Table 3 (*c*) and Fig. 9 (*c*).

Discussion of Results

A comparison of the deflection of the single piles and the monoliths for different loads is given in Fig. 10 (*a*). It will be noted that the least deflection was shown by Monolith No. 6, on four concrete piles (see Fig. 1). That of Monolith No. 5 on four timber piles was greater than that of Monolith No. 6 by a maximum of $\frac{1}{8}$ in. at 10 tons, and, for loads from 25 to 30 tons per pile, the movement of the two monoliths was the same. The maximum deflection for any of the monoliths at 4 tons was $\frac{1}{8}$ in. and at 6.5 tons, $\frac{9}{32}$ in. For all practical purposes it appears that for loads less than about 6 tons per pile the deflection of all monoliths was about the same.

It will be noted by referring to Fig. 9 that sustained loads and repetitions of load resulted in progressive deflection. In the case of Monolith No. 1, 53 cycles of load from 0 to 6.5 tons resulted in an increase in deflection from $\frac{5}{32}$ in. to $\frac{1}{4}$ in., and 53 cycles from 0 to 10 tons resulted in an increase from $\frac{15}{32}$ in. to $\frac{13}{16}$ in. The effect of sustaining the load appeared to be less than frequent repetitions of the same load; for example, applying a sustained load of 6.5 tons for 48 hr on Monolith No. 1 resulted in no increase in deflection, whereas 53 cycles from 0 to 6.5 tons added $\frac{3}{32}$ in. to the deflection. The greater deflection of Monolith No. 1 may have been due, in large measure, to the fact that it was subjected to 128 cycles, whereas the other monoliths underwent less than 40 cycles.

Level readings taken on a point fixed in the top of Monolith No. 1 indicated that no vertical movement occurred during the test on that monolith. There was a permanent deflection or set for all monoliths for loads of 4 tons, or more. For loads of 6.5 tons this permanent set amounted to from $\frac{1}{16}$ in. to $\frac{1}{8}$ in. For maximum loads of 30 tons per pile the maximum deflection of Monoliths Nos. 5 and 6 was $1\frac{3}{4}$ in. and the permanent deflection, or set, was $\frac{15}{16}$ in. Even under such severe loading there was no definite failure, and subsequent examination did not disclose any distress in the fibers of the piles.

Observations taken on the up-stream end of Monolith No. 1 near the base and at the top of Monolith No. 4 indicated that there was no tilting. Tilting would not be expected, however, unless the vertical loads on the piles at the toe caused settlement, or unless the lateral loads were such that the piles at the heel might be pulled upward, or both. An examination

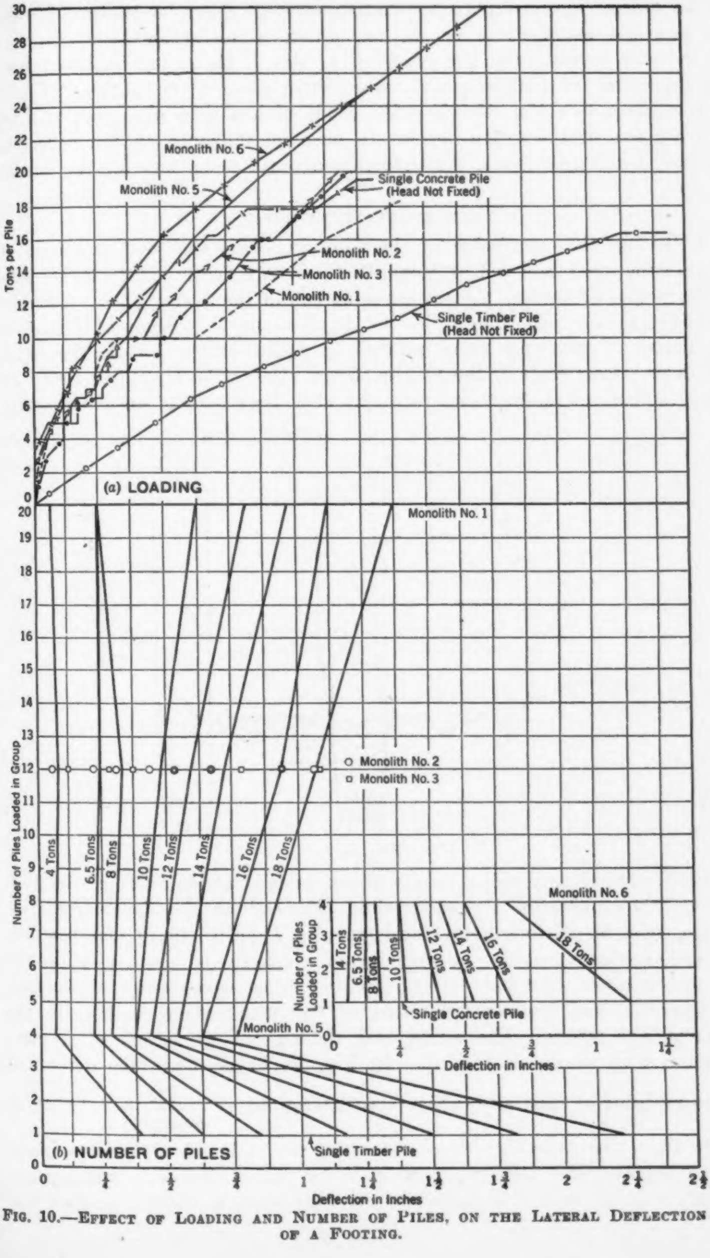

Fig. 10.—Effect of Loading and Number of Piles, on the Lateral Deflection of a Footing.

of the sizes of the piles indicates that the average shear for loads of 6.5 tons per pile was about 85 lb per sq in., which is not serious.

In order to determine the effect of the size of the group of piles loaded, the movement of each monolith was plotted against the number of piles in the group (see Fig. 10 (*b*)). For loads of less than about 6.5 tons per pile the size of the group appears to have no influence on the deflection, whereas, for higher loads, the deflection appears to be less for the smaller group.

Fiber Stress Investigation

Following the completion of the foregoing tests the sand was removed beneath the up-stream end of Monolith No. 2 to a depth of 2.17 ft, the level of the line of saturation, thereby exposing two of the timber piles. A careful examination of these piles failed to disclose any indication of failure in the fibers. Plugs were then inserted on 10-in. centers in the up-stream and down-stream sides of the two up-stream piles. The top plugs were 8 in. below the base of the monolith (see Fig. 11). By means of an extensometer,

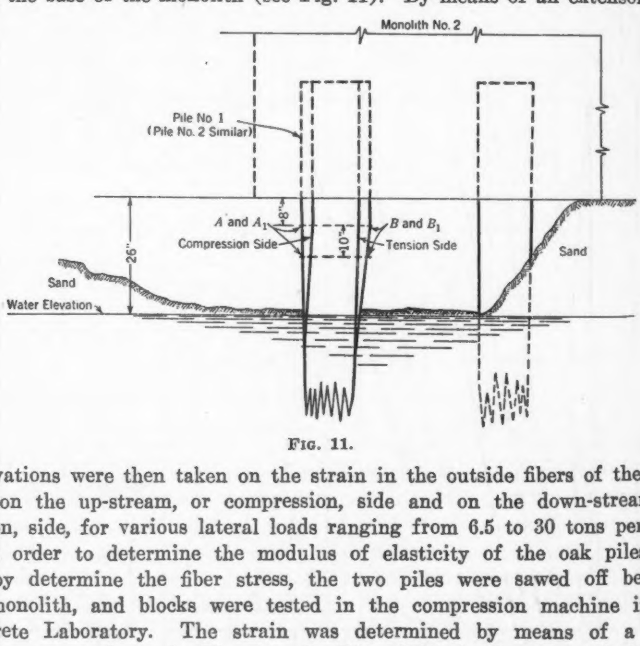

Fig. 11.

observations were then taken on the strain in the outside fibers of the piles both on the up-stream, or compression, side and on the down-stream, or tension, side, for various lateral loads ranging from 6.5 to 30 tons per pile.

In order to determine the modulus of elasticity of the oak piles and thereby determine the fiber stress, the two piles were sawed off beneath the monolith, and blocks were tested in the compression machine in the Concrete Laboratory. The strain was determined by means of a compressometer as shown in Fig. 12. In Fig. 13 (*b*) is shown the derivation of the modulus of elasticity, which was determined as $\frac{432}{0.000230} = 1\,878\,260$, and in Fig. 13 (*a*), the fiber stress in bending for various loads as determined by the extensometer measurements both for the compression and tension side of the piles. It will be noted that the fiber stress in the compression side

was only about 60% of that in the tension side. This would seem to indicate that there was a tendency to pull the pile upward which partly counterbalanced the compression from bending in the compression side and increased the tension on the tension side. It is probable that the strain measured may have been affected by the fact that the plugs were inserted between the point of fixation of the head of the pile and the point of contraflexure. The data shown in Fig. 13 are based on observations repeated with great care and are believed to be essentially correct. Prior to the time that they were taken, however, Monolith No. 2 had been subjected to lateral loads from both directions during the tests outlined previously herein (under the heading "Sequence of Tests") with loads as great as 20 tons per pile. Under the maximum load of 20 tons, with the jack between Monoliths Nos. 2 and 3, Monolith No. 2 had received a permanent deflection, or set, of $\frac{5}{16}$ in. These data are included, therefore, only as an indication of the extreme fiber stresses created above the point of contraflexure, following a series of reversals of load.

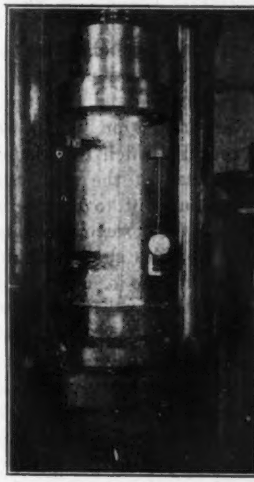

Fig. 12.—Determining Modulus of Elasticity of Oak Block Cut from Pile Beneath Test Monolith No. 2.

It is apparent that, although the observed fiber stresses under loads within the range normally used for design are quite low, and well within allowable working stresses, nevertheless a permanent deflection was produced by loads equal to or exceeding about 4 tons per pile. A possible explanation is that greater stresses may have been set up within the pile below

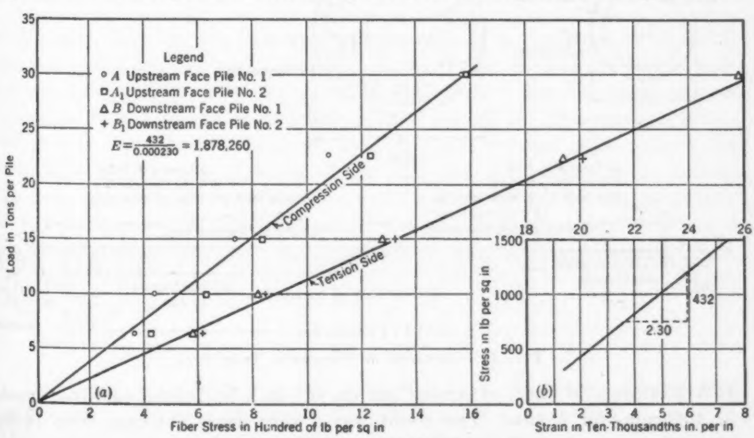

Fig. 13.—Fiber Stress Determination.

the point of contraflexure not only in bending but in direct tension as a result of an upward force tending to pull up the pile. The point at which the elastic limit is reached is somewhat conjectural, as lateral movement of the pile may be accompanied by a displacement of the sand which might fill the space left on the back side of the pile, thereby preventing its full return to its original position. An examination of these piles at the base of the concrete showed that under load the bond between the pile and the concrete was broken on the down-stream, or tension, side of the pile, forming a crack in which the blade of a pocket-knife could be inserted. Nevertheless, the head of the pile was still firmly held in the concrete. The sand was also dug out to the water-table beneath a part of Monoliths Nos. 5 and 6 after the foregoing tests. A careful examination of both concrete and timber piles showed no indication of distress, although these piles had been subjected to a lateral load of 30 tons per pile.

Plugs were then inserted, on 10-in. centers, in the up-stream and down-stream sides of one of the concrete piles, with the top plugs 8 in. below the base of the monolith. The jack was again set between these monoliths and observations were taken as before with an extensometer. Again, it was found that the observed strain on the down-stream or tension side exceeded that in the compression side. The resulting computed stress did not reach 600 lb. per sq in. until the load was increased to 28.5 tons per pile. The load was then increased to 40 tons per pile. Between 30 and 40 tons per pile several circumferential cracks developed in the concrete piles, but there was no indication of distress in the timber piles, all of which were of oak. The concrete piles, which were typical of the concrete foundation piles driven under the lock walls (see Fig. 14), were manufactured by spinning a very

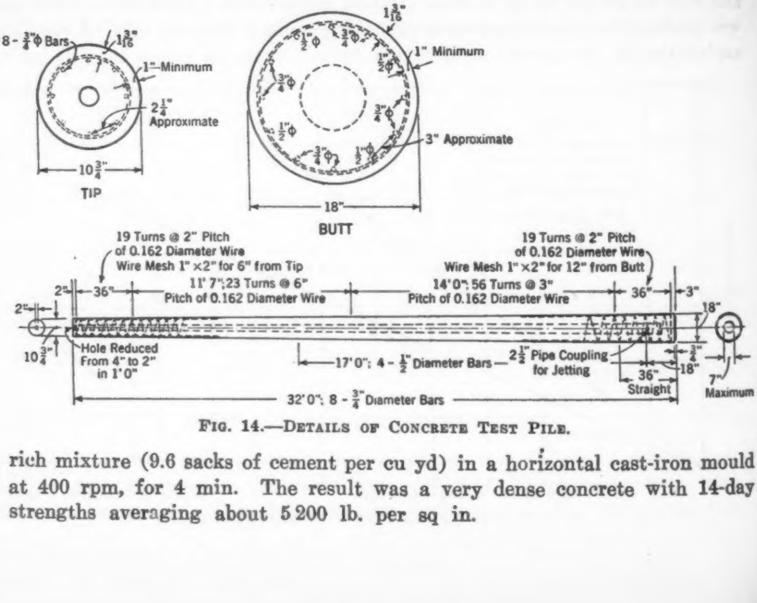

FIG. 14.—DETAILS OF CONCRETE TEST PILE.

rich mixture (9.6 sacks of cement per cu yd) in a horizontal cast-iron mould at 400 rpm, for 4 min. The result was a very dense concrete with 14-day strengths averaging about 5 200 lb. per sq in.

The movement of the monoliths was so rapid at the higher load that the resistance was insufficient to permit the building up of a load greater than 40 tons per pile. When the ram of the jack was fully extended, Monolith No. 6 had moved a total of 10 in. and Monolith No. 5, a total of 8 in., measured at a point 2 ft 3 in. below the top of the monoliths (see Fig. 15). In view of the tilting, the corresponding horizontal movement

FIG. 15.—TILTING OF TEST MONOLITHS NOS. 5 AT LEFT, AND NO. 6 AT RIGHT, UNDER LATERAL LOAD OF 40 TONS PER PILE, WITH RAM OF JACK FULLY EXTENDED.

of Monolith No. 6 at the base was approximately 6 in., and that of Monolith No. 5 about 5 in. This difference in movement of the two monoliths may be accounted for, at least partly, by the probability that the piles beneath Monoliths Nos. 1, 2, and 3, contributed resistance to the movement of Monolith No. 5. Under this maximum load the two concrete piles nearest the jack were pulled upward about 3 in., and the two timber piles nearest the jack, about 2 in., resulting in corresponding tilting of the monoliths. It was again observed that under load the bond between the pile-head and the concrete was broken on the tension side of the concrete and timber piles, forming a crack in which the blade of a knife could be inserted. Nevertheless, the piles were still firmly held in the concrete.

RESISTANCE OF SOIL RELATIVE TO THAT OF PILES

In Fig. 16 are shown four curves of deflection of concrete piles plotted against load. Curve A represents the deflection of a pile tested in the open while lying in a horizontal position on a testing rack with the fulcrum

at the mid-point and the load at the butt, but with the butt not fixed. Curve B is similar to Curve A, with the exception that the fulcrum is at the third point. The other two curves represent the deflection of piles driven in the foundation sand, one with head not fixed and the other with heads fixed in Test Monolith No. 6. All these piles were of the same size and were similarly reinforced. It will be noted, as might be expected, that the deflection at the yield point decreased quite rapidly as the moment arm was decreased.

When a load of approximately 30 tons per pile was being applied during the final test, it was found that a carpenter's rule could be inserted to a depth of 6 ft in the space between the pile and the adjacent foundation sand on the side of the hole nearest the jack. This would indicate that the moment arm on the pile was slightly more than 8 ft, as the sand had been excavated to a depth of 26 in. Probably the length of pile above the second point of contraflexure did not exceed about 10 ft, which is

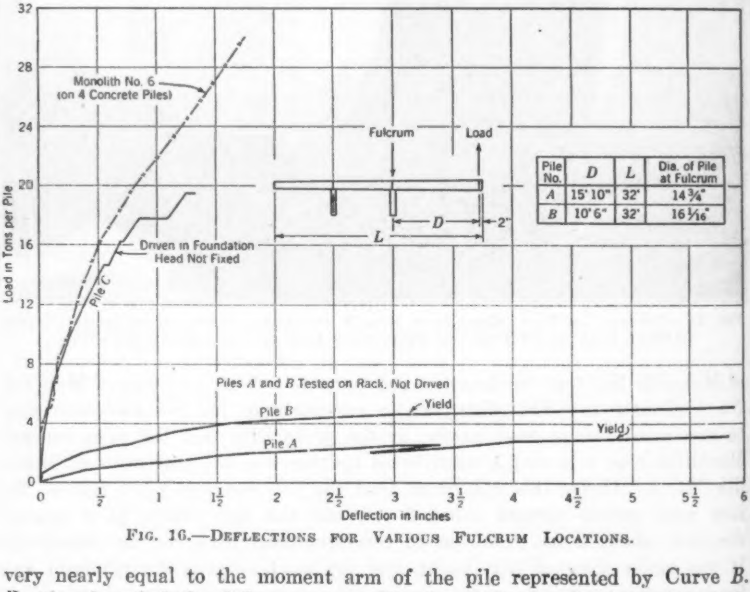

FIG. 16.—DEFLECTIONS FOR VARIOUS FULCRUM LOCATIONS.

very nearly equal to the moment arm of the pile represented by Curve B. Bearing in mind the difference in application of load and of fixation, it is noted nevertheless that loads producing any given deflection up to $1\frac{3}{4}$ in. in the pile represented by Curve B, were uniformly only about 14% of the loads required to produce corresponding deflections in the piles under Monolith No. 6. It appears, therefore, that by far the greater part of the resistance to lateral movement was supplied by the passive pressure of the soil than by the resistance of the pile itself. In view of the importance of limiting lateral movements in structures to a minimum, it is believed,

nevertheless, that the structural rigidity of the pile itself is of primary concern, especially for about 10 ft below the base of the concrete foundation, as the line of support of the soil lies several feet below the top of the soil.

Effect of Tests on Concrete in Monoliths

After completing all the tests a careful examination of all the monoliths failed to reveal a single crack in the concrete, with the exception of Monolith No. 5, in which diagonal cracks developed on one side near the base during application of the final load of 40 tons per pile. Incidentally, in order to determine (as a matter of interest) the resistance of the concrete to punching, the steel plate used throughout the tests to distribute the load from the jack, was removed after the lateral test between Monoliths Nos. 1 and 2 was completed. The load was again increased to 366 tons, with the 9-in. ram of the jack bearing directly on the concrete, thereby concentrating this load on an area of 63.6 sq in., or 11 500 lb per sq in., without giving any evidence of crushing the concrete.

Conclusions

It is recognized that conclusions of a general nature are warranted only by extensive and conclusive tests under a wide variety of conditions. The following conclusions, therefore, are confined to the soil conditions and piling arrangements under which the tests were made

(*a*) For structures built on timber piles in which lateral movement of not more than $\frac{1}{4}$ in. is allowable, a maximum lateral load of not more than 4 tons per pile should be allowed if the piles are subject to fatigue by frequent repetitions or reversals of load, or 4.5 tons per pile if the load is merely to be sustained;

(*b*) For structures built on timber piles in which a lateral movement of not more than $\frac{1}{2}$ in. is allowable, a maximum lateral load of not more than 6.5 tons per pile should be allowed if the piles are subject to fatigue by frequent repetitions or reversals of load, or 7.0 tons if the load is to be sustained;

(*c*) Walls supported by piles having adequate vertical bearing capacity, when subjected to lateral loads as great as 20 tons per pile, will remain vertical when moved in a horizontal direction;

(*d*) Fixing the heads of the piles is essential in order to determine, accurately, the movement of structures under lateral loads;

(*e*) Frequent repetition of lateral loads results in slightly greater lateral movement than a sustained load of the same magnitude;

(*f*) For lateral unit loads as great as about 6.5 tons per pile on a group of piles arranged in two rows, as under the test monoliths, the total resistance to movement increases in direct proportion to the number of piles. (As the unit lateral load increases above about 6.5 tons per pile, this no longer applies and the resistance per pile becomes less as the number of piles in the group increases); and

(*g*) The use of concrete piles of the type tested under Monolith No. 6, will permit increasing the designed lateral loads given in Conclusions (*a*) and (*b*) by from 1 ton to 2 tons per pile.

Acknowledgments

The tests herein described were made in connection with the construction by the United States Government of the Twin Locks of Lock and Dam No. 26, which were designed under the supervision of W. H. McAlpine, M. Am. Soc. C. E. The construction work is under the supervision of Captain B. M. Harloe, Corps of Engineers, U. S. Army, District Engineer, St. Louis District, with Captain W. W. Wanamaker, Corps of Engineers, U. S. Army, Military Assistant, in local charge.

The writer wishes to acknowledge the able assistance of Messrs. C. E. Wuerpel, Assistant Engineer, and G. A. Allen, Junior Engineer, in making the field observations and assembling data, and of J. A. Adams, Associate Engineer, in preparing the illustrations accompanying this paper. Acknowledgment is especially made of the helpful suggestions of Captain Wanamaker, who conceived the idea of making the tests. The test monoliths were constructed and the tests were performed by Bruce Gordon, Superintendent for the John Griffiths and Son Company, General Contractor for the construction of the Twin Locks.

DISCUSSION

A. E. CUMMINGS,[2] M. AM. SOC. C. E. (by letter).—A considerable store of valuable information on the lateral deflection of foundation piles is contained in this paper. The writer is fortunate in having had a number of opportunities to discuss these tests with the author and the method of analysis herein proposed was developed for the particular purpose of attempting to check, theoretically, the experimental data presented.

The assumption is made that the upper end of the pile is embedded deeply enough in the foundation to be fixed against rotation. It is also assumed that the lower part of the pile is fixed and that some unknown length, L, of the upper part is bent into a deflection curve as shown in Fig. 17(a). The

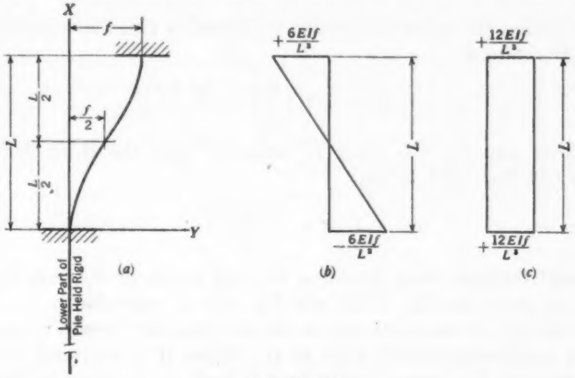

FIG. 17.

positive directions of the co-ordinate axes are taken as shown and the point of reverse curvature is assumed to be at a distance of $\frac{1}{2}$ L from the top, at which point the deflection is one-half the total deflection, f.

The pile is considered first as a free standing column and the surrounding soil is ignored temporarily. It is assumed that the equation of the central line of the deflected pile can be expressed by the power series[3]:

$$y = a_1 \left(\frac{x}{L}\right)^2 + a_2 \left(\frac{x}{L}\right)^3 + a_3 \left(\frac{x}{L}\right)^4 \dots\dots\dots\dots\dots (1)$$

It is then necessary to determine the coefficients of the series in such a way that the boundary conditions of the problem will be satisfied and the resulting equation will represent the elastic curve of the deflected pile. The assumptions as to the shape of the deflection curve furnish the following boundary conditions, from which these coefficients are determined: (1) Since the deflection curve is to have a vertical tangent at the top and at the bottom, the first derivative of Equation (1) is zero at $x = 0$ and at $x = L$; (2) since the point

[2] Dist. Mgr., Raymond Concrete Pile Co., Chicago, Ill.

[3] "Drang und Zwang", von Föppl, Vol. 2, p. 312.

of inflection is to be at the middle of the deformed part of the pile the second derivative of Equation (1) is zero at $x = \frac{L}{2}$; and (3) the deflection is f at $x = L$. These three sets of boundary conditions serve to establish the equation:

$$y = \frac{3\,f\,x^2}{L^2} - \frac{2\,f\,x^3}{L^3} \quad \text{.......................(2)}$$

which is the equation of the deflection curve of the bent pile.

Equation (2) is then differentiated, successively, three times. By using the differential equation of the elastic curve of a bent beam:

$$E\,I\,\frac{d^2y}{dx^2} = -\,M \quad \text{.......................(3)}$$

and substituting the second derivative of Equation (2), the following moment equation is obtained:

$$-\,M_f = E\,I\left(\frac{6\,f}{L^2} - \frac{12\,f\,x}{L^3}\right) \quad \text{...................(4)}$$

In a similar manner, the shear is obtained from the third derivative of Equation (2), the result being,

$$V = +\,\frac{12\,E\,I\,f}{L^3} \quad \text{.......................(5)}$$

The moment diagram from Equation (4) and the shear diagram from Equation (5) are shown in Fig. 17(*b*) and Fig. 17(*c*), respectively.

When the pile stands vertically in the soil, the earth pressures are approximately in equilibrium on all sides of it. When it is subjected to the horizontal deflection, f, a certain earth load is built up in front of the pile due to the passive resistance of the soil. It will be assumed that this earth load at any point is equal to the deflection times the elastic modulus of the soil. It will also be assumed that the elastic modulus of the sand increases directly with the depth.[4] With the positive directions of the co-ordinate axes chosen as shown in Fig. 18, the equation of the elastic modulus of the soil may be written:

$$E_s = \frac{U\,(L - x)}{\omega} \quad \text{.........(6)}$$

in which U = the weight per unit volume of soil and ω = a dimensionless coefficient determined by the elastic property of the soil.

The unit earth pressure on the front side of the deflected part of the pile is then given by,

$$p = E_s\,y \quad \text{.............(7)}$$

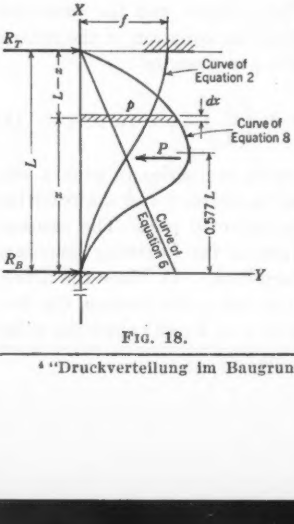

FIG. 18.

[4] "Druckverteilung im Baugrunde", von O. K. Froehlich, p. 89.

in which y is the deflection curve of Equation (2) and the assumption is made that the shape of this curve is not materially changed by the earth load. This unit pressure is:

$$p = \frac{U(L-x)}{\omega}\left[\frac{3fx^2}{L^2} - \frac{2fx^3}{L^3}\right] \qquad (8)$$

The total earth load is, then,

$$P = \int_0^L p\,dx = \frac{Uf}{\omega}\int_0^L \left[\frac{3x^2}{L} - \frac{5x^3}{L^2} + \frac{2x^4}{L^3}\right]dx \qquad (9)$$

which when integrated, gives,

$$P = \frac{3}{20}\,\frac{UfL^2}{\omega} \qquad (10)$$

The earth pressure curve in Fig. 18 is given by Equation (8). The point of maximum earth pressure can be found by differentiating Equation (8) with respect to x; setting this derivative equal to zero; and then solving for x. The maximum is slightly above the center (see Fig. 18).

The earth-load reactions are computed by taking moments about the top and bottom points of the deflected part of the pile. Referring to Fig. 18, the reaction at the top is:

$$R_T = \int_0^L \left(\frac{x}{L}\right) p\,dx = \frac{Uf}{\omega}\int_0^L \left[\frac{3x^3}{L^2} - \frac{5x^4}{L^3} + \frac{2x^5}{L^4}\right]dx \qquad (11)$$

or,

$$R_T = \frac{1}{12}\,\frac{UfL^2}{\omega} \qquad (12)$$

The reaction at the bottom is:

$$R_B = \int_0^L \frac{(L-x)}{L}\,p\,dx = \frac{Uf}{\omega}\int_0^L \left[\frac{3x^2}{L} - \frac{8x^3}{L^2} + \frac{7x^4}{L^3} - \frac{2x^5}{L^4}\right]dx \qquad (13)$$

or,

$$R_B = \frac{1}{15}\,\frac{UfL^2}{\omega} \qquad (14)$$

The sum of these two reactions is equal to the total earth load as given by Equation (10).

To calculate the bending moments and deflections caused by the earth load, use will be made of the method of super-position.[5] Referring to Fig. 19(a), the moment due to the couple at the top is:

$$M_T = \int_0^L p\,dx\,\frac{x^2(L-x)}{L^2} \qquad (15)$$

[5] "Strength of Materials", by S. Timoshenko, Vol. 1, p. 209.

Substituting the value of p from Equation (8) and integrating gives,

$$M_T = \frac{1}{60} \frac{U f L^3}{\omega} \qquad (16)$$

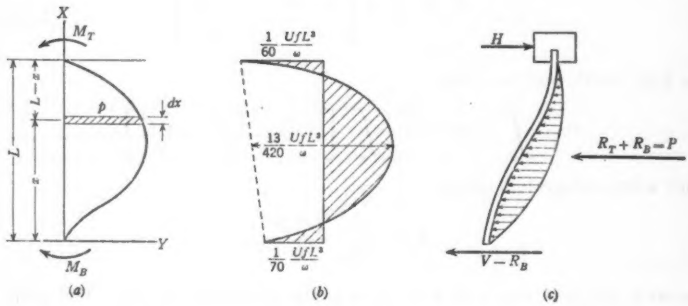

FIG. 19.

The moment due to the couple at the bottom is:

$$M_B = \int_0^L p \, dx \, \frac{x (L - x)^2}{L^2} \qquad (17)$$

Substituting the value of p and integrating gives:

$$M_B = \frac{1}{70} \frac{U f L^3}{\omega} \qquad (18)$$

The moment produced by the distributed earth load when the pile is considered as a simple beam is,

$$M_S = \int_0^L p \, dx \, \frac{x (L - x)}{L} \qquad (19)$$

Substituting for p and integrating,

$$M_S = \frac{13}{420} \frac{U f L^3}{\omega} \qquad (20)$$

Combining the moment diagram from Equation (20) with the diagram from the two end couples, produces the combined moment diagram shown in Fig. 19(b).

In computing the deflections due to the earth load, it will be assumed that the maximum deflection occurs at the center of the span although as has already been shown the earth load is not quite symmetrical. The equation[6] of the deflection curve due to the couples at the ends is,

$$\Delta_c = \frac{M_T (x) (L^2 - x^2)}{6 E I L} + \frac{M_B (L - x) (2 L x - x^2)}{6 E I L} \qquad (21)$$

[6] "Strength of Materials", by S. Timoshenko, Vol. 1, p. 168.

Substituting $x = \frac{L}{2}$ and the values of M_T and M_B from Equations (16) and (18) gives, at $x = \frac{L}{2}$:

$$\Delta_c = \frac{13}{6\,720} \frac{U f L^5}{E I \omega} \quad \text{.......................(22)}$$

The deflection[7] at the center of the span due to the distributed earth load and considering the pile as a simple beam, for $x = \frac{L}{2}$, is:

$$\Delta_S = 2 \int_0^{\frac{L}{2}} p\, dx \frac{x}{48\, E I} (3\, L^2 - 4\, x^2) \quad \text{..............(23)}$$

Substituting the value of p from Equation (8) and integrating $\left(\text{for } x = \frac{L}{2}\right)$:

$$\Delta_S = \frac{89}{43\,008} \frac{U f L^5}{E I \omega} \quad \text{.......................(24)}$$

It should be noted that these deflections are in opposite directions and that they are approximately equal since the numerical coefficient of Equation (22) is 0.00193, whereas that of Equation (24) is 0.00207.

One of the quantities measured in the experiments was the jack load. This is an external horizontal force applied near the top of the pile, and it is resisted partly by shear in the pile itself and partly by the earth load built up in front of the pile. Referring to Fig. 19(*c*), the equilibrium condition for the horizontal forces is,

$$H = (V - R_B) + (R_T + R_B) = V + R_T \quad \text{...........(25)}$$

Substituting Equations (5) and (12) into Equation (25) gives:

$$H = \frac{12\, E I f}{L^3} + \frac{1}{12} \frac{U f L^2}{\omega} \quad \text{....................(26)}$$

Equation (26) indicates that the deflection is a linear function of the external load so that the work done during deflection may be expressed by,

$$W = \frac{H f}{2} \quad \text{.........................(27)}$$

Substituting Equation (26) into Equation (27) gives:

$$W = \frac{6\, E I f^2}{L^3} + \frac{1}{24} \frac{U f^2 L^2}{\omega} \quad \text{..................(28)}$$

The assumption is then made that during deflection the pile follows the principle of least action and that the bent length, L, adjusts itself so as to make the total work of deformation a minimum. Differentiating Equation (28) with respect to L:

$$\frac{\partial W}{\partial L} = -\frac{18\, E I f^2}{L^4} + \frac{1}{12} \frac{U f^2 L}{\omega} \quad \text{...............(29)}$$

[7] "Strength of Materials", by S. Timoshenko, Vol. 1, p. 164.

The condition for a minimum is,

$$-\frac{18\,E\,I\,f^2}{L^4} + \frac{1}{12}\,\frac{U\,f^2\,L}{\omega} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (30)$$

Solving for L gives:

$$L = \sqrt[5]{\frac{216\,E\,I\,\omega}{U}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

This is a minimum since the second derivative of Equation (28) with respect to L is positive.

The foregoing theoretical equations will be used to check some of the test results on Monoliths Nos. 2, 3, and 5, of Mr. Feagin's paper. These monoliths contained only wood piles, for which a Young's modulus was determined and for which the moment of inertia can easily be computed. The average diameter at a point 5 ft below the heads of all the piles in these three monoliths is found to be 12.077 in., or 1.0064 ft. The moment of inertia of a circular area of this diameter is 0.0503 $ft.^4$ The Young modulus of one of the wood piles was determined as 1 878 260 lb per sq in., or 270 469 440 lb per sq ft. The average weight of the sand on this site is 112.5 lb per cu ft, dry. The percentage of voids varies from 30 to 37 so that in a thoroughly saturated state the sand surrounding these piles weighs about 133 lb per cu ft. This is a very dense sand[8] and the dimensionless coefficient, ω, will be taken as 0.005.

Using these numerical values in Equation (31), the calculated length of the deformed part of the pile is 10.2 ft. With this value of L and with the same values of E, I, U, and ω, a series of calculations was made with Equa-

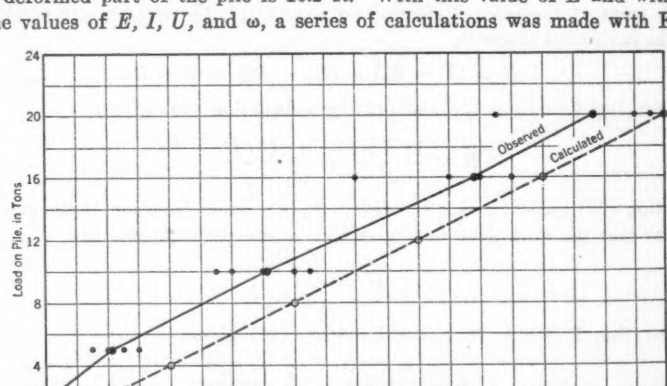

FIG. 20.

tion (26). For loads of 4, 8, 12, 16, and 20 tons per pile, the theoretical deflections were computed and the results are plotted as a dotted line in Fig. 20. The observed load-deflection curve (which is the average of the

[8] "Erdbaumechanik", by Charles Terzaghi, M. Am. Soc. C. E., pp. 11-12, and Table 24, p. 92.

data for Monoliths Nos. 2, 3, and 5, taken from Table 3) is plotted on the same diagram. It is seen that the computed curve falls somewhat below the observed curve, but, in general, the variations between the two are no greater than those among the observations themselves. The computed curve is on the safe side. In two other ways there are indications of agreement between observation and theory. Mr. Feagin mentions a measurement of the deformed length of one of the piles and reports this as about 10 ft, although the measurement was made on a concrete pile. He also mentions the fact that the earth in front of the pile provided the greater proportion of the resistance against deflection, which conclusion is checked by Equation (26).

Fig. 21(a) shows a combined moment diagram at a load of 16 tons per pile, which corresponds to a theoretical deflection of 1 in., the values of

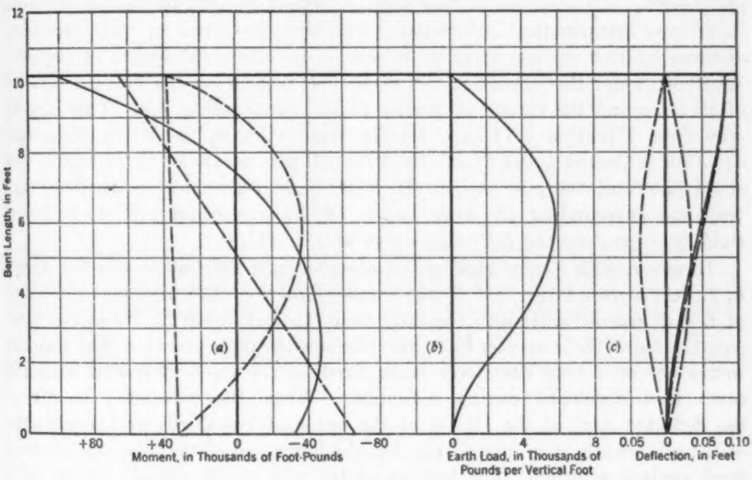

FIG. 21.

L, E, I, U, and ω being the same as before. Fig. 21(b) is an earth-load diagram for the same numerical values, and Fig. 21(c) is a combined deflection diagram for the same conditions, the solid line representing the final deflection.

In any analysis of this kind it is necessary to make some assumptions. The analysis having been completed and having been applied to experimental data it is usually desirable to reconsider the basic assumptions. Stated in general terms, this problem may be said to involve the determination of the stresses and deflections of an elastic rod of relatively high flexural rigidity submerged vertically in a more or less elastic medium of relatively low elastic resistance, the rod being moved horizontally at the top but fixed against rotation at that point so that the tangent to the elastic curve remains vertical at the surface. This general statement involves no assumptions, but

it contains only one boundary condition which is the requirement that the tangent to the elastic curve shall remain vertical at the surface. This is the only known boundary condition of the problem and in order to develop any kind of analysis it is necessary to begin by making assumptions.

It is sometimes assumed[9] that a pile embedded in the ground and subjected to a horizontal force at the top, will pivot about a point somewhere down in the ground. The movement of the pile is approximately a rotation as a rigid body; but it would appear that this could not happen in the case of the monoliths described by Mr. Feagin because of the fixed-end condition at the top. The assumption can be made that the elastic curve is a wavy line of gradually diminishing amplitude similar to a damped vibration curve. This involves further assumptions as to the rate at which the amplitude is damped out and the number of wave lengths that shall be included in the pile length. An analysis of this kind is almost certain to become involved in serious mathematical difficulties. The analysis given in this discussion assumes fixation against rotation at some point along the length of the pile. Whether or not this condition can occur will depend on the flexural rigidity of the pile and the elastic properties of the surrounding soil. This can be seen from Equation (31) and, for the wood piles in the Alton tests, this equation indicated a length of the deflected part of about 10 ft, which was about one-third the pile length. It would seem reasonable to conclude that the sand surrounding the lower 20 ft of the pile could provide sufficient rigidity to produce the deflection curve of Fig. 21(*c*).

However, with a very rigid pile embedded in a soft loose soil—for which E, I, and ω were large, and U was small—Equation (31) might give a value of L that was as great as, or greater than, the pile length. When the computed value of L is greater than the pile length, it is probable that the pile would act as a long cantilever beam fixed at the top and loaded with the earth load developed during deflection. When the calculated length of the deflected part of the pile is of the order of two-thirds or three-fourths of the pile length, it is improbable that the lower end of the pile could remain fixed against rotation. The bottom of the pile would probably move in a direction opposite to that of the deflection at the surface. In either case it would be necessary to revise the fixed-end assumption and to repeat the analysis with some other assumed deflection curve.

It should be noted that Equation (31) provides a means of determining whether or not the fixed-end assumption is justified. It should also be noted that this equation does not contain the deflection, but it should not be concluded from this that the bent length is independent of the deflection. Equation (31) is a combination of Equations (5) and (12). Equation (5) is based on the usual theory of elastic structures in which the displacements are required to be very small in comparison with the dimensions of the structure. Equation (12) is based on similar assumptions. Equation (31), therefore, applies only to small deflections even if the deflection itself does not appear in the equation.

[9] *Civil Engineering*, December, 1934, p. 622.

In order to determine the relative behavior of rods of different flexural rigidities embedded in a granular material, a simple experiment was performed on a small scale. The results are shown in Figs. 22 and 23. Three

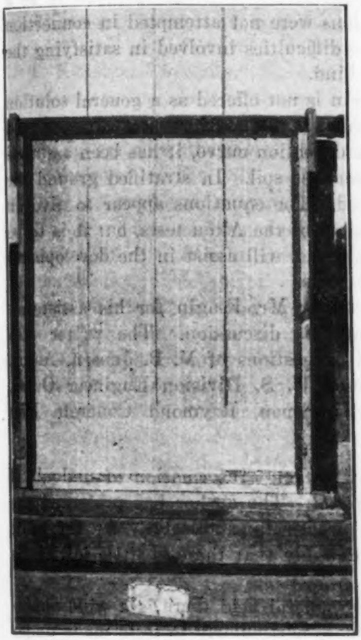

FIG. 22.

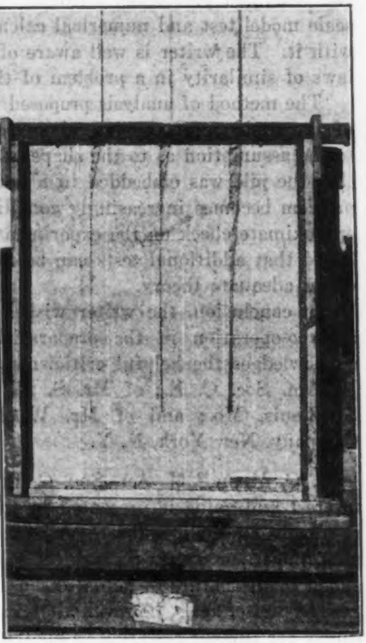

FIG. 23.

steel rods were placed in a vertical position inside the glass front of the box and dry sawdust was then poured in and tamped lightly. The sizes of the rods, from left to right, were $\frac{3}{32}$ in. round, $\frac{1}{8}$ in. square, and $\frac{1}{4}$ in. square. The upper ends of the rods were fixed against rotation by being clamped between two notched steel bars, and vertical lines were marked on the glass for comparison as shown in Fig. 22.

The steel bars holding the upper ends of the rods were then moved slowly about 1 in. to the right with the results shown in Fig. 23. This was an excessive deflection but it was used in order to produce sufficient movement to photograph. Each rod deflected in a reverse curve and the horizontal lines on the glass mark the bottoms of these curves. The smallest rod had a very short deflection curve, and there was no apparent lateral movement of the lower part of the rod. The middle rod had a longer deflection curve and just below the curve there was a slight movement of the rod toward the left. This movement was very small in comparison with the deflection at the top and it did not become apparent until the top deflection was nearly an inch. The deflection curve of the largest rod amounted to almost three-fourths

of the embedded length of the rod. The lower part of the rod was incapable of maintaining its vertical position and the bottom of the rod moved about $\frac{1}{4}$ in. to the left. As nearly as could be determined the lower part of the rod remained practically straight. This experiment is not intended to be a scale model test and numerical calculations were not attempted in connection with it. The writer is well aware of the difficulties involved in satisfying the laws of similarity in a problem of this kind.

The method of analysis proposed herein is not offered as a general solution of the problem of the lateral deflection of a foundation pile. In addition to the assumption as to the shape of the deflection curve, it has been assumed that the pile was embedded in a homogeneous soil. In stratified ground the problem becomes increasingly complicated. The equations appear to give an approximate check on the experimental data of the Alton tests, but it is to be hoped that additional tests can be made which will assist in the development of an adequate theory.

In conclusion, the writer wishes to thank Mr. Feagin for his assistance and co-operation in the preparation of this discussion. The writer also acknowledges the helpful criticisms and suggestions of V. P. Jensen, Assoc. M. Am. Soc. C. E.; of Mr. S. M. Gleser, U. S. Division Engineer Office, St. Louis, Mo.; and of Mr. W. P. Kinneman, Raymond Concrete Pile Company, New York, N. Y.

J. C. Meem,[10] M. Am. Soc. C. E. (by letter).—Information of undoubted interest and value is presented in this paper. The author has presented the results in such a way as to make them practically applicable. As far as it goes, the paper covers the subject so thoroughly that there is little left to be added in the nature of actual discussion.

The writer feels, however, that in this general field there is a wide opportunity for further research, as applying more particularly to tests made under otherwise similar conditions on piles or foundations that bear on widely varying types of soils, such as clay, loam, sand, gravel, etc. For instance, in his preliminary paragraph of conclusions, the author states: "* * *. The following conclusions, therefore, are confined to the soil conditions and piling arrangements under which the tests were made."

Wherever it is possible to do so, measurements should be made and tabulated of lateral thrust against structures and of resistance to such thrust under conditions similar to those noted. After all, the resistance of the soil to lateral thrust is only secondary in a minor degree, if at all, to that of the pile or structure itself, and conditions exist, or may readily be conceived, in which the instability of the soil is such that tie-backs or lateral bracing must be introduced.

A case in point, which is of paramount interest, is that in which a monolithic concrete pier of a bridge at Grand Coulee Dam, in Washington, was tilted by movement of the glacial drift surrounding it. This movement[11] was such that it reached a maximum of 9 in. at the top, approximately 150 ft above the base.

[10] Cons. Engr., Brooklyn, N. Y. Mr. Meem died June 24, 1936.
[11] *Engineering News-Record*, November 7, 1935.

Such glacial movement could only occur in soils having a predominating clay or equivalent content. It illustrates, however, the necessity for a full understanding of soil conditions where the structure is subject to lateral stresses and, more particularly, where there is a possibility that future operations may tend to change the status of the existing conditions.

T. KENNARD THOMSON,[12] M. AM. SOC. C. E. (by letter).—Experiments are always interesting, but care must be exercised against drawing unwarranted conclusions, especially in subsoils where borings may be inadequate. The author is very wise, therefore, in stating that: "In view of the fact that these tests were conducted in only one type of soil, and in view of the many variables involved, no mathematical analysis is included."

The writer has read many papers supported by beautifully drawn diagrams showing uniform curves of underground pressure, in which regularity might be imagined, but probably never exists. In the sense that no two blades of grass are identical, probably no two cubic feet of subsoil are identical either; conditions created by the material, the pressure exerted by Nature in compacting the mass, variations in the ground-water level, the roots of trees, boulders, etc., are probably different in each case.

Such uniform or symmetrical lines of pressure might possibly occur in man-made piles of sand—but never in foundations on original subsoil.

Many years ago, the writer received a letter from an architect about 300 miles away, containing a long and apparently full description of a proposed foundation, and was asked to telegraph his fee for giving his opinion as to the safe load per square foot permissible to be placed on the foundations. The proposition seemed so plain and simple that the writer was almost misled by it, but suddenly changed his mind and telegraphed that he would not give such an opinion without first examining the site. The architect made no reply, but some time afterward the writer, by mere chance, heard that the "proposed" building had been constructed in another city and had collapsed before the architect had tried to secure the writer's endorsement.

The only time that one can feel really sure about stresses underground is when they are purely hydrostatic—and even then the surrounding conditions must be understood thoroughly. In pneumatic caisson work for buildings in Manhattan, the writer has seldom noticed the air pressure to vary more than a few pounds from the theoretical head, with no allowance for weight of soil, adjoining buildings, etc.; but the horizontal Hudson River Tunnels are different, probably due to the great speed of construction as well as to the closed shields, where sometimes only one-half the anticipated air pressure is required. Slow progress would probably greatly increase the amount of air pressure involved in any case by giving the water above a chance to circulate.

The proportions of sand, clay, boulders, etc., vary in every location even a few feet apart. Sometimes, the engineer finds more than a dozen distinct layers, with different colors of sand and clay in a single vertical foot.

Clay, dry or mixed with sand, boulders, etc., often makes a natural concrete so compact that deep excavations may be made without any side

[12] Cons. Engr., New York, N. Y.

pressures, and, consequently, without sheathing or shoring, but a small quantity of clay in sand under water, often makes the entire mass slide with disastrous results. The author's experiments apply the tests at or near the tops of the piles; but, in actual work, the stresses might occur near the bottom of the piles, or anywhere between the bottom and top, due to quicksand or wet clay in the subsoil stratification.

Some of the reasons for observing the locations (not always made clear in the reports of borings) are to determine the location and character of any adjoining buildings, rivers, lakes, etc., and the heights and character of any adjacent hills. The borings themselves should give the ground-water level and whether or not it varies. Of course, "core" borings are more definite than auger or "wash" borings but in some cases where the engineer knows, the subsoil conditions at the particular site—"core" borings would simply be a waste of money.

Some years ago, about 12 acres of land dropped 20 ft, sliding down hill and carrying buildings, a 200-ft chimney, etc., with it in a few seconds. A geologist from the South and another from the North had each made twenty-five auger borings, and then the writer was consulted. As he could not find the cause from the borings, he decided to sink a 4-ft shaft, which penetrated good compact material for a depth of about 30 ft. At that depth, a stratum of very sloppy clay, almost soup, was encountered, which explained everything. The site of the factory was surrounded on two or three sides by high hills, and above the factory was a fair-sized lake.

There had recently been a very rainy season and some of the rain had found its way to the clay stratum, which was at the level of the creek at the foot of the slope. The slide resulted, moving the creek itself about 20 or 30 ft. The first day the writer saw the site he advised draining the lake (which was above the most important building left standing) and this was done at once. It had been claimed that a pile of broken stone, covering a comparatively small area was responsible for the damage; but the broken stone did not weigh 1 ton per sq ft on the small area it covered. Furthermore, a section of virgin forest near-by had also sunk.

That stresses may occur at any point along the entire length of a pile is demonstrated by still another case. A railroad company had constructed a high earth-fill leaving an opening for an existing railroad at right angles to its line. This opening was provided for by driving 1 600 wood piles, on top of which were built two side walls, $8\frac{1}{2}$ ft thick, of concrete. These side walls were 33 ft apart and connected at the top by a concrete arch, supporting the new fill, but had no connection at the bottom above the wooden platform on the piles.

When the writer examined the site he found the concrete abutments badly shattered, having moved horizontally 10 ft at one end and 3 ft at the other. The elevation of the original ground was about 1 300 ft above sea level, and the hills near-by were about 700 ft higher.

It was obvious that the water must have found its way from these hills to a clay or quicksand stratum at a level somewhere above the bottom of the foundation piles. In this case the piles may have weakened instead

of strengthened the structure. If a circular concrete tunnel had been constructed in the first place, it would not have required as much material as was actually used in the abutments or side walls, and could not have collapsed. It might even have stood without any pile foundation.

As each site requires a special study, an unlimited number of examples might be quoted.

August E. Niederhoff,[13] Jun. Am. Soc. C. E. (by letter).—The lateral pile-loading tests in this paper shed additional light on a subject that has long been obscure. Mr. Feagin's excellent record of the test data and the evident care and methodical procedure in gathering and presenting the information deserve commendation from the profession. It is noted that he is careful to state the limitations under which his findings were obtained, and invites discussion that will contribute to the general store of information on this subject.

Early in the period for designing locks and dams on the Upper Mississippi River, it was realized that specific knowledge of the resistance of round, wood, bearing piles to lateral loads was necessary. The design of these structures was based upon the assumption that all vertical loads were to be transmitted to the sub-strata by piles, leaving nothing for surface soil bearing, and it was believed to be just as logical an assumption to resist all lateral loads by piles and to omit all frictional resistance between the bottom of the structure and the ground surface. The design analysis, therefore, had to be based upon a certain allowable value and to arrive at this value a series of tests were inaugurated about December 19, 1933, at the proposed site of Lock No. 3 on the Mississippi River, immediately up stream from Red Wing, Minn.

This site was chosen for conducting the tests because borings indicated that soil conditions for a foundation were less desirable than at other Mississippi River lock and dam sites within the St. Paul (Minn.) District Office of the U. S. Corps of Engineers. A boring made where the tests were conducted is shown in Fig. 24. Both piles subjected to lateral loads were of red oak, 30 ft long, and with the tip diameters about 7 in. and 8 in., respectively, and ground-line diameters of about 12 in. each. The piles were driven about 28 ft through a mixture of silt and clay with a 3 000-lb steam hammer with a 33-in. stroke under 110-lb steam pressure. Allowing a penetration of 0.63 and 1.35 in. under the last blow, the indicated bearing capacity by the *Engineering News* formula for Pile No. 2 was 10 tons and for Pile No. 6, 5 tons. This indicated bearing value is given only to show that the soil was not very compact. Some idea of the surface material can be obtained from the information that a man rolled up his sleeve and stuck his arm into the mud alongside one of the driven piles until it came above his elbow.

The equipment for the tests is shown in Fig. 25. The arrangement for testing Pile No. 1 at the upper end of the framework is shown in the plan view. Section *A–A* indicates the cable arrangement about the test pile. A load applied to the test pile by exerting a pull with a ratchet, *R*, at the other end of the lever beam, *A*, was measured on the 5 000-lb dynamometer to the

[13] With Hydr. Eng. Dept., Aluminum Co. of America, Pittsburgh, Pa.

left of, and attached to, the anchor pile, X. The lever beam, A, was pivoted on a case-hardened steel fulcrum supported by a frame work of 12 by 12-in. timbers. When sufficient load was applied by Ratchet R, the top of Test Pile

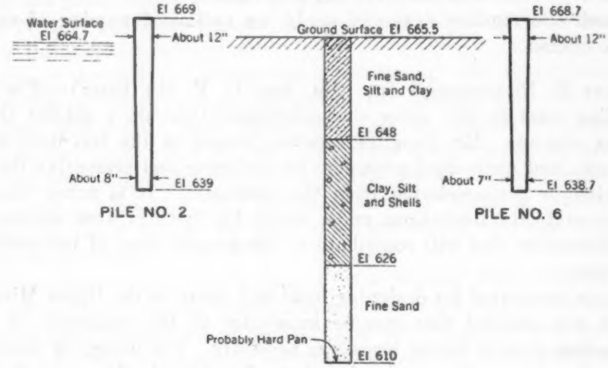

FIG. 24.

No. 1 assumed an inclined position that was registered by an originally vertical flag attached firmly to the test specimen. To simulate the restraining action of the pile-butt embedded in concrete masonry, the flag was returned to a vertical position by pulling with Ratchet S. Transits checked the movement of the test specimen and kept the flag in a vertical position. The actual load on the pile, of course, was the difference in the readings of the two dynamometers on either side of the anchor pile, X, corrected by the ratio of the lever arms of Beams A and B. If the 5 000-lb gauge had been used to capacity, the maximum moment in Beams A and B, Fig. 25, would have been 1 620 000 in-lb and the extreme fiber stress, 27 500 lb per sq in., but because very few stiffeners had been provided the two beams showed a tendency toward diagonal buckling before they could be stressed to these values.

The nature of the equipment, therefore, limited the load that could be applied to the test specimen to 18 kips. Prior to running the tests, the soil around the test specimens had been frozen to a depth of approximately 6 in. When testing Piles Nos. 2 and 6, this frozen ground was removed from around the pile for a distance of 4 in. It was believed that the remaining frozen ground would prevent the surrounding soil from bulging during the tests just as effectively as a concrete footing would act in preventing soil bulge. To obtain some idea of the effect of frozen soil on the resistance of a vertical pile to lateral loads, Pile No. 1 was tested to the limit of the apparatus.

From the arrangement shown in Fig. 25 it was possible to measure three factors entering into the analyses of a vertical pile subjected to a lateral load. The deflection at the ground surface was measured to the nearest 0.02 in.; the applied load causing the deflection was measured on dynamometers graduated to 100 lb; and the moment in the pile produced by the arrangement of the two cables that simulated the restraining action of embedment of the butt in

masonry was measured by the known force exerted by each cable and the measured moment arm between the cable attachments on the test specimen. The recorded observations and the computed moment in the pile are presented in Table 4. A load of 17 kips was applied on Pile No. 6 (see Table

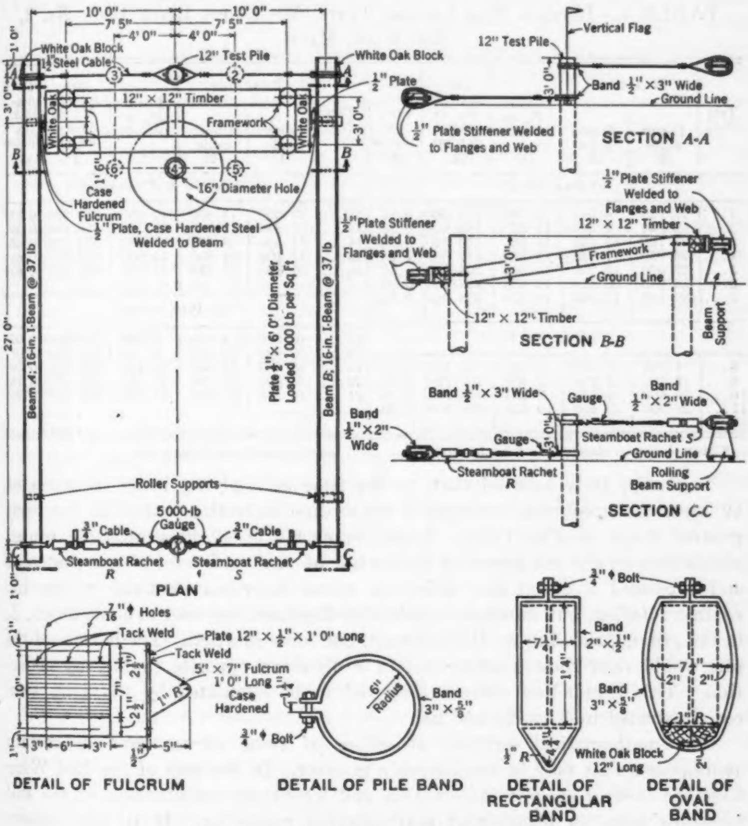

FIG. 25.—ARRANGEMENT FOR PILE TESTS.

4(b)) for a sustained 5-min interval. The pile continued to move under the influence of this load, thus substantiating the theory of plastic flow of the foundation soil.

Comparing the results of the Red Wing tests with the Alton, Ill., tests, it should be kept in mind that the former did not evaluate the effect of a lateral load applied to a group of piles. Recognizing this, it is remarkable that at Alton the maximum deflection of $\frac{9}{32}$ in. of a monolith when stressed to a lateral load per pile of 6.5 tons is comparable with the deflection of 0.28 and 0.39 in., respectively, of the piles at Red Wing when subjected to approxi-

mately an equivalent load. Among other considerations not evaluated by the Red Wing tests were: (*a*) The effect of confining soil around the pile in preventing or restraining plastic flow of foundation material; and (*b*) the effect of vertical load applied in conjunction with the lateral load.

* 24-in. between clamps. † 5-min. intervals. ‡ Load released and re-applied.

Logically, it is believed that, to the time of applying loads in excess of 12 kips, the specimens assumed a center-line deflection curve of the same general shape as Fig. 17(*a*). Loads in excess of 12 kips probably caused plastic flow of the soil governed by the law of viscous flow in plastic materials and produced a center-line deflection curve described as fixed at the top against rotation, but showing considerable displacement, and at some depth, *L*, in the ground, showing no displacement, but some rotation. The bottom of the pile would then show a movement in a direction opposite to the top deflection. This center-line curve is believed to be simulated by the $\frac{1}{4}$-in. steel rod illustrated in Figs. 22 and 23.

The mathematical analysis of either of these curves involves certain assumptions that may be considerably in error. In the case of the Red Wing tests the lack of specific information and laboratory examination of the soil forestalls even an attempt at mathematical reasoning. If it were known definitely just what the volume change of the soil would be when subjected to increased pressure and the permeability and cohesion of the foundation material, a satisfactory attempt at induction might be tried, based primarily on soil mechanics.

On the basis of the Red Wing tests the District Engineer, at St. Paul, concluded that lateral load resistance of vertical round, wood piles is determined to a great extent by the nature and characteristics of the soil rather than by the flexural rigidity of the pile itself. There are certain limitations to this statement, of course, but for round, wood piles longer than 30 ft and with butt and tip dimensions in accordance with the standards specified in

the A. S. T. M. specifications, the foregoing statement is believed to be valid. The extreme fiber stress on the pile that carried a maximum moment was 2 417 lb per sq in., and there was no apparent distress in the fibers. In making comparisons between the results of the tests and the behavior of actual vertical pile foundations when subjected to lateral loads, it might be mentioned that a lateral movement of a lock-wall occurred at Lock No. 5*A* on the Mississippi River when the computed horizontal load per round, wood pile did not exceed 3.5 tons. This lock-wall movement was approximately 9 in. in a foundation soil composed principally of sand with a thin clay stratum lying at considerable depth below the structure. It is believed that the combined effect of slippery clay and pile-driving in the vicinity of the wall produced this extraordinary lateral movement. The arresting fact is that construction conditions and the hydrostatic head that helped to move the wall at Lock No. 5*A* had been previously duplicated (although perhaps not quite so severely) at Lock No. 5. These conditions at Lock No. 5 had probably stressed the piles by a horizontal load of approximately 3 tons per wood pile. The foundation soil at Lock No. 5 is principally sand with some indications of gravel far below the lock-walls. The fact that no lateral deflection took place confirms the belief that soil investigation is of primary importance, and arbitrary "safe" values for lateral loads on piles are figments of the imagination.

LAZARUS WHITE,[14] M. AM. SOC. C. E. (by letter).—The experiments made by Mr. Feagin and his associates are familiar to the writer and the paper describing them constitutes a valuable contribution in a field in which reliable information is scanty. The conditions under which the experiments were conducted are carefully described and the author's conclusions are properly limited to the soil conditions and piling arrangements under which the tests were made.

It will interest most engineers to note that the lateral resistance of the piles tested was less than the ratios ordinarily assumed in such designs. That piles about 30 ft long—of white oak and concrete, driven into firm sand, and capable of sustaining a vertical load of, say, 30 tons, with their ends firmly fixed into a solid concrete block—should have a resistance of 4 to $4\frac{1}{2}$ tons for a lateral movement of $\frac{1}{4}$ in., is rather startling. It is startling, furthermore, to discover that well made concrete piles have a lateral resistance of only 1 ton or 2 tons more. For a lateral movement of $\frac{1}{2}$ in. the indicated lateral load is only 7 tons. That the values are really low is borne out by observations on the movements of walls founded on wooden piles driven in sand (see Fig. 26). These walls moved several inches.

Tests made on the holding-down power of wooden piles indicate a high value in most cases. A vertical load of 20 to 75 tons is required to pull one pile out of a concrete block, so that it is probably correct to assume fixed-end conditions.

The writer wishes to call attention to the danger of extending observations or calculations made on single piles or on a small group, to a large group,

[13] With Hydr. Eng. Dept., Aluminum Co. of America, Pittsburgh, Pa.

such as is ordinarily done The piles of a large group may grip enough soil to act as a diaphram much as one may retain a bank with longitudinal or vertical sheeting with wide open joints. In this case the resistance against lateral movement is that of an approximately vertical plane of earth bounding the group, much the same as the resistance of a line of very stiff steel sheeting.

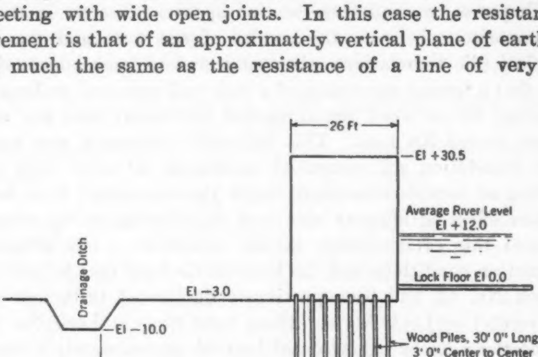

FIG. 26.

The writer has observed large movements of groups of piles serving as foundations to concrete walls. When the lateral resistance of the earth surrounding them has diminished due to near-by excavations, the walls move as a unit. These walls were also supported on lines of steel sheeting serving as cut-off walls. Much of this diminution of resistance, in the writer's opinion, was due to the lateral flow of water in the adjacent excavation, rendering the sand surrounding the piles partly quick. It is apparent, therefore, that under field conditions, the lateral resistance of piles may be highly variable, and, at times, it may be only a few tons per pile. The lesson is that under the conditions described it is wise to supplement the lateral resistance of vertical piles with other, more positive, means. Steel sheeting below the walls does not provide this resistance, as, in the cases quoted, the tops of the steel sheeting utilized as cut-offs were incorporated in the wall. The more positive means may be struts or ties or battered piles, advantageously placed.

Y. L. CHANG,[15] ESQ. (by letter).—These valuable tests on the lateral deflection of foundation piles give rise to much useful information on this subject not hitherto available. The need of some definite information and a method of analysis is certainly urgent, owing to the rapidly increasing use of piles and sheet-piling in foundation work. Mr. Feagin has taken the opportunity of conducting tests on piles driven in river sand, with a view to determining the resistance of such piles to movement under lateral loads caused by back-fill on a lock or by water pressure on a dam. The Huai River Commission in China is at present (1936) constructing three locks on the Grand Canal to improve navigation, and, at the same time, to maintain a definite

[15] Scholar of Board of Trustees, Nanking, China; Research Student, Victoria Univ., Manchester, England.

slope to facilitate local irrigation. A general knowledge of the lateral deflection of piles, such as that presented by the author, will certainly be of great help in such a case.

The problem is equally interesting in the case of a sheet-pile; and, since it is usually designed with a comparatively low section modulus, an investigation of its movement under lateral load is of special importance.

The author has mentioned that an exact mathematical analysis to verify the experimental data is not at all easy, owing to the fact that so many variables are involved and that conditions vary widely for different localities. An attempt at such an analysis, with the aid of model tests of the pile, would provide a close guide to apply in a given case. When small elastic rods are embedded in granular material and subjected to lateral pressure they will bend in the form of a reverse curve, and the bottom of the rod will move slightly in a direction opposite to that of the displacement at the top. At a certain intermediate depth there is rotation, but no displacement.

An approximate analysis is suggested herein, involving the assumption that the "elastic modulus of soil", E_s, is a constant, and it follows that the foregoing phenomena can be demonstrated quite rationally. By assuming an arbitrary value for E_s (the true value of which should be determined at the site locally), a curve can be plotted to agree quite satisfactorily with Mr. Feagin's experimental data.

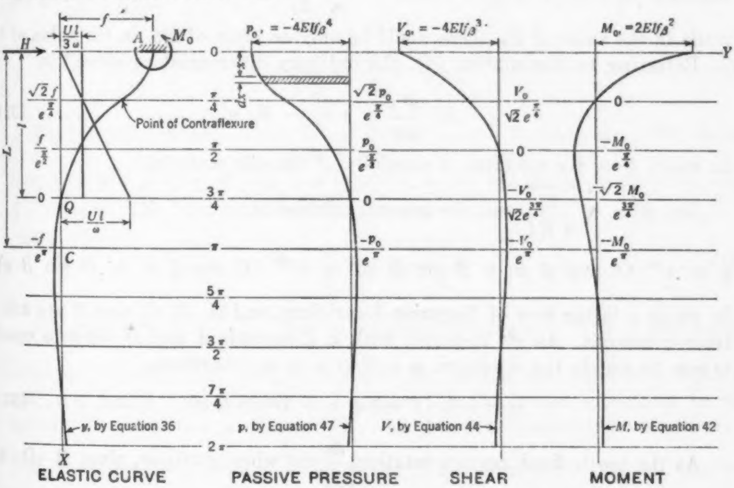

FIG. 27.

The assumptions upon which the analysis is based are as follows:

(1) The upper end of the pile is embedded deeply enough in the monolithic foundation to be fixed against rotation;

(2) The pile is infinitely long (as will be shown subsequently, the lateral movement of a pile at depths greater than l (Fig. 27), is so small that any pile of sufficient length may be assumed to be infinitely long);

(3) The elastic modulus of soil, E_s, is constant throughout the depth; and,

(4) The passive pressure, p, on a pile is proportional to its displacement; that is, $p = - E_s\, y$, in which y is the lateral deflection of the elastic curve.

Regarding Assumption (3), moreover, the soil itself will be compacted, more or less, to the same degree and uniformity, due to the overlapping of the pressure cones that are created when all the piles are driven to their proper depths. Since most foundations are designed on the assumption that the supporting power is distributed properly both on the piles and on the bearing area of the earth foundation, it follows that the earth must be quite compact even at the surface. Therefore, it is not necessary to assume that the "elastic modulus of soil" is a straight line, varying with the depth. As a matter of fact, its value depends on the properties of the soil at different strata and on the intensity and the distribution of the vertical loads. If it is assumed, tentatively, that this constant modulus is one-third of what the variable modulus would be at the depth, l (Fig. 27), a simple substitution can be made. The reason for making E_s less than the mean value of a triangular variation may be justified by considering that the upper part of a pile, being subjected to much more pronounced lateral movement, is surrounded by earth of comparatively low elasticity. It will be shown subsequently that l is proportional to $\dfrac{1}{\sqrt[4]{E_s}}$, so that if an error of 10% is made in the value of E_s, there would be only an error of 2% in the value of l.

Referring to Assumption (4), the ordinary differential equation[16] is,

$$EI\,\frac{d^4 y}{dx^4} = p = - E_s\, y \quad \ldots\ldots (32)$$

in which E = the modulus of elasticity of the pile material.

Let, $\beta = \sqrt[4]{\dfrac{E_s}{4\,EI}}$ and, the general solution is,

$$y = e^{\beta x}\,(A \cos \beta x + B \sin \beta x) + e^{-\beta x}\,(C \cos \beta x + D \sin \beta x)$$

in which e is the base of Naperian logarithms, and A, B, C, and D are arbitrary constants. As $e^{\beta x}$ increases with x, Constants A and B must be equal to zero to satisfy the condition, $y = 0$ at $x = \infty$; therefore,

$$y = e^{-\beta x}\,(C \cos \beta x + D \sin \beta x) \quad \ldots\ldots (33)$$

As the top is fixed against rotation, $\dfrac{dy}{dx} = 0$ when $x = 0$; or, since $C - D = 0$,

$$\frac{dy}{dx} = - \beta\, e^{-\beta x}\,[(C - D) \cos \beta x + (C + D) \sin \beta x] = 0 \quad \ldots (34)$$

and, therefore, Equation (33) becomes,

$$y = C\, e^{-\beta x}\,(\cos \beta x + \sin \beta x) \quad \ldots\ldots (35)$$

---

[16] "Strength of Materials", by S. Timoshenko, Pt. II, p. 402, Equation (1).

At $x = 0$, $y = f$, from which $C = f$; and,

$$y = f\ e^{-\beta x}\ (\cos \beta\ x + \sin \beta\ x) \qquad (36)$$

and,

$$\frac{dy}{dx} = -\ 2\ \beta\ f\ e^{-\beta x} \sin \beta\ x \qquad (37)$$

The point of zero deflection (see Point Q, Fig. 27) can be found by making $y = 0$ and $x = l$ in Equation (36), from which,

$$e^{-\beta l}\ (\cos \beta\ l + \sin \beta\ l) = 0 \qquad (38)$$

One solution of Equation (38) is given by $l = \infty$; or, $\cos \beta\ l + \sin \beta\ l = 0$; $\tan \beta\ l = -\ 1$; and,

$$\beta\ l = \left(n - \frac{1}{4}\right)\pi \qquad (39)$$

in which $n = 1, 2, 3$, etc. The foregoing analysis demonstrates that the elastic curve for an infinitely long pile should be a harmonic wave, damping away rapidly after each successive wave length, $2\ l$. For the least value, $\beta\, l = \frac{3\ \pi}{4}$, and,

$$l = \frac{3\ \pi}{4\ \beta} = \frac{3}{4}\ \pi \sqrt[4]{\frac{4\ EI}{E_s}} \qquad (40)$$

For the point of zero slope, $\frac{dy}{dx} = 0$, and $x = L$ in Equation (37); therefore, $e^{-\beta L} \sin \beta\ L = 0$. In one solution, $L = \infty$; or, $\sin \beta\ L = 0$; and, $\beta\, L = n\ \pi$. The least value is $\beta\ L = \pi$, and,

$$L = \frac{\pi}{\beta} = \pi \sqrt[4]{\frac{4\ EI}{E_s}} \qquad (41)$$

By proportion, $l = \frac{3}{4} L$. It is to be noted that for $n = 2$, L is very nearly equal to l, showing that the pile is practically vertical and rigid at a depth of one wave length. At the depth, L (Fig. 27), the lateral movement in the opposite direction is a maximum. To find this deflection, substitute $\beta\ x = \pi$ into Equation (36), and $y = -\frac{f}{e^{\pi}}$, which amounts to 4.3% of the top deflection in the opposite direction.

For the point of maximum slope, differentiate Equation (37) with respect to x; thus: $\sin \beta\ x = \cos \beta\ x$; and $\beta\ x = \frac{\pi}{4}$. To compare the foregoing with Equations (40) and (41), $x = \frac{l}{3} = \frac{L}{4}$. To find an expression for

moment, Equation (37) is differentiated further:

$$\frac{d^2 y}{dx^2} = 2\, f\, \beta^2\, e^{-\beta x}\, (\sin \beta\, x - \cos \beta\, x)$$

and,

$$M = -\, 2\, E\, I\, f\, \beta^2\, e^{-\beta x}\, (\sin \beta\, x - \cos \beta\, x) \quad \text{(42)}$$

At $x = 0$,

$$M_0 = 2\, E\, I\, f\, \beta^2 \quad \text{(43)}$$

The point of zero moment, determined by $\sin \beta\, x = \cos \beta\, x$, occurs at the point of contraflexure. Differentiating again:

$$\frac{d^3 y}{dx^3} = 4\, f\, \beta^3\, e^{-\beta x} \cos \beta\, x \quad \text{(44)}$$

At $x = 0$, the shear, V_0, equals:

$$V_0 = -\, 4\, E\, I\, f\, \beta^3 = -\, H \quad \text{(45)}$$

in which H = the external force applied at the top of a pile, and, at $x = L$,

$$V_L = 4\, E\, I\, f\, \beta^3\, e^{-\pi} = -\, \frac{V_0}{e^{\pi}} \quad \text{(46)}$$

which is only 4.3% of V_0.

For the point of zero shear, or for that of maximum moment, $\cos \beta\, x = 0$; $\beta\, x = \left(n - \frac{1}{2}\right)\pi$; and the first point occurs at a depth of $\frac{L}{2}$.

The passive pressure on the pile is:

$$p = -\, E_s\, y = -\, E_s\, f\, e^{-\beta x}\, (\cos \beta\, x + \sin \beta\, x) \quad \text{(47)}$$

Considering a pile of infinite length, the total passive pressure on the pile is:

$$P = \int_0^\infty p\, dx = -\, E_s f \left[\int_0^\infty e^{-\beta x} \cos \beta\, x\, dx + \int_0^\infty e^{-\beta x} \sin \beta\, x\, dx \right]$$

$$= -\, 4\, E\, I\, f\, \beta^3 = -\, H \quad \text{(48)}$$

If Equation (48) is integrated to the point of zero deflection,

$$P = \int_0^l p\, dx = 4\, E\, I\, f\, \beta^3\, e^{-\beta x} \cos \beta\, x \Big]_0^{\frac{3\pi}{4\beta}} = -\, 4\, E\, I\, f\, \beta^3 \left(1 + \frac{1}{\sqrt{2}\, e^{\frac{3}{4}\pi}}\right)$$

$$= -\, 1.067\, H \quad \text{(49)}$$

The difference between the total passive pressure when assuming that the pile does not bend beyond the depth, l, is only 6.7% in excess of that on an infinitely long pile. This difference is due to the decreasing pressure intensity as the depth increases. The length of pile that is subject to passive pressure can also be determined by considering the minimum internal energy set up in a pile during elastic deformation, thus:

$$W = \frac{1}{2} \int_0^d p\, y\, dx = -\, \frac{1}{2} \int_0^d E_s\, f^2\, e^{-2\beta x}\, (\cos \beta\, x + \sin \beta\, x)^2\, dx \quad \text{(50)}$$

in which the upper limit, d, denotes the depth, or, finally,

$$W = \frac{E_s f^2}{8\beta}\left[e^{-2\beta d}\left(\cos 2\beta d + \sin 2\beta d + 2\right)\right] \ldots\ldots\ldots (51)$$

As before,

$$\frac{\partial W}{\partial d} = -\frac{E_s f^2}{2}\left[e^{-2\beta d}\left(\sin 2\beta d + 1\right)\right] = 0 \ldots\ldots\ldots\ldots (52)$$

In one solution, $d = \infty$; or, $\sin 2\beta d = -1$; that is,

$$2\beta d = \left(2n - \frac{1}{2}\right)\pi \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (53)$$

For $n = 1$, $2\beta d = \frac{3}{2}\pi$, and,

$$d = \frac{3\pi}{4\beta} = l = \frac{3}{4}\pi\sqrt[4]{\frac{4EI}{E_s}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

which is also the expression for l in the case of zero deflection (see Equation (40)). Equation (54) shows that a similar expression for a definite bent length, l, can always be derived by considering either that the pile is rigid beyond this depth or that it is deformed in damping waves throughout the entire length.

Let E (the modulus of elasticity of the pile) $= 270\,469\,440$ lb per sq ft; $I = 0.0503$ ft^4; $U = 133$ lb per cu ft; and $\omega = 0.005$. Then, by the foregoing assumption, $E_s = \frac{Ul}{3\omega} = \frac{133\,l}{3 \times 0.005} = 8\,866\,l$. These values, substituted in Equation (40) yield, $l = 11.35$ ft; or, $E_s = 100\,700$ lb per sq ft. Then, by substituting, in the expression, $\beta = \sqrt[4]{\frac{E_s}{4EI}}$, $\frac{1}{\beta} = \sqrt[4]{541}$; or $\frac{1}{\beta^3} = 112.2$. Equation (45) gives the relation between the horizontal load applied at the top of the pile and the lateral deflection of the top of the pile; that is, substituting the foregoing values and solving for f:

$$f = \frac{H}{4EI\beta^3} = \frac{H}{20.2} \ldots (55)$$

in which f is in inches and H is in tons.

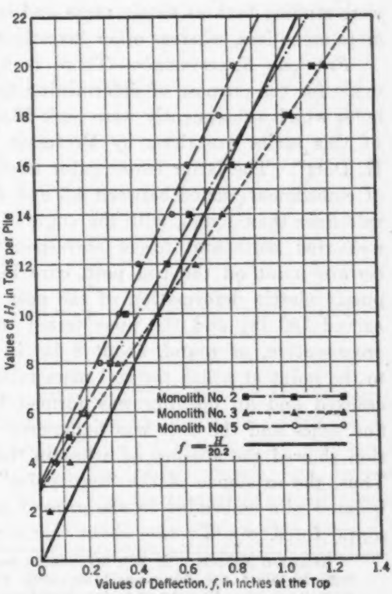

FIG. 28.

When Equation (55) is plotted (see Fig. 28) the curve has nearly the same slope as the experimental curves of M_2 and M_5 in Mr. Feagin's paper. In the author's "Conclusions", a value of 7 tons has been suggested as the maximum lateral load on the top of a pile if a lateral movement of not more than 0.5 in. is allowable. Adopting 0.5 in. as a practical limit, Fig. 28 gives 10 tons as the maximum lateral load. Reference to this curve shows that for deflections of less than 0.5 in., the experimental data for M_2, M_3, and M_5 follow lines of the same general slope as those defined by Equation (55); in fact, they are on the safe side.

The best empirical equation that will fit the field data is evidently of the form:

$$f = \frac{H}{a} - b \quad \text{.........................(56)}$$

in which a and b are constants.

In conclusion, the writer wishes to thank Professor A. H. Gibson and Mr. J. Allen, of the Victoria University of Manchester, England, and A. E. Cummings, M. Am. Soc. C. E., for their helpful criticism of this discussion.

D. P. KRYNINE,[17] M. AM. SOC. C. E. (by letter).—The lateral pile-driving tests at Alton, Ill., described in this paper, were made on a considerably larger scale than any other experiments known to the writer. Therefore, they approach the actual loading conditions more closely. Furthermore, the piles were studied both as single units and in groups, with heads embedded in concrete monoliths, whereas other investigators have dealt with isolated piles only.

Previous Experiments.—There is a series of older German experiments made for the purpose of determining the resistance of posts placed in narrow holes which subsequently were back-filled with earth. Among the experiments of this series are those by Professor Engel[18], H. Fröhlich[19], and those by H. Dörr[20]. The latter investigator used posts about 18 ft high, and the depth of embedment varied between 4.3 and 6.1 ft. The soil was Rhine sand, as a rule finer than 1 mm, with the angle of natural slope about 40 degrees. Dörr measured horizontal forces corresponding to horizontal displacements of a certain point on the test post, care being taken to substract therefrom the purely elastic deformation of the post itself. The horizontal forces did not exceed 700 lb; and the piles tested were rectangular, about 6 by 9 in. in cross-section, or round, about 8 in. in diameter. The tests were conducted to the point at which the soil mass failed so that the ground close to the pile cracked and an opening was formed behind it. This hole was filled with fine ashes and the post was hammered down somewhat. Subsequent excavation showed the absence of ashes in the lowest third of the embedded depth. Thus, the existence of the "zero point" was established experimentally. An isolated pile embedded in the ground and subjected to the action of a horizontal force, would rotate about that zero point.

Experiments conducted at North Carolina State College, Raleigh, N. C., and by the State Highway Board of Georgia[21] have shown that the resistance of a pole to overturning is proportional to the square of the penetration depth. This fact induces one to believe that the resistance of a pile to the action of a lateral force is connected with the configuration of some body of rotation which develops within the earth mass close to the pile under consideration. The North Carolina tests were conducted in hard clay, and those in Georgia in clay containing about 50 to 60% of sand,

Introducing the following notations: P_0 = an overturning force, in pounds; d = depth of embedment or penetration, in feet; and c = a coefficient. The overturning force may then be expressed as:

$$P_0 = c\,d^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

The value of the coefficient, c, was found to be 1 250 in North Carolina and 300 in Georgia.

In 1928 the writer made some field and laboratory tests on pile models loaded horizontally. These tests were made in co-operation with Messrs. G. I. Pokrowski and N. V. Laletine[22] who later continued this work alone.[23] Wooden

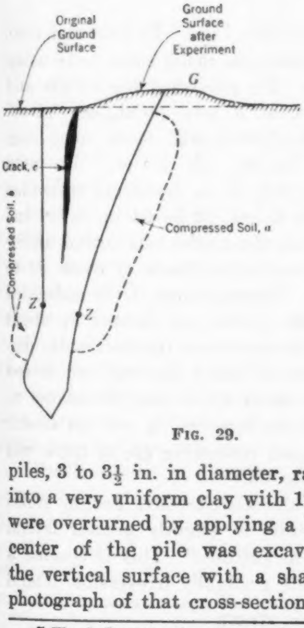

FIG. 29.

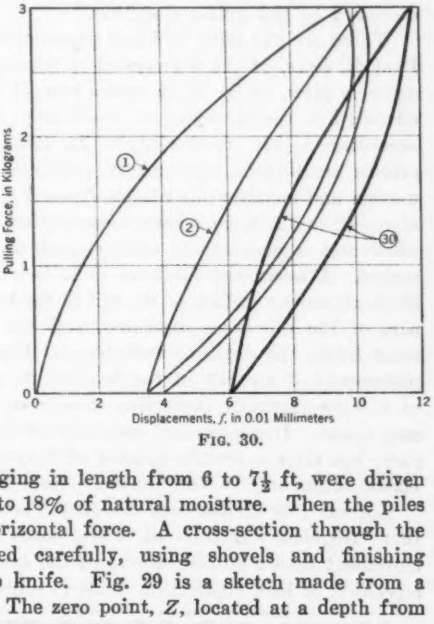

FIG. 30.

piles, 3 to $3\frac{1}{2}$ in. in diameter, ranging in length from 6 to $7\frac{1}{2}$ ft, were driven into a very uniform clay with 17 to 18% of natural moisture. Then the piles were overturned by applying a horizontal force. A cross-section through the center of the pile was excavated carefully, using shovels and finishing the vertical surface with a sharp knife. Fig. 29 is a sketch made from a photograph of that cross-section. The zero point, Z, located at a depth from

[23] "Soil Investigations in 1929–1930" (printed in Russian), pp. 15–33.

0.52 d to 0.69 d, is clearly seen; and it appears that the overturning process consists of two phases. In the first phase the pile rotates slightly about its zero point, Z, being resisted by both the compressive resistance of the soil (compressed zones, a and b) and by its tensile strength (Crack c). The second phase is characterized by the breaking down of the shear resistance. The center of rotation gradually moves from the zero point, Z, to the surface of the ground, G, following the curve, ZG; and, finally, an earth cone is pushed out. A weak pile breaks during this second phase.

It follows from these experiments that a structure founded on piles and subject to lateral forces, is kept in place by the compressive resistance of the adjacent earth mass. This compressive resistance, however, does not control the ultimate, or the limit of equilibrium of the structure. As soon as the acting force overcomes the value of the shearing resistance of the soil, the deformation takes the path of least resistance, and the mass fails by shear. Hence, the actual lateral force should not be greater than an nth part of the shearing resistance, in which n is the safety factor. Furthermore, there is a sharp difference between the failure of the earth mass and the failure of the structure itself, since owing to the excessive compressibility of an earth mass, the structure may move laterally and fail before the adjacent earth mass is disturbed by shear. A further development of these experiments has been discussed by the writer elsewhere.[34]

There are two more series of experiments of this kind. In 1928 and 1930, Paul E. Raes, of the University of Ghent, Belgium, made some tests using concrete piles, 12 by 12 in. and 14 by 14 in. He published his results and advanced a theory which is essentially that of a zero point, or "pivot" according to his terminology[35]. In 1933, M. Nakamura[36] made some very precise small-scale experiments concerning lateral pile action. He used wooden and metallic pile models (from $2\frac{5}{16}$ to $3\frac{5}{16}$ in. in diameter) embedded about 10 to 12 in. in a sand mass confined in a box, 24 by 24 in. by 16 in., which was supposed to be large enough to leave the model pile action undisturbed. A horizontal force up to 10 lb was applied at levels of about 22 to 28 in. above the surface of the soil in the box. Deformations of the embedded part of the pile were measured, and the zero point was located at about seven-tenths the depth of embedment. Fig. 30 represents the horizontal displacements of the pile at the level of the ground under the repeated action of a force gradually increasing from zero to about 6.6 lb and decreasing to zero again. Displacements consisted of both an irreversible and an elastic part; but after a certain number of loading and unloading cycles there was elastic action only. (Note the heavy lines in Fig. 30.)

Lateral Pile Action and Loading Tests Interrelated.—Mr. Feagin states that "frequent repetition of lateral loads results in slightly greater lateral movement than a sustained load of the same magnitude." This is because a repetition of load application tends to eliminate gradually irreversible lateral

movements, as shown in Fig. 30. The case of a pile acted upon by a horizontal force is a special case of the loading of an earth mass; hence analogics should be sought between such an action and the action of a loaded plate placed at the surface of an earth mass. Fig. 31 shows the settlement curve in an experiment made by the writer[27]. A confined sand layer, 3 in. in diameter and about $1\frac{1}{4}$ in. thick, was subjected to compression, using loads ranging from 16 to 65 lb per sq in. applied to a metallic piston acting at the sand surface. Curves A and B, Fig. 31, correspond to the total settlement of the sample in the loaded and unloaded condition, respectively, so that the difference between them denotes the elastic rebound at a given stage of the experiment. Similar curves may be obtained by joining the upper and the lower points of the curves in Fig. 4(*e*), or in Fig. 9.

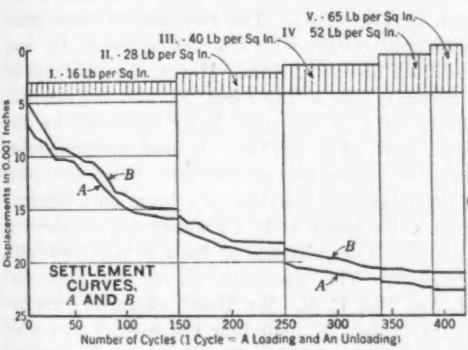

FIG. 31.

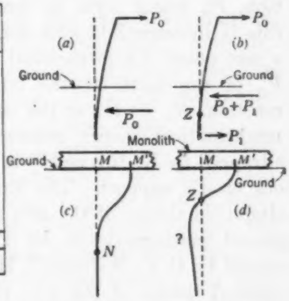

FIG. 32.

In connection with Fig. 30 it should be stated that each pair of curves corresponding to a loading and unloading cycle, is analogous to a hysteresis loop in loading experiments. Order numbers of loading and unloading cycles are indicated by the numbers in circles in Fig. 30. After a certain number of such cycles (thirty in Fig. 30) the hysteresis loops become closed, which means that the earth mass has attained perfect elasticity under the action of a given stress. This elasticity is not the same, however, as that required by Hooke's law, since displacements are not proportional to the stresses. It is also remarkable that this state of elasticity may be destroyed as soon as a stress greater than that used in compression is applied (see Fig. 31).

"Pre-Testing" of Piles by Lateral Pull.—If instead of a confined sand sample (Fig. 31) a plate is placed at the ground surface and loaded repeatedly, the results would be practically the same[28]. If a pile is subjected to repeated vertical loading, an analogous action occurs. Using this property, Lazarus White, M. Am. Soc. C. E., developed a so-called "pre-test" method of foundation construction applied principally to piles[29]. It is well known that the

[29] *Loc. cit.*, p. 113, Fig. 61.

surface of an earth road that is reasonably moist becomes elastic under traffic; and this surface is easily destroyed should a few heavy loads pass over the road. All kinds of pavements are automatically "pre-tested" by traffic. Assembling all the foregoing facts, it may be stated that practically every earth structure, except perhaps the case of saturated plastic soils, can be "pre-tested" within the meaning of the term introduced by Mr. White. This suggests that irreversible deflections of piles subjected to lateral forces could be also eliminated by duly "pre-testing" them during construction. How this "pre-testing" could be done—pile by pile, or otherwise—and whether such a method is economically feasible are questions to be decided for each individual case.

Theory of the Zero Point.—Fig. 32 represents a hypothetical weightless pile loaded at its top with a horizontal force, P_0. If there is no zero point, the pile would deflect as shown in Fig. 32(*a*). The resultant of earth reaction, P_1, would form an unbalanced couple with the acting force, P_0, and this is incompatible with conditions of equilibrium. Hence, the existence of a zero point is a mechanical necessity, the acting force, P_0, and the reaction, P_1, of the earth at the bottom part of the pile being balanced by the reaction, $P_0 + P_1$, at the upper part (Fig. 32(*b*)). A most comprehensive mathematical theory concerning the location of the zero point has been advanced by K. Hayaschi[30] in describing the behavior of a beam on a continuous elastic support. The Russian Professor I. P. Prokofiev has advanced a simplified theory of the zero point[31]. The existence of the zero point was also proved mathematically by Prudon[32]. The zero-point theory has been discussed by C. C. Williams[33], M. Am. Soc. C. E. Mr. Raes[25] advanced a mathematical theory of the zero point ("pivot"), including the case of two piles with heads embedded in a concrete monolith. Mr. Raes comes to the conclusion that in the latter case one of the two piles is pulled, and the other pushed, and that the "pivot" exists in all cases.

In the experiments by Mr. Feagin there is no direct indication as to whether or not there is a "pivot" in the case of piles with embedded heads. The elastic line in this case may be visualized either according to Fig. 32(*c*) or Fig. 32(*d*). In the former case there are vertical tangents at Points *N* and *M'*, and the elastic line in the latter case has been drawn quite arbitrarily only to show that, in the opinion of the writer, there is a zero point located rather high. Mr. Feagin testifies that between the pile and the concrete (Point *M'*) there was "a crack in which the blade of a pocket-knife could be inserted". Hence, it is doubtful whether the tangent to the elastic line at Point *M'* was vertical. On the other hand, in Fig. 32(*c*), the line, *NM'*, is longer than the line, *NM*; and neglecting the deformations of the pile, one may conclude that the pile should be pulled out at Point *N*, which contradicts the assumption of ideal embedment at that point. The writer believes that only in the case of feebly rigid piles the assumption of Fig. 32(*c*) may

[30] "Theorie des Balkens auf elastischer Unterlage", Berlin, 1921, p. 228 *et seq.*

[31] "Theory of Structures", Pt. II, p. 232 *et seq* (printed in Russian in 1928).

[32] *Le Génie Civil*, No. 5, 1926, p. 117.

[33] "The Design of Masonry Structures and Foundations", Second Edition, 1930, p. 478 *et seq.*

lead to a rather satisfactory working theory. In a general case, however, the attention of the investigators should be directed toward the location of the zero point, Z (Fig. 32(d)). Mr. Feagin states: "It was found that a carpenter's rule could be inserted to a depth of 6 ft in the space between the pile and the adjacent foundation sand on the side of the hole nearest the jack." Probably that rule reached Point Z, as shown in Fig. 32(d).

Extension of the Experiments Suggested.—The excellent experiments by Mr. Feagin should be extended somewhat further: First, it seems necessary to investigate whether or not the "pre-test" method as applied to piles deflected laterally can decrease the lateral movement of locks; and, second, the shape of the elastic line of such piles should be investigated more closely. For economy, smaller pile models driven into uniform natural clay may be used in these particular field tests. It would be very important, furthermore, to study the characteristics of batter piles.

Additional Remarks on Irreversible Earth Deformations.—The following observation by Mr. Feagin is to be emphasized: A pile loaded horizontally never returns to its original position upon removal of the load. Actually, even a perfectly elastic pile is restrained from returning to its initial position owing to irreversible deformations of the earth mass. This fact may cause serious secondary stresses in a framework, such as a wooden bridge.

Action of Forces at a Lock.—If there were no piles, horizontal stresses due to the difference of levels in both the upper and the lower pool (Fig. 3(a)) would develop under the structure. The piles driven into the ground form, with the soil, a mass of "reinforced earth", and it is very probable that the horizontal stresses referred to, are taken up by that mass which works as a whole. A graphic method of computing these horizontal stresses has been advanced by the writer elsewhere[34]. Assuming the earth material under the structure to be elastically isotropic, the value of such a stress pushing the structure down stream, would be approximately: $0.5 \times 62.5 \times (38.0 - 15.2) = 713$ lb per ft of width of the structure and per lin ft of the length of the piles. This value should be less in the case of sands. The values given do not pretend to any degree of accuracy; the writer wishes only to state that an additional force pushing the lock down stream may exist and that this force is due to the difference of water levels in the pools.

Conclusion.—As a rule, the closer a soil model is to a full-sized structure, the more trustworthy are the results. In this respect Mr. Feagin's experiments with large models are unusually interesting. To increase the value of the experiments, it seems necessary to extend their scope somewhat, but even in their present form, Mr. Feagin's experiments are an important contribution to the field of soil mechanics and a valuable source of information for both the practical engineer and the theoretical worker in that field.

LAWRENCE B. FEAGIN,[35] M. AM. SOC. C. E. (by letter).—A wide range of thought and of methods of considering the problem of the reaction of piles to lateral loads is reflected in the discussions of the paper. The inter-

[34] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1292, Fig. 19.

[35] Senior Engr., U. S. Engr. Office, St. Louis, Mo.

est and consideration accorded it are gratifying and appreciated. The problem has been approached both from the standpoint of mathematical analysis and from that of experience.

Mr. Cummings and Mr. Chang have both contributed ingenious mathematical analyses. They have sought to derive equations whereby the following may be determined: (*a*) The curve of deflection of the central axis of a pile subjected to a lateral load; (*b*) the horizontal deflection of a pile subjected to a given lateral load; (*c*) the length of the pile from the top downward, which is moved, also referred to as the bent length; (*d*) the relationship of the portion of the load resisted by the rigidity of the pile itself to that resisted by the soil; and (*e*) the stresses in the pile.

The writer has studied, with interest, each of these discussions as well as the assumptions made in each, and believes that perhaps a brief comparison may be of assistance to those who may hereafter have occasion to refer to them.

Mr. Cummings has assumed that the equation of the central line of the deflected pile can be expressed by the power series, Equation (1), and assumes certain boundary conditions whereby the formula of the deflection curve of the bent pile is established in the form of his Equation (2).

Mr. Chang has applied the theory presented by Professor S. Timoshenko[36] for determining the deflection of a bar supported along its entire length by a continuous elastic foundation, and has arrived at a corresponding formula of the deflection curve of the pile (his Equation (36)).

It will be noted that Equation (36) is of a form which will produce a sinusoidal curve of diminishing amplitude. In general, this latter type of equation will give a curve which is more nearly in keeping with the actual movement of the pile.

After proceeding with his analysis far enough to determine an expression for the bent length of the pile, Mr. Chang, however, concludes that the pile is practically vertical and rigid at a depth of one wave length, thus indicating that Mr. Cummings was justified in assuming that for all practical purposes the deflection curve has a vertical tangent at depth, L.

In order, for comparison, that it may have the same unknowns as occur in Equation (36), by substituting from Equation (31), Equation (2) becomes:

$$y = \frac{3\,f\,x^2}{\left(\dfrac{216\,E\,I\,\omega}{U}\right)^{\frac{2}{5}}} - \frac{2\,f\,x^3}{\left(\dfrac{216\,E\,I\,\omega}{U}\right)^{\frac{3}{5}}} \qquad (58)$$

Equations (36) and (58) both have two unknowns which must be determined by test; that is, f and E_s, the elastic modulus of the soil. Mr. Cummings assumes that the elastic modulus of the sand increases directly with the depth of the sand, whereas Mr. Chang assumes that the elastic modulus is a constant. The writer believes that the former assumption is more nearly correct, notwithstanding the possibility, as suggested by Mr. Chang, that the elastic modulus may be affected by the compaction of the soil in the driving of the piles.

[36] "Strength of Materials", by S. Timoshenko, Pt. II, p. 402.

Mr. Cummings determined the relationship between the horizontal load, H, and the top deflection of the pile as expressed by his Equation (26). It is interesting to note that in this formula the first term, representing that part of the load carried due to rigidity of the pile, is much less in magnitude for large values of L, than the second term which represents the part carried by the soil. This indicates the important rôle played by the soil in resisting lateral loads. On the other hand, it will be observed that for small values of f, which it seems reasonable to assume will also be accompanied by correspondingly small values of the bent length, L, the first term will represent a large proportion of horizontal load, H. This indicates the importance of the structural rigidity of the top few feet of the pile if the top deflection, f, is to be kept small. It should be borne in mind, however, that the extent to which results from this equation can be relied on depends primarily upon the accuracy with which the bent length, L, and the elastic properties of the soil (represented by ω) are determined.

Mr. Chang has developed a corresponding expression (see his Equation (55)) which may be written as:

$$f = \frac{H}{4\,E\,I\left(\dfrac{E_s}{4\,E\,I}\right)^{\frac{3}{4}}} = \frac{H}{\sqrt[4]{4\,E\,I}\;(E_s)^{\frac{3}{4}}} \quad \ldots\ldots\ldots\ldots(59)$$

In Equation (55) he has combined in a single term the resistance due to the rigidity of the pile and to the passive resistance of the soil. The reliability of this equation is also dependent upon the accuracy of determination of E_s which, in turn, is dependent on the bent length of the pile, as well as the elastic properties of the soil.

It will be noted that both Mr. Cummings and Mr. Chang have developed a single value of bent length of pile and each has used his respective single value throughout in computing deflections for the various loads as a basis for comparison with the test data (see Fig. 20 and Fig. 28). This probably accounts in large measure for the fact that the calculated results by both equations show greater deflections for the lower range of loads than the test results. Mr. Cummings uses a computed bent length of 10.2 ft, and Mr. Chang uses $L = 11.35$ ft. Attention is invited to the fact that the writer stated in the paper that at a load of approximately 30 tons per pile and with a top deflection, f, of $1\frac{3}{4}$ in., it was estimated that the bent length of the pile was about 10 ft. For small loads, it is undoubtedly less.

It is believed to be apparent that the depth to which movement occurs in a pile subjected to a lateral force at the top is dependent upon: (a) The physical characteristics of the pile, such as E and I; (b) the elastic modulus of the soil; and (c) the amount of the horizontal force and the resulting lateral movement at the top of the pile.

It is believed, therefore, that any mathematical expression which purports to give the depth of movement should, either directly or indirectly, contain all these factors. The formula developed by Mr. Cummings is Equation (31) and the corresponding formula developed by Mr. Chang is Equation (40). In

each of these two expressions it will be noted that terms for both the physical characteristics of the pile and the elastic modulus of the soil are included, but there is no term for either the amount of the horizontal force, H, or the deflection, f. The results from these formulas are largely dependent on the values assumed for the "dimensionless coefficient, ω," and E_s. Based on these formulas the depth of movement would be the same with a deflection, f, of either 0.25 in. or 6 in. at the top, or with a lateral load, H, of 5 tons or 40 tons. It is obvious that this is not correct. The small-scale model tests made by Mr. Cummings (see Figs. 22 and 23) indicate quite clearly that the large rods had a greater depth of movement than the smaller rods. The top deflection of all three rods was about the same (1 in.), but a greater force, H, was required to move the $\frac{1}{4}$-in. rod than the $\frac{3}{32}$-in. rod, thereby causing a greater depth of movement in the more rigid rod.

Mr. Cummings was evidently aware of this and in his discussion states that "it should not be concluded from this that the bent length is independent of the deflection." He then justifies Equation (31) on the grounds that it is a combination of Equations (5) and (12) both of which are "based on the usual theory of elastic structures in which the displacements are required to be very small in comparison with the dimensions of the structure."

The writer does not desire that the foregoing comments on these two excellent discussions be construed as implying that he does not believe that the mathematical analyses are of practical value; they mark an important beginning in a field in which much remains to be done. He does desire, however, to point out the limitations of certain of the equations, in order that they may be used with proper caution. The equations for deflection check the particular tests results described in the paper quite well and, for loads within the range normally pertinent to design problems, give results which, subject to the additional considerations given subsequently, appear, in general, to be on the side of safety. Furthermore, a careful consideration of the derivations of the bent length provides an approach for the problem of determining the length of pile required to be driven to resist a given lateral load.

Both Mr. Meem and Mr. Thomson have emphasized very properly the fact that the conclusions given in the paper were distinctly limited to the soil conditions and piling arrangements under which the tests were made. The writer recalls reading at one time that Darwin is reputed to have said in effect that "the greatest danger to scientific investigation is generalization based on limited experience." This statement is especially applicable to investigation of problems relating to soil foundations. It is apparent that when movement occurs in the entire foundation, such as that resulting from the movement of the glacial drift described by Mr. Meem, or from quicksand or wet clay in the subsoil stratification in the cases cited by Mr. Thomson, the results of the tests described in the paper are clearly not applicable. Each foundation should be treated as a distinct problem in itself, and the extensiveness of field investigations and office study made dependent upon the importance of the stability of the foundation.

Mr. Niederhoff has ably presented the results of lateral loading tests conducted under the direction of Major Dwight F. Johns, Corps of Engineers,

U. S. Army, District Engineer at St. Paul, Minn., in the vicinity of Lock No. 3, near Red Wing, Minn. An ingenious method simulating a condition of fixation of the top of the pile was used. It is rather surprising that in the soft material such as that described by Mr. Niederhoff no greater lateral movement occurred. This may have been due, in part, to the fact that except for a 4-in. space adjacent to the test pile the ground was frozen to a depth of 6 in., thus confining the soil. Furthermore, the low temperature may have greatly retarded or prevented plastic flow of the foundation soil which might otherwise have occurred. With the exception of Tests Nos. 12 and 16 for which notations of 5-min. intervals are given, the length of time that each test load was sustained is not given. If the loads had been sustained for several days it is possible that greater deflections might have occurred.

Mr. Niederhoff has referred briefly to the lateral movement of 9 in. of a portion of the river wall of Lock No. 5A on the Mississippi River, at a time when the lateral force computed by usual methods was only about 3.5 tons per pile. This force was caused by an unbalanced hydrostatic load which, in the writer's opinion, may have produced a partly quickened condition in the foundation sand, giving rise to a much greater actual active load on the foundation piling, especially on the steel sheet-pile cut-off wall, and, at the same time, reducing the passive resistance of the foundation sand. This condition, combined with the presence of slippery clay and the vibration from pile-driving in the immediate vicinity, can easily account for the movement. The presence of wet clay alone might have caused it. Under these conditions it is quite probable that the lateral movement may have extended to the tips of the piles. It is interesting to note that notwithstanding a movement of about 9 in. this wall remained vertical and did not settle appreciably.

Quite properly, Mr. White calls attention to the "danger of extending observations or calculations made on single piles or on a small group, to a large group, such as is ordinarily done." In some soils under certain conditions such an extension may be entirely satisfactory, whereas for other soils under the same conditions, or for the same soils under other conditions, extrapolation of observations on single piles or a small group to a large group, might result in failure. Mr. White very ably discusses large movements of groups of piles serving as foundations to concrete walls, and the writer is in accord with his suggestion that, in many instances, more positive means of insuring lateral stability by use of struts or ties or other precautionary measures may be highly desirable. The possible effect on structures subjected to lateral loads of vibration such as that resulting from driving piles within a radius of 50 or 75 ft, should be carefully considered, especially when the structure rests on a foundation soil which itself may be affected by vibration.

Professor Krynine has added to the value of the paper by citing and briefly discussing a number of other tests on this interesting subject, including tests made by himself on pile models. He has also given an interesting discussion of the "Theory of the Zero Point." The writer agrees that there is a zero point, but believes that, for piles of the length described in the paper, instead of rising from some point, Z (see Fig. 29), to the ground surface with

increasing horizontal load, the zero or pivot point (or point about which rotation occurs, as others refer to it), is nearest the surface with small lateral loads and moves downward with increasing loads. The location of the zero point, which serves to define the bent length of the pile, is regarded by the writer as being a variable which depends on the relationship between the physical properties of the pile (such as size, shape, elastic modulus, and length) and the elastic properties of the soil, and upon the magnitude of the lateral load.

Professor Krynine suggests that in Fig. 32(*c*) the line, *N M*, is longer than the line, *N M'*; and concludes that the pile is pulled out at Point *N*, which contradicts the assumption of ideal embedment at that point. The writer agrees that, in order that lateral movement may occur, either the pile must be slightly pulled up, or the top of the pile slightly lowered as it is bent, or the pile must be elongated. That there is a tendency even at low loads for the pile to be pulled up is believed to be clearly indicated by the extensometer readings described in the paper. These readings indicated that the fiber stress in the compression side was only about 60% of that in the tension side (see Fig. 13). Furthermore, in the final test on Monolith No. 6, with an extreme load of about 40 tons per pile, the two concrete piles nearest the jack were actually pulled up about 3 in., whereas the lateral movement was about 6 in. For all practical purposes, however, within the range of lateral loads normally considered in designs, it is believed that it may be assumed that the lower part of the pile is fixed.

The writer agrees heartily with Professor Krynine that it is very desirable that the scope of the tests described in the paper be extended, particularly to other types of soils and other piling arrangements, including piles battered in both directions.

In conclusion, the writer wishes again to call attention to the fact that the conclusions given in the paper were confined to the soil conditions and piling arrangements under which the tests were made.

SEDIMENTATION IN QUIESCENT AND TURBULENT BASINS

By J. J. Slade[1], Jr., Esq.

With Discussion by Messrs. Thomas R. Camp, Harry H. Hatch, Harry H. Moseley, George J. Schroepfer, and J. J. Slade, Jr.

Synopsis

In a paper which has become a classic[2] the late Allen Hazen, M. Am. Soc. C. E., stated the problem of sedimentation with characteristic clearness. For sediment consisting of particles of constant hydraulic value in a completely turbulent basin (the term will be defined subsequently) Hazen's theory is complete; but actual sediment is usually far from uniform, and, therefore, Hazen's formulas are not always applicable.

The purpose of this paper is to continue the analysis and to develop a workable theory which takes into account the variation in hydraulic value of the consituent elements of actual sediment as well as the variation in the degree of turbulence of the basin. The procedure followed herein is such that the formulas obtained may be generalized to any desired degree; that is, only practicability need limit the number of constants entering into them and the consequent flexibility of the curves representing the processes.

The constants required will be found to fall into three distinct classes: (1) Those which represent the characteristics of the sediment; (2) those which represent the characteristics of the settling basin; and (3) those which depend on both the character of the sediment and the degree of agitation of the fluid. The separation of the constants into these three categories will, it is hoped, suggest experimental procedures for the study of settling-tank characteristics and be an aid in the understanding of this complex phenomenon.

Notation.—The symbols used in this paper are introduced as they occur and are presented, for convenience of reference, in the Appendix.

Note.—Published in December, 1935, *Proceedings*.

The Quiescent Basin

It is necessary to investigate thoroughly the mechanics of sedimentation in the still basin before attempting to analyze the phenomenon in the turbulent tank. Assume, then, a tank of still water of constant depth, h, which holds in suspension a quantity, B, of solid matter, which has a constant hydraulic value, v. Assume also that at the beginning of the process the solid matter is uniformly distributed throughout the liquid and that there is a quantity, b, per unit of volume. The time required for a particle to fall from a height, y, to the bottom of the tank is:

$$t_y = \frac{y}{v} \quad \text{.............................(1)}$$

and the time required for a particle to fall from the surface is:

$$t = \frac{h}{v} \quad \text{.............................(2)}$$

Eliminating v between Equation (1) and Equation (2), the following relation is derived:

$$y = \frac{h t_y}{t} \quad \text{.............................(3)}$$

The quantity of sediment that falls to the bottom in time, $a = t_y$, is $b\ y\ A$ (in which A is the horizontal area of the tank), and this is equal to $\frac{b\,A\,h\,a}{t}$, using the value obtained for y in Equation (3). Since $b\ A\ h = B$, however, the quantity of solid matter remaining in suspension at the end of time, a, is:

$$B_a = B\left(1 - \frac{a}{t}\right) \quad \text{.............................(4)}$$

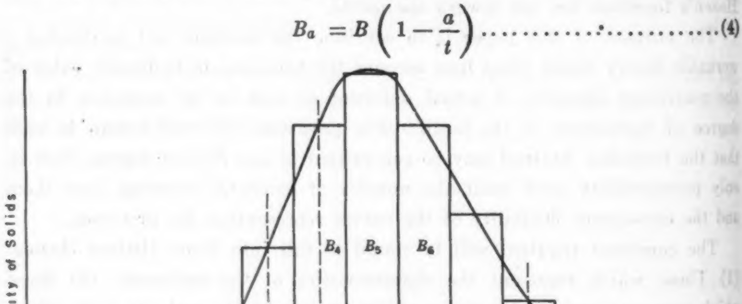

FIG. 1.

This is Hazen's first formula. It is of fundamental importance, all subsequent expressions being obtained from it by means of integrations and summations.

Assume now that, instead of a constant hydraulic value, the constituent particles have values, v, ranging continuously from a minimum, v_M, to a maximum, v_m, and let t be the time it takes the particles of hydraulic value, v, to fall from the surface to the bottom of the tank; t will then range from a minimum, t_m, to a maximum, t_M, since $t = \frac{h}{v}$. In general, it will not be known what proportion of the suspended solid matter has a given hydraulic value; but this unknown distribution function of the times of subsidence may be designated as $\phi(t)$; thus, $\phi(t)\,dt$ is the quantity of suspended matter having times of subsidence between t and $t + dt$; or, what amounts to the same thing, having hydraulic values lying between v and $v + dv$ (see Fig. 1). Before attempting to determine this function it is well to note some of its formal properties.

If it is required to find the quantity of sediment, dB_a, remaining in suspension at the end of time, dt, the hydraulic values of which lie between v and $v + dv$, Equation (4) and the definition of the distribution function yield:

$$dB_a = \phi(t)\left(1 - \frac{a}{t}\right)dt \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

The total quantity remaining at the end of time, a, will be the integral of this expression; that is:

$$B_a = \int_{p(a)}^{t_M} \phi(t)\left(1 - \frac{a}{t}\right)dt \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

The integration, being with respect to the times of subsidence, must range from t_m to t_M. The upper limit of this integral is certainly t_M. At first, the lower limit must be t_m, because particles of all hydraulic values are falling; but after a time, $a = t_m$, those particles of greatest hydraulic value will all have fallen. In general, at the end of time, $a = t_1$, say, all particles of hydraulic values greater than v_1 will have fallen to the bottom of the tank. Consequently, after a time of settling, $a = t_m$, the lower limit of the integral must be a.

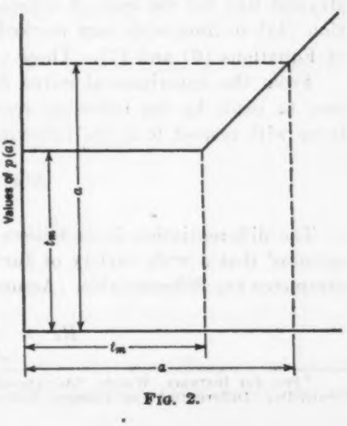

FIG. 2.

Referring to Fig. 2, let $p(a)$ equal t_m for all values of a less than t_m; and a for all values of a between t_m and t_M. Then Equation (6) as it stands will give the quantity of suspended solids remaining at the end of time, a, for all

values of a from 0 to t_M, when all the solids will have settled. This formula applies, of course, to the settleable solids.

What is considered settleable and colloidal solids is probably an arbitrary, although convenient, classification. In practice, some upper limit for the time of subsidence, t_M, might be set, particles having a greater time of subsidence than this being classed with the colloids. If the quantity of this colloidal and near-colloidal material is B_c, Equation (6) becomes:

$$B_a = \int_{p(a)}^{t_M} \phi(t) \left(1 - \frac{a}{t}\right) dt + B_c \ldots\ldots\ldots\ldots\ldots (7)$$

From the definition of the distribution function it is also to be noted that:

$$\int_{t_m}^{t_M} \phi(t)\, dt = B - B_c = B_s \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

Equation (8) merely states that the sum of all particles of all hydraulic values from v_m to v_M at the beginning of the process (that is, when $a = 0$) is equal to the quantity of settleable material.

The Distribution Function

In order to make use of Equations (6) and (7) as they stand it would be necessary to know the form of the function, $\phi(t)$, for the sediment in question, and, by experiment, this would be difficult. The direct procedure would consist in sorting the settleable solids according to size and applying Stokes' law (which gives the relation between size of particles and their hydraulic values) to the various classes found. The quantity in each class, plotted against the time of sedimentation thus found, would give $\phi(t)$.

It will now be shown, however, that $\phi(t)$ may be determined easily by using its formal properties, together with the experimental curve for B_a. This experimental sedimentation curve is readily determined; in fact, its determination constitutes a large part of the experimental work that has been done in the past on sedimentation investigations. Its shape varies from a straight line for the case of constant hydraulic value (represented by Equation (4)) to lines with very marked curvature given by formulas of the types of Equations (6) and (7). These types are sketched in Fig. 3.

From the experimental curve for B_a a graphical determination of $\phi(t)$ may be made by the following reasoning: If Equation (7) is differentiated twice with respect to a, the following relation is obtained,

$$\phi(a) = a \frac{d^2 B_a}{da^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

The differentiation is as follows: It is shown in treatises on the integral calculus[8] that a wide variety of functions defined by definite integrals with a parameter are differentiable. Assume that,

$$B_a = \int_{g(a)}^{f(a)} F(a, t)\, dt \ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

[8] See, for instance, Woods, "Advanced Calculus", Ginn & Co., 1926, pp. 141–143; also, Granville, "Differential and Integral Calculus", Ginn & Co., 1911, pp. 22–23.

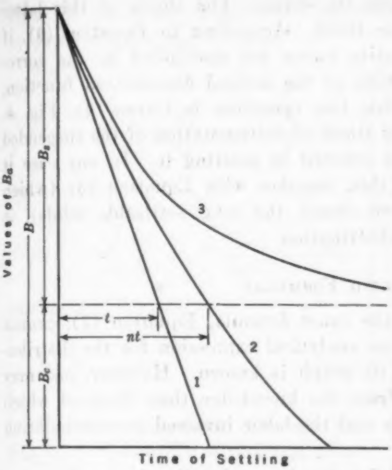

FIG. 3.

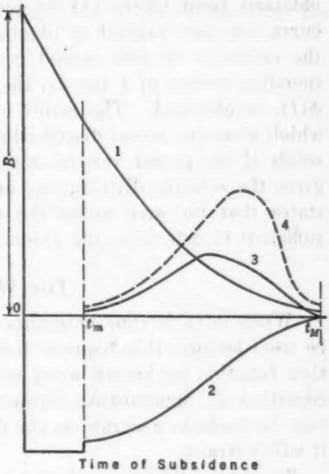

FIG. 4.

in which the limits are functions of the parameter, a, then the formula for differentiation is:

$$\frac{dBa}{da} = \int_{g(a)}^{f(a)} \frac{\partial F(a, t)}{\partial a} \, dt + F(a, f(a)) \frac{df(a)}{da} + F(a, g(a)) \frac{dg(a)}{da} \quad ..(11)$$

Applying Equation (11) to Equation (6) once:

$$\frac{dB_a}{da} = -\int_{p(a)}^{t_M} \frac{\phi(t)}{t} \, dt - \phi(a) \left[1 - \frac{a}{p(a)} \right] \frac{dp(a)}{da} \quad ......(12)$$

in which the middle term has disappeared because the derivative of the upper limit is zero. Now, the last term also vanishes because $\frac{dp(a)}{da} = 0$ for values of a less than t_m, and $\frac{a}{p(a)} = 1$ for values of a greater than t_m (see Fig. 2).

Applying Equation (11) to Equation (12):

$$\frac{d^2B_a}{da^2} = \frac{\phi[p(a)]}{p(a)} \frac{dp(a)}{da} = \frac{\phi(a)}{a} \quad ....(13)$$

which is Equation (9).

It is to be noted first that $\phi(a)$ is exactly the same thing as $\phi(t)$, because a and t assume the same values in the range, t_m to t_M. Since a derivative curve is the graph of the slopes of the original curve, Equation (9) indicates how to find $\phi(t)$ from the graph of B_a; that is, from the experimental sedimentation curve.

In Fig. 4, Curve (1) shows the quantity of solids remaining in suspension plotted against the time, as determined experimentally. Curve (2) has been

obtained from Curve (1) by plotting its slopes. The slopes of this latter curve are then plotted to obtain the third. According to Equation (9), if the ordinates of this second derivative curve are multiplied by the corresponding values of t (or a), the graph of the desired distribution function, $\phi(t)$, is obtained. The result of this last operation is Curve (4), Fig. 4, which gives the actual distribution of times of sedimentation of the suspended solids if the proper vertical scale is selected in plotting it. In any case it gives the relative distribution, and this, together with Equation (8) (which states that the area under the curve equals the total settleable solids), is sufficient to determine the absolute distribution.

The Working Formulas

When $\phi(t)$ is thus determined, the exact formula, Equation (7), cannot be used because this requires that the analytical expression for the distribution function be known when only its graph is known. However, one may construct an approximate formula from the knowledge thus obtained which may be made as accurate as the data and the labor involved in manipulating it will warrant.

To obtain this approximate equation break up the distribution function into a convenient number of parts, say n, as shown in Fig. 1, and take the average hydraulic value of each part. Equation (7) then becomes:

$$B_a = \sum_{r=1}^{n} B_r \left(1 - \frac{a}{t_r}\right) + B_c \quad \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

in which B_r is the quantity of sediment with an average hydraulic value, v_r; t_r is the corresponding time of subsidence.

Attention is called to the fact that when $a = t_1$ all the sediment with a hydraulic value of v_1 has fallen to the bottom and that, therefore, in Equation (14) the first term appears only for values of a less than t_1. As a increases past the value of each t_r, each term of Equation (14) drops out, successively. This progressive dropping of terms corresponds to the variable lower limit in the exact Equation (7). Obviously,

$$\sum_{r=1}^{n} B_r = B_s \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

This is merely the approximate form of Equation (8).

Discontinuous Distributions

It may happen that the sediment does not have a continuous distribution of hydraulic values, but that there are n kinds of particles of quantities, $B_1, B_2, \ldots\ldots, B_n$, with corresponding hydraulic values, $v_1, v_2, \ldots\ldots, v_n$. The experimental curve will then take the form of the broken line, Curve (1) of Fig. 5. In this case Equation (14) is the exact form, and the distribution function is the set of B-values. To obtain these quantities first differen-

tiate B_a given by Equation (14) with respect to a. Remembering the progressive dropping of terms:

For $a < t_1$:

$$D_1 = -\left(\frac{B_1}{t_1} + \frac{B_2}{t_2} \dots + \frac{B_n}{t_n}\right). \quad (16a)$$

for $t_1 < a < t_2$,

$$D_2 = -\left(\frac{B_2}{t_2} \dots + \frac{B_n}{t_n}\right) \dots . (16b)$$

and for $t < a < t_n$:

$$D_n = -\frac{B_n}{t_n} \quad \dots\dots\dots\dots\dots (16c)$$

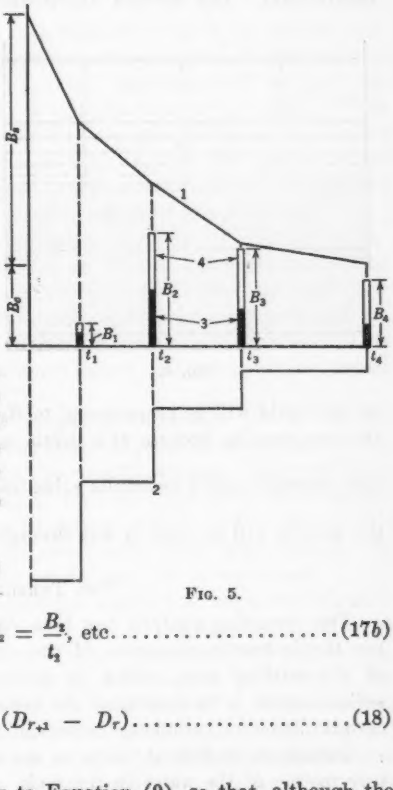

FIG. 5.

The step function (Curve (2), Fig. 5) is the result of plotting these quantities; that is, it is the graph of the slopes of the broken line, Curve (1), Fig. 5. The differences of every two successive values of D are expressed as:

$$D_2 - D_1 = \frac{B_1}{t_1} \quad \dots . (17a)$$

$$D_3 - D_2 = \frac{B_2}{t_2}, \text{ etc.} \dots\dots\dots\dots\dots\dots (17b)$$

or, generally,

$$B_r = t_r\,(D_{r+1} - D_r) \dots\dots\dots\dots\dots\dots (18)$$

in which $r = 1, 2, \dots, n$.

Equation (18) corresponds exactly to Equation (9), so that, although the step function given by Equation (16) cannot be properly said to possess a derivative other than zero, still the differences of the ordinates at the points of discontinuity are equal to the quantities, B, when multiplied by the corresponding values of t. These differences are shown by Ordinates 3 of Fig. 5, while Ordinates 4, obtained from Ordinates 3 by multiplying by the corresponding abscissas, represent the discontinuous distribution function; that is, they represent the set of Q-values.

STRATIFICATION OF SEDIMENT

It may be well to note here that quiescent sedimentation is characterized by the stratification that will occur in the upper regions of the basin. At the end of time, a, there will be a clear layer (except for fine colloids) of depth, $v_M\,a$, as shown in Fig. 6. From that level down to a depth, $v_m\,a$, the

suspended material will be found in increasing density (in layers if the distribution of hydraulic values is discontinuous, and gradual if the distribution is continuous). The vertical distribution of the density of suspended matter

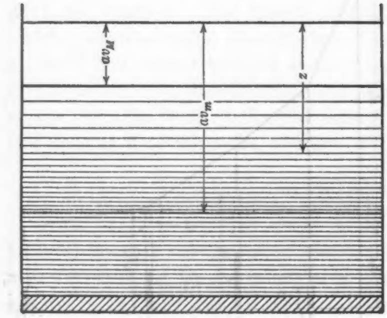

FIG. 6.

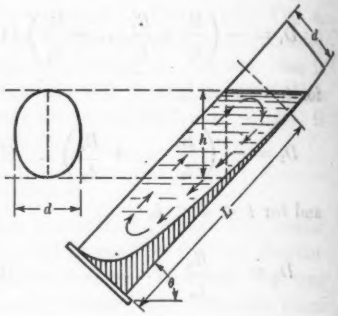

FIG. 7.

in the liquid will be proportional to B_a in Equation (7) or Equation (14), as the case may be, because at a depth, z, below the surface there will be found only material with a hydraulic value less than $\frac{z}{a}$. At a depth greater than $v_m a$, the density will be what it was throughout the basin originally.

THE TURBULENT TANK

The foregoing analysis has been developed for the purpose of determining the hydraulic properties of the solid material suspended in the liquid of the settling tank, which is seldom still. The important problem of sedimentation is to determine the behavior of the suspended matter when a certain degree of turbulence is present in the tank.

Turbulence is defined herein as the average degree of agitation or circulatory motion of the water in the tank. It is conceivable that this turbulence might be defined as some function of the average velocity but, for the purpose of the following analysis, this correlation with velocity need not be made. Just as in the preceding development it was not necessary to determine the masses or sizes of the constituent particles, so now the turbulence in the tank will be considered only as it affects the hydraulic behavior of the suspended material.

As treated in this paper, therefore, turbulence is quite a relative term. A certain amount of circulation in a tank which would not affect, appreciably, the time required for grains of sand to subside, for instance, might be sufficient to pick silt from the bottom and keep it in suspension as long as the circulation persisted. From the writer's point of view this same circulation would present two distinct degrees of turbulence, in this example: One with respect to the sand; and the other with respect to the silt. The degree of turbulence

is a difficult concept, but it seems reasonable to make the following simplifications (an extension of this classification will no doubt be made necessary by the results of future experiments).

Assume, first, the suspended matter in a basin of water to be uniform and of constant hydraulic value, v. If a slight circulatory motion be imparted to the water, the first appreciable effect which this agitation will have will be to lengthen the time of subsidence of the material from t to kt, say. With respect to this material the motion at this stage is termed "incomplete turbulence", the only appreciable effect of which is to lengthen the time of subsidence. Except for this increase, sedimentation in a tank in which the water is only slightly turbulent will be identical with quiescent sedimentation.

Assume, next, that the agitation is gradually increased. A state of turbulence will eventually arise in which the phenomenon of sedimentation will be radically different from that of the preceding state. The material that remains in suspension will be mixed thoroughly so that its density is uniform throughout the basin, and that which settles will remain at the bottom. This is the state of turbulence required in Hazen's theory. Herein it will be termed "complete turbulence".

Finally, if the agitation increases, a state of turbulence will be reached in which the material will not settle. The solids that may be at the bottom will be picked up and held in suspension, thoroughly mixed. This condition will be termed "critical turbulence". In all likelihood, the transition from one state of turbulence to another will not be sharply defined, and careful experiments may show transition stages that need to be taken into account. In what follows, however, only these three conditions will be considered.

Thus far, turbulence has been defined for material of constant hydraulic value, and, consequently, for variable circulation of the liquid. If, as is the usual case, a material of variable hydraulic values and fairly uniform circulation of the water is encountered, the foregoing notions may be applied in the following manner: Assume the material to have hydraulic values ranging from v_m to v_M, and assume the water to have a given uniform and constant degree of agitation; then there will be a value, v_i, such that for all particles with hydraulic values greater than v_i the turbulence will be incomplete. There will also be a value, v_c, such that the turbulence will be complete for particles with hydraulic values between v_i and v_c. This same agitation will be critical for all particles with hydraulic values less than v_c.

If the material in a tank is distributed with respect to its times of subsidence, as shown in Fig. 1, then, for a given agitation of the water, there will be two values of t — t_i and t_c, say—such that the turbulence is incomplete, complete, and critical in the intervals, t_m to t_i, t_i to t_c, and t_c to t_M, respectively. For some other degree of agitation these transition points will be t'_i and t'_c.

Incomplete Turbulence

For the state of incomplete turbulence the formulas obtained for quiescent sedimentation will hold with slight modifications. The only alteration will occur in the time of sedimentation of the various particles, which will increase

according to some law, $k(t)$, t being the time of settling in a quiescent basin. This law must be determined experimentally. Assuming it to be known, Equation (5) becomes:

$$dB_a = \phi(t)\left[1 - \frac{a}{k(t)}\right] dt \quad \ldots\ldots\ldots\ldots\ldots(19)$$

Equation (19) gives the quantity of sediment remaining in suspension at the end of the time in which the hydraulic values (in a quiet tank) lie within the interval, t and $t + dt$. For the total quantity of sediment remaining at the end of this time, instead of Equation (6) the formula is,

$$B_a = \int_{p(a)}^{t_M} \phi(t)\left[1 - \frac{a}{k(t)}\right] dt \ldots\ldots\ldots\ldots\ldots(20)$$

If instead of the function, $k(t)$, a set of factors, $k_1, k_2, \ldots, k_n$, is determined which, for a given degree of agitation, gives the times of subsidence, $k_1 t_1, k_2 t_2, \ldots, k_n t_n$, of particles for which the times of subsidence in the still tank are $t_1, t_2, \ldots, t_n$, respectively; then the approximate Equation (7) becomes:

$$B_a = \sum_{r=1}^{n} B_r \left(1 - \frac{a}{k_r t_r}\right) \ldots\ldots\ldots\ldots\ldots(21)$$

These factors, k_r, depend both on the hydraulic values of the particles and on the degree of turbulence in the tank.

Complete Turbulence

It is with the state of complete turbulence, as defined herein, that Hazen was chiefly concerned.[3] The characteristic feature of this state is that the turbulence is sufficient to keep the sediment uniformly distributed throughout the tank, but not sufficient to pick up that which has once fallen to the bottom.

To determine the quantity of sediment (assumed at present to have a constant hydraulic value, v) that remains in suspension at the end of time, a, it is proposed to follow Hazen's procedure in its essentials: The time, a, is divided into n equal parts, each interval, $\frac{a}{n}$, being so small that the water in the tank may be considered quiet during that time. At the end of the first interval, the quantity, B_1, of sediment remaining will be, by Equation (4),

$$B_{1a} = B\left(1 - \frac{a}{n\,t}\right) \quad \ldots\ldots\ldots\ldots\ldots(22)$$

At the end of the second interval the quantity remaining will be,

$$B_{2a} = B_1\left(1 - \frac{a}{n\,t}\right) = B\left(1 - \frac{a}{n\,t}\right)^2 \ldots\ldots\ldots\ldots(23)$$

Repeating the process n times the quantity at the end of time, a, will be:

$$B_a = B\left(1 - \frac{a}{n\,t}\right)^n \qquad \text{.....................(24)}$$

This is, substantially, Hazen's second formula. This is the form in which it was presented and has since been retained, but it is awkward to apply. However, it attains a definite limit as the number, n, of divisions is made indefinitely great, which is, of course, the actual condition.

The base of natural logarithms is usually defined[3] as:

$$e = \underset{(m=0)}{\text{limit}}\,(1 + m)^{\frac{1}{m}} \qquad \text{.....................(25)}$$

If $m = -\dfrac{a}{n\,t}$, Equation (24) becomes:

$$B_a = B\,(1 + m)^{-\frac{a}{m\,t}} = B\left[(1 + m)^{\frac{1}{m}}\right]^{-\frac{a}{t}} \qquad \text{............(26)}$$

and, in the limit, n becomes infinite, m becomes 0, and the expression in brackets becomes e (Equation (25)). Therefore (see Fig. 3, Curve (3)):

$$B_a = B\,e^{-\frac{a}{t}} \qquad \text{..........................(27)}$$

If, as before, instead of material with constant hydraulic value, the water carries in suspension solids with times of subsidence distributed according to the function, $\phi(t)$, then the quantity of material remaining in suspension at the end of time, a, is:

$$B_a = \int_{t_m}^{t_M} \phi\,(t)\,e^{-\frac{a}{t}}\,dt \qquad \text{...................(28)}$$

It is to be noted that, in Equation (28), unlike the case of Equation (6), the lower limit is t_m throughout the process, because, since the turbulence is complete, none of the material ever settles completely. This expression does not yield a simple relation connecting the sedimentation curve with the distribution function analogous to that of Equation (9). It is for this reason that it is necessary to determine the function, $\phi(t)$, from the sedimentation curve for the quiescent state. The distribution function is a property of the sediment only, of course, and so is quite independent of the state of turbulence.

Mathematically, Equation (28) presents no great difficulty. By a slight transformation it becomes what is known as an integral equation of the Laplace-Fourier type. Such integral equations have wide application in physics and engineering. There are many useful relations known that exist between the sedimentation curve, B_a, and the distribution function, $\phi(t)$, connected as in Equation (28); but the writer has failed to find one with a simple graphical interpretation such as that of Equation (9).

From this formula (Equation (28)), an approximate formula is derived:

$$B_a = \sum_{r=1}^{n} B_r\,e^{-\frac{a}{t_r}} \qquad \text{......................(29)}$$

which is the exact form when the distribution is discontinuous.

Critical Turbulence

Material for which the turbulence in a settling tank is critical does not settle, because that which reaches the bottom is picked up again. For turbulence of this type, $B_a = B_c$, in which B_c is the material with time of subsidence greater than t_c as previously defined.

The Actual Basin

In any settling tank there will ordinarily be material with a wide range of hydraulic values, so that the normal circulation of the water in the basin will be turbulence of one or another of the types described herein for some part of the sediment. As has already been stated, a proportion of the sediment will have times of subsidence between t_m and t_i for which the turbulence will be incomplete, another portion with times of subsidence between t_i and t_c for which the turbulence will be complete and, finally, a part with times of subsidence greater than t_c for which the turbulence will be critical (see Fig. 1).

The constants, t_i and t_c, are characteristic of the tank. They measure the turbulence of the fluid in it. They are taken into account in the general formula for the settling basin by noticing that they become limits of integration. Combining all results, the general expression for the sediment remaining in suspension at the end of time, a, is:

$$B_a = \int_{p(a)}^{t_i} \phi(t) \left[1 - \frac{a}{k(t)} \right] dt + \int_{t_i}^{t_c} \phi(t)\, e^{-\frac{a}{t}}\, dt + B_c \ldots\ldots (30)$$

From Equation (30) the approximate expression is obtained, which will be exact for the case of discontinuous distribution of hydraulic values, by dividing the range, t_m to t_c, into n parts, of which the first, s, will be in the range from t_m to t_i. Summing over these ranges:

$$B_a = \sum_{r=1}^{s} B_r \left(1 - \frac{a}{k_r\, t_r} \right) + \sum_{r=s+1}^{n} B_r\, e^{-\frac{a}{t_r}} + B_c \ldots\ldots\ldots (31)$$

This general expression may be carried to any degree of refinement, but in engineering practice a very few terms should suffice. It exhibits at once the constants of the theory and their categories: The B-values which are characteristic of the sediment; the limits of summation (or integration), which separate the expression into three groups, corresponding to the three kinds of turbulence, and which are characteristic of the basin; and the k-values, which depend both on the basin and the sediment.

Examples

A. W. Dilling, Assoc. M. Am. Soc. C. E., and Langdon Pearse, M. Am. Soc. C. E., report[4] the results of certain experiments which may be used to illustrate the theory developed herein. Samples of sludge were settled in

[4] Rept. on Industrial Wastes from the Stockyards and Packingtown in Chicago, by A. W. Dilling and Langdon Pearse, Vol. II, January, 1921 (The Sanitary Dist. of Chicago), pp. 140–141.

glass cylinders and the sedimentation curves recorded. The cylinders were held upright and also inclined at various angles. These experiments were intended to show the effect of inclination on the rate of settling. What actually happens is that the height, L, through which the sediment falls in the upright cylinder is reduced to the height, $h = d \sec \theta$, as is shown in Fig. 7, when the cylinder is inclined at an angle, θ. A circulatory motion is steadily induced in the liquid, probably due to the downward slipping of the sediment on the side of the glass.

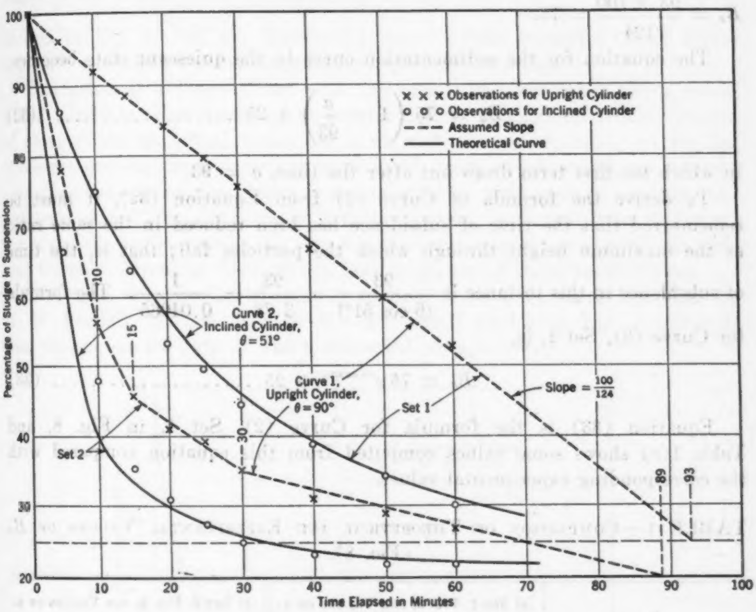

FIG. 8.

Consequently, there is: (1) Quiescent settling through the height, L, in the upright cylinder; and, then (2), turbulent settling through the height, $h = d \sec \theta$. Two sets of curves from the report by Messrs. Dilling and Pearse are shown in Fig. 8; in both sets, Curve (1) is for the upright cylinder ($\theta = 90°$), and Curve (2) is for the cylinder inclined at an angle of $\theta = 51$ degrees. Messrs. Dilling and Pearse do not give the dimensions of the cylinders. It will be assumed that $d = \frac{L}{6}$. From the description given of the circulation in the inclined cylinder, the turbulence may be assumed to be complete for the sludge of the experiments. If, from the curve for the upright cylinder, the distribution of hydraulic values of the sediment are determined, it should be possible to predict the behavior of the sediment in the inclined cylinder.

Curve (1), Set 1, for the upright cylinder, shows the sediment to have quite a uniform value, as far as the experiment has been run. The curves are not extended far enough to determine the quantity of colloidal and near-colloidal matter in the sediment, but all those for the inclined cylinders in this particular experiment seem to approach a horizontal line 25 units above the horizontal axis; for this reason the value of B_c was adopted. Since there is only one type of settleable material, $B_s = 100 - 25 = 75$. This value may also be determined by the use of Equation (18) (see Fig. 8, Set 1); thus,

$$B_s = \frac{93 \times 100}{124} = 75.$$

The equation for the sedimentation curve in the quiescent state becomes:

$$B_a = 75\left(1 - \frac{a}{93}\right) + 25 \quad \text{.................... (32)}$$

in which the first term drops out after the time, $a = 93$.

To derive the formula of Curve (2) from Equation (32), it must be remembered that the time of subsidence has been reduced in the same ratio as the maximum height through which the particles fall; that is, the time of subsidence in this instance is $\frac{93}{(6 \cos 51°)} = \frac{93}{3.78} = \frac{1}{0.04065}$. The formula for Curve (2), Set 1, is,

$$B_a = 75\, e^{-0.04065a} + 25 \quad \text{.................... (33)}$$

Equation (33) is the formula for Curve (2), Set 1, in Fig. 8, and Table 1(a) shows some values computed from this equation compared with the corresponding experimental values.

TABLE 1.—COMPARISON OF THEORETICAL AND EXPERIMENTAL VALUES OF B_a (FIG. 8).

By:	(a) SET 1, FIG. 8, FOR VALUES OF a:					(b) SET 2, FIG. 8, FOR VALUES OF a:				
	0	10	20	40	60	0	10	20	40	60
Formula	100	75	58.3	39.8	31.5	100	39.6	29.9	23.7	21.5
Experiment	100	75	53	39	30	100	48	31	23	21.5

Curve (1), Set 2, Fig. 8, for the upright cylinder, represents sediment with a variety of hydraulic values. For reasons similar to the previous case, B_c is assumed as 20. As shown in Fig. 8, four slopes are taken, and their values are determined, by scaling, to be: $D_1 = 4.350$; $D_2 = 2.195$; $D_3 = 0.700$; and $D_4 = 0.224$, and the corresponding times of subsidence are (see Fig. 8, Set 2): $t_1 = 10$; $t_2 = 15$; $t_3 = 30$; and $t_4 = 89$.

From Equation (18): $B_1 = t_1 (D_1 - D_2) = 10 (4.350 - 2.195) = 21.55$; and, $B_2 = 22.50$; $B_3 = 14.30$; and $B_4 = 20$. If there were no errors in the process, these would be the actual values of B. The scaling has not been done very accurately, however, and the sum of these quantities (which, by

Equation (15), should be 80) is 78.35. Stating these quantities in round numbers: $B = 22, 23, 15$, and 20, respectively. Consequently, the equation of Curve (2), Set 2, is:

$$B_a = 22\,e^{-\frac{3.78a}{10}} + 23\,e^{-\frac{3.78a}{15}} + 15\,e^{-\frac{3.78a}{30}} + 20\,e^{-\frac{3.78a}{89}} + 20 \ldots\ldots (34)$$

In this case, as in that of Equation (33), and for the same reason, the times of subsidence must be multiplied by the factor, $\dfrac{1}{3.78}$. This curve is plotted in Fig. 8, Set. 2. Table 1(*b*) shows values computed from Equation (34) compared with corresponding experimental values.

The writer is not acquainted with the results of other experiments which would illustrate these relations in greater detail. He has seen many curves of observations on actual tanks, but none with the corresponding curves for quiescent settling, and no experiments at all from which an estimate might be made of the transition points from one state of turbulence to another. As has been stated, the distribution function cannot be found from the curve for turbulent sedimentation, so that wherever the writer has applied the general formula, Equation (31), it has been a matter of mere curve fitting.

The next example is selected at random from data made available by H. N. Lendall, M. Am. Soc. C. E. The small circles in Fig. 9 represent observations on the rate at which untreated sewage settles.

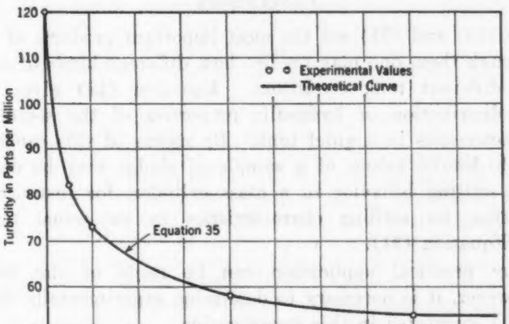

Fig. 9.

To fit a curve to these data by Equation (31) it was assumed that one term would be sufficient to take into account the portion of the sediment for which the turbulence in the basin was incomplete, and two terms for the portion for which the turbulence was complete; that is, Equation (31) became simply:

$$B_a = B_1\left(1 - \frac{a}{k_1\,t_1}\right) + B_2\,e^{-\frac{a}{t_2}} + B_3\,e^{-\frac{a}{t_3}} + B_c \ldots\ldots\ldots (35)$$

To a certain extent the value one selects for the times of subsidence is a matter of choice. Fig. 1 shows the B-values determined from a certain distribution function for one choice of t-values, and Fig. 10 shows the B-values determined from the same distribution function for another choice of t-values. It was assumed that $k_1 t_1 = 15$ (since k_1 is not known, it is impossible to state the corresponding values, t_1); $t_2 = 30$; and $t_3 = 120$. By trial and error, or by any other method of curve fitting, the B-values are determined to be 25, 30, 13, and 52, respectively.

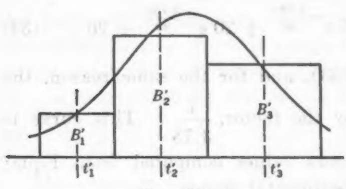

FIG. 10.

Equation (35) then, becomes,

$$B_a = 25\left(1 - \frac{a}{15}\right) + 30\, e^{-\frac{a}{30}} + 13\, e^{-\frac{a}{120}} + 52 \ldots\ldots\ldots\ldots (36)$$

in which it must be remembered that the first term drops out for values of a greater than 15.

In a way, of course, this curve-fitting procedure furnishes a means of determining the distribution function (the B-values), but since the distribution function is not what one usually wants, no importance should be attached to it.

CONCLUSIONS

Equations (18) and (31) are the most important products of this investigation. Through them one may predict how different kinds of sediment will settle under different tank conditions. Equation (18) gives the relation between the distribution of hydraulic properties of the sediment and its settling characteristics in a quiet tank. By means of this equation the distribution of hydraulic values of a sample of sludge may be determined by observing its settling behavior in a glass cylinder, for instance. Knowing this distribution, its settling characteristics in an actual tank may be predicted by Equation (31).

Before any practical application can be made of the theory herein developed, however, it is necessary to determine experimentally the constants, (t_i, t_c, k_r, etc.), suggested in this investigation.

APPENDIX

NOTATION

a = time during which sedimentation occurs; $p\,(a)$ = function of a;
b = quantity of solids, B, per unit volume;
c = a subscript denoting "colloidal", "complete", or "critical", as defined in each case;
d = inside diameter of a glass cylinder;

$f =$ } functional symbols;
$g =$ }
$h =$ height; depth of a settling basin;
$i =$ a subscript denoting "incomplete";
$k =$ a coefficient; k_1, k_2, etc. = coefficients that produce the average times of subsidence, $k_1 t_1$, $k_2 t_2$, etc., under certain conditions of turbulence for particles with times of subsidence in a still basin equal to t_1, t_2, etc.;
$m =$ a substitution factor $= -\frac{a}{nt}$; as a subscript denoting "minimum" when used with times of settling, and "maximum" when used with hydraulic values, $t_m = \frac{h}{v_m}$;
$n =$ a number, such as a number of parts;
$p =$ a functional symbol;
$s =$ a number of parts, less than n; as a subscript, s denotes "settleable";
$t =$ time of subsidence; t_m = minimum time corresponding to v_m; t_M = maximum time corresponding to v_M; t_1 and t_2 = times corresponding to v_1 and v_2, respectively; t_r = time corresponding to v_r; t_c = time required for complete or critical turbulence; $\phi(t)$ = distribution function of hydraulic values of suspended matter; as a subscript, t denotes "total";
$v =$ a hydraulic value or the limiting velocity of a particle as it settles in a liquid; v_m = a maximum value: v_M = a minimum value; v_i = limit value for incomplete turbulence (turbulence is incomplete for $v_i < v$); v_c = limit value for complete or critical turbulence (turbulence is complete for $v_i < v < v_c$ and critical for $v < v_c$);
$y =$ distance of a suspended particle above the floor of a settling basin;
$z =$ distance from the water surface to a given depth;
$A =$ horizontal area of a tank or stilling well;
$B =$ quantity of solids; B_a = quantity remaining in suspension at the end of time, a; B_t = total quantity in a given basin; B_s = quantity of settleable matter in a basin; B = quantity in a colloidal state, including that part of the settleable solids with hydraulic values, v, so small that, for practical purposes, they may be considered as in colloidal suspension; B_1, B_2, etc., = quantities with hydraulic values, v_1, v_2, etc.; B_r = quantity with an average hydraulic value, v_r;
$D =$ a derivative of B_a in Equation (14);
$F =$ a functional symbol;
$L =$ length of a glass cylinder;
$M =$ a subscript denoting "maximum", when used with t; "minimum" when used with v;
$\theta =$ inclination of a glass cylinder, with the horizontal;
$\phi =$ a function; $\phi(t)$ = distribution function of hydraulic values of suspended matter.

DISCUSSION

THOMAS R. CAMP,[5] M. AM. SOC. C. E. (by letter).—In his paper Professor Slade revives interest in the development of a theory which is much needed for the design of sedimentation basins. Considerable attention has been given to this subject for a great many years among those concerned with water and sewage clarification. Despite this interest, it appears that an effective attack upon the problem in a rational way has not yet been made. The author's attempt to use a "distribution function" to describe the suspension is a step in the right direction. It is to be regretted, however, that so much of the paper is premised upon the validity of the assumptions made by the late Allen Hazen, M. Am. Soc. C. E., in his paper[6], published in 1904, setting forth what has become known as "Hazen's theory of sedimentation". Although Hazen's paper contained something of value toward the development of a rational theory, it fell far short of presenting a complete theory of sedimentation. Moreover, Hazen's theory contains so many invalid assumptions that it is of little practical use to sanitary engineers in design.

In order to discuss the present paper, it will be necessary to revive the discussion of Hazen's paper and also to refer to the paper entitled "Cleaning Water by Settlement"[7] by the late James Alexander Seddon, M. Am. Soc. C. E., which influenced Hazen considerably in the development of his theory.

As pointed out by Professor Slade, the settling in still water of a suspension of discrete particles, each of which settles at a constant velocity, will result in a faster clearing near the top of the basin than below it. The concentration of suspended matter will be reduced continuously during the settling period, but it will be greater near the bottom than near the top. Seddon anticipated this stratification, but found in experimenting with the sedimentation basins of the St. Louis (Mo.) Water-Works that the density was practically the same at depths of 2, 4, 6, and 8 ft. He considered both vertical mixing and coagulation in order to explain this inconsistency, and he concluded that the uniform density distribution was due to vertical mixing and not to flocculation. No scientific observations were made to support this conclusion, and it was drawn in spite of the fact that an increase in wind velocity over the basin from zero to 11 miles per hr produced no measurable effect upon the settling.

Hazen accepted the observations of Seddon that the concentration of suspended matter did not vary appreciably with depth, and he also accepted Seddon's conclusion that the cause was vertical mixing. No experimental data were presented by Hazen to substantiate either Seddon's observations, or his conclusions, and coagulation was definitely excluded in Hazen's theory as a contributing cause of uniform concentration.

It is well known that practically all the suspensions dealt with by sanitary engineers are composed of particles which are subject to flocculation during

[5] Associate Prof. of San. Eng., Mass. Inst. Tech., Cambridge, Mass.

[7] *Journal*, Assoc. of Eng. Societies, 1889, p. 477.

settling. It is not well known, however, that flocculation takes place to so great an extent in most cases as to invalidate the assumption that each particle settles at a constant velocity. Even with clay suspensions, such as Seddon was dealing with, flocculation takes place. In making wet mechanical analyses of clays by the hydrometer method, it is necessary to treat the suspensions with a peptizing agent, such as sodium silicate, in order to avoid the effects of coagulation.

The writer has been studying sedimentation both theoretically and experimentally during the past several years. In some of the experiments, the settling of ferric hydrate floc was studied in glass tubes equipped with sampling cocks at various depths below the water surface. Some samples, drawn simultaneously during settling from different depths, have shown substantially the same iron concentration. Other simultaneous samples have indicated slightly higher concentrations near the bottom, and still others have indicated slightly higher concentrations near the top. Similar analyses made in terms of suspended solids upon the suspension in the coagulation basin of the Cambridge (Mass.) filter plant, where alum is used for coagulation, have indicated a very small increase in concentration with depth. In the glass-tube experiments protected from temperature changes residual mixing currents could be observed for a period of only about 20 min after filling, but substantially uniform concentration throughout the depth was observed in some of the samples withdrawn as late as 7 hr after the water became quiet. Coalescence of particles during settling could be seen at any time during the period. Larger particles were observed to overtake smaller ones, enmesh them, and thus increase their size and hydraulic value.

In his discussion of Hazen's paper, the late Galen W. Pearsons, M. Am. Soc. C. E., describes[8] some experiments made under his direction preparatory to the design of the Kansas City (Mo.) settling basins. Three glass tubes, 3 in. in diameter and 5, 10, and 15 ft high, respectively, were filled with Missouri River water which was allowed to settle. To quote Mr. Pearsons,

> "As it cleared gradually the writer was able to see particles descending near the bottom of the 15-ft tube; at times, something of the same could be discerned in the 10-ft tube, but with difficulty, and none at any time in the 5-ft tube.
>
> "These particles, by their uniform shape, explained their origin and action; they were pear-shaped, or rather like little tadpoles swimming head down, the tails tapering to invisibility; plainly some larger particle by its quicker descent had overtaken and joined smaller ones, and, increasing by constant addition, had at last become visible, their motion near the bottom being so rapid that, if it had been uniform, but a few minutes would have been required for the whole descent."

The writer does not conclude as a result of these observations that the effect of coagulation will be the same for all suspensions or the same throughout the settling period for any one suspension. There is every reason to suppose that coagulation may be completely absent with certain granular suspensions, and may exhibit its effects in varying degrees with other suspen-

[8] *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 72.

sions. In some cases the concentration may be greater near the bottom and in others it may be less, all due to the degree of flocculation without any consideration of vertical mixing.

It is not the writer's contention that no vertical mixing takes place in sedimentation basins. Eddy currents are obvious in most basins of the continuous-flow type at the influent end. These eddy currents do not occupy any appreciable portion of the volume of the basin, however. Eddy currents are also produced by obstructions in basins, such as baffles, and by sludge-removal equipment. Convection currents due to temperature changes are sometimes present. Eddy currents so uniform in type and distribution throughout the basin as to produce the uniform distribution of suspended matter throughout the depth which has been observed, certainly do not exist for any considerable time in any basin. By means of dyes, the writer has observed the time required to damp the eddies produced by small submerged jets with a velocity of 1 ft per sec, and has found few of the eddies to last more than about 15 min.

It should be clearly understood that Hazen assumed the existence of vertical mixing in order to account for the uniform vertical distribution of suspended particles. There was no other object for this assumption. If vertical mixing is the cause of uniform concentration, the clarification process will be less rapid than in the case of still water. If flocculation is the cause, clarification will be more rapid than with discrete particles in still water. The importance of this assumption is thus apparent. That flocculation is the cause is evidenced again by the much greater speeds with which clays which have not been peptized will settle out in wet, mechanical, soil analysis. If the concentration of suspended matter in a basin is the same from top to bottom, but decreases as the time of settling increases, it is difficult to escape the conclusion that the removal is a function of the detention period and is thus not independent of the basin depth.

Acceptance of the validity of Hazen's equations results in the conclusion that the percentage removal of sediment for a given discharge is a function of the surface area of the basin and independent of the depth. The introduction of the author's distribution function into Hazen's equations does not modify this conclusion. It is well to note that the author's equations apply to both fill and draw basins and continuous flow basins. As applied to continuous flow basins, the direction of flow is assumed to be horizontal and the velocity is assumed to be uniform over any cross-section of the basin. If the depth of the basin is reduced to $\frac{h}{2}$, for example, the settling period, a', will be equal to $\frac{a}{2}$; t' becomes $\frac{t}{2}$; and,

$$B'_a = B' e^{-\frac{a'}{t'}} = B' e^{-\frac{a}{t}} \quad \text{.....................(37)}$$

Since $B'_a = \frac{1}{2} B_a$ and $B' = \frac{1}{2} B$, the removal expressed as a ratio is,

$$\frac{B'_a}{B'} = \frac{B_a}{B} = e^{-\frac{a}{t}} \quad \text{.....................(38)}$$

The point is that Hazen's theory maintains that depth has no influence upon removal, a conclusion in support of which there is no experimental evidence from basins clarifying water and sewage.

The selection of the experiments of Dilling and Pearse[4] upon the consolidation of sewage sludges in glass cylinders, by Professor Slade to illustrate his theory was an unfortunate one. In the first place, flocculation was present in these tests to a marked degree and was described fully by the experimenters. In the second place, the portion of the liquid occupied by the sludge was observed by noting the position of the top of the sludge blanket. This percentage of sludge by volume as reported by the experimenters is a very different thing from the percentage of sludge in suspension, the interpretation given by the author. After a brief time, none of the sludge is in suspension. All of it is supported by the bottom, and each particle thereafter settles at a diminishing rate. Consolidation is a vastly different phenomenon from free sedimentation. In sedimentation, the resistance to settlement is due entirely to the viscosity of the fluid. In consolidation, this resistance is augmented by the supporting power of the particles below.

The writer has made use of a distribution function in a theory of sedimentation of discrete particles, flocculation being excluded. Although this theory cannot be used for most of the suspensions dealt with by sanitary engineers, nevertheless it may be of value toward the development of a complete theory

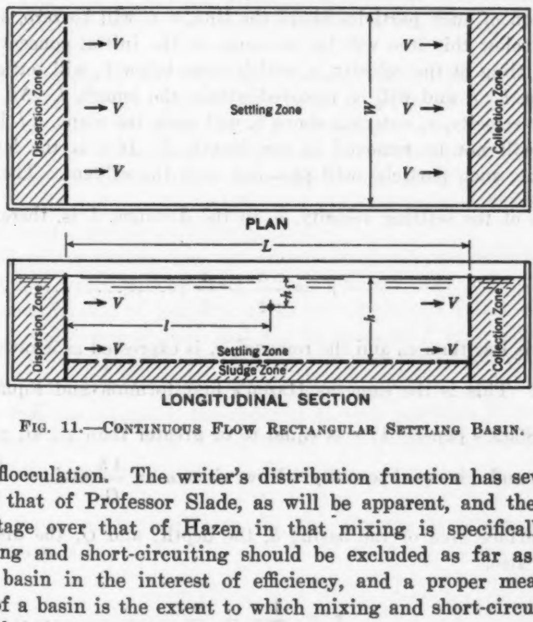

FIG. 11.—CONTINUOUS FLOW RECTANGULAR SETTLING BASIN.

including flocculation. The writer's distribution function has several advantages over that of Professor Slade, as will be apparent, and the theory has the advantage over that of Hazen in that mixing is specifically excluded. Both mixing and short-circuiting should be excluded as far as possible in an actual basin in the interest of efficiency, and a proper measure of the efficiency of a basin is the extent to which mixing and short-circuiting reduce the removal.

The notation used by Hazen and by Professor Slade will be utilized as far as is convenient. The theory will be presented for a "perfect", continuous-flow, rectangular basin. In such a basin it will be assumed that all settling takes place in a "settling zone", as shown in Fig. 11. As conceived by Hazen, a particle will be assumed to be removed if it reaches the bottom of the basin, or the top of the sludge blanket within the settling zone. Flow in the settling zone is assumed to be uniformly horizontal and at the same velocity, V, and direction throughout. The concentration of all suspended particles is assumed to be the same at all points in the plane of entrance to the settling zone.

In view of the assumptions made, the paths of the particles will be straight lines and all particles settling at the same velocity will move in parallel lines. The velocity and direction of settling of each particle will be the vector sum of its own hydraulic value and the velocity of flow of the liquid. Moreover, the settling pattern will be the same in all longitudinal sections of the settling zone, and any longitudinal section may be considered as shown in Fig. 12, in order to study the removal.

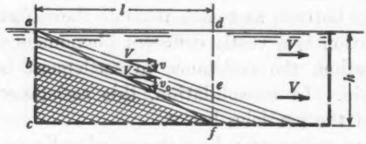

FIG. 12.—LONGITUDINAL SECTION, SHOWING PATHS OF PARTICLES IN SETTLING ZONE.

Consider any part of the length, l, of the settling zone. Particles which settle at the velocity, v, will move along paths parallel to the line, $a\ e$. The concentration of such particles above the line, $a\ e$, will be zero, and the concentration below this line will be the same as the initial concentration. All particles settling at the velocity, v, which enter below b, will settle within the shaded zone, $b\ c\ f$, and will be removed within the length, l. All particles of the settling velocity, v, entering above b, will cross the plane, $d\ f$, below e and, therefore, will not be removed in the length, l. If l is the length of the settling zone, such particles will pass out with the effluent. The removal, r, of particles of the settling velocity, v, in the distance, l, is, therefore, $\frac{b\,c}{h}$, or,

$$r = \frac{v\,a}{v\,t} = \frac{a}{t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (39)$$

in which v is less than v_0 and the removal, r, is expressed as a ratio; r is equal to $1 - \frac{B_a}{B}$. This is the same as Hazen's first formula and Equation (4) of Professor Slade's paper. If v is equal to or greater than v_0, all particles will be removed and r is equal to unity. Now, since $a = \frac{A\,h}{Q}$ and $t = \frac{h}{v}$, in which A is the surface area of the basin; h, the depth; and Q, the discharge; the removal is, also,

$$r = \frac{A\,v}{Q} = \frac{v}{v_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

Equation (40) is Hazen's formula[9] and the writer's fundamental equation for discrete particles. From this equation, it may be noted that the removal of particles which settle at any constant velocity, v, less than v_0, is directly proportional to the surface area for any given discharge and is independent of the depth; or that the removal of such particles is inversely proportional to the "overflow rate", v_0. It may be noted that v_0 is equal to $\frac{Q}{A}$. The overflow rate is equivalent to a velocity, although it is most frequently stated in terms of the discharge per unit of surface area. All particles that settle at velocities equal to or in excess of v_0 will be removed. Hence, the removal from a suspension of discrete particles of varying hydraulic value will be a function of the surface area and independent of the depth of the basin.

An analysis of the suspension in terms of the settling velocities (that is, a distribution function) is required in order to predict removal for suspensions composed of discrete particles of different hydraulic values. Professor Slade has chosen to state his distribution function in terms of the time of settling of each particle from top to bottom. Although the function thus stated does describe the suspension, it is not independent of the depth of the basin. The writer prefers to state the function in terms of the hydraulic values of the particles. This practice has another advantage in that the settling velocity of very fine particles approaches zero, and zero may be used as a limit for integration. The time of settling of such particles approaches infinity, and, as the author has discovered, involves difficulties in the selection of an upper limit for integration.

The writer prefers to state the distribution function in terms of a mass curve, such as Fig. 3 of the paper, rather than as a rate curve such as Fig. 1. The distribution function thus stated will be analogous to a sieve analysis curve for sand. The advantages of this practice are that quantities are shown as linear dimensions rather than as areas; such a distribution function is more easily determined experimentally; and the computations for the removal of suspended matter are simplified very much.

Using Hazen's practice, the concentration of all the sediment in the unsettled or raw water will be designated as unity. Let P be the ratio of the initial concentration of particles which have hydraulic values of v, or less, to the total initial concentration; and P_0, the value of P corresponding to v_0. A typical distribution function of this type is shown by the curve of Fig. 13.

Since all particles which settle faster than v_0 will be 100% removed in the time, a, and the length, l, the removal of such particles in terms of the initial suspension is $1 - P_0$. The removal of particles having any settling velocity, v, which is less than v_0 is $r = \frac{v}{v_0}$, and since the ratio of such particles to the total initial concentration is dP, the removal in terms of the total initial suspension is,

$$r\,dP = \frac{1}{v_0}\,v\,dP \qquad (41)$$

[9] *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 55, Equation (7).

To obtain the total removal of particles which settle at velocities of less than v_o, it is necessary to integrate Equation (41) between the limits of zero and P_o. The total removal, R, of all particles during the time, a, is therefore expressed as follows:

$$R = 1 - P_o + \frac{1}{v_o} \int_0^{P_o} v\, dP \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

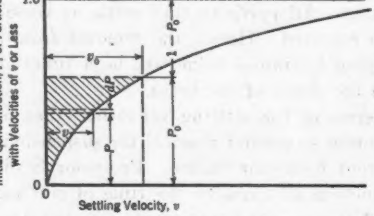

FIG. 13.—TYPICAL SETTLING VELOCITY ANALYSIS CURVE OF SUSPENSION.

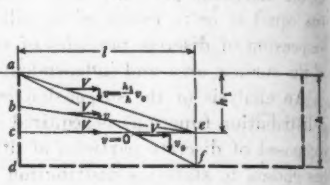

FIG. 14.—LONGITUDINAL SECTION OF SETTLING ZONE, SHOWING METHOD OF ESTIMATING CONCENTRATION AT A POINT.

If the equation of the analysis curve (that is, the distribution function) is known, the value of v in terms of P, or of dP in terms of dv, must be substituted in Equation (42), in order to solve the integral analytically. The expression under the integral sign, however, is the area on Fig. 13 shown shaded, and the last term of Equation (42) is the average vertical distance from the curve to the horizontal line at P_o. Hence, the removal may be measured graphically with sufficient accuracy by means of a planimeter, or with only a scale and slide-rule, without knowing the equation of the curve.

The concentration of suspended matter at any point in the settling zone, such as Point e on Fig. 14, may be estimated from the position of the point and the velocity-analysis curve of the original suspension.

Particles having any settling velocity, v, must cross the plane of entrance to the settling zone at b, in order to reach Point e. The concentration of such particles will be the same at Point e as at b, since they move along parallel paths, and the ratio to the total initial concentration, therefore, will be dP. Only particles that settle at velocities between zero and $\frac{h_1}{h} v_o$ can reach Point e. If the value of P on the velocity analysis curve which corresponds to the velocity, $\frac{h_1}{h} v_o$, is designated by P_1, the concentration of suspended matter, X, at any point, e, in terms of initial concentration will be,

$$X = \int_0^{P_1} dP = P_1 \ldots\ldots\ldots\ldots\ldots\ldots (43)$$

The value of the integral is simply P_1, which may be read from the velocity

analysis curve for any value of $\frac{h_1}{h} v_0$. The capital letter, X, has been used for the concentration at a point to distinguish from the average concentration in a vertical cross-section of the basin which Hazen denoted by the small letter, x. Now, since v_0 has one value at a given flow at any cross-section of the basin, it is obvious from Equation (43) that the density of suspended matter will be less near the top of the basin when settling discrete particles.

Equations (39) to (43) are also applicable to radial flow basins in settling discrete particles if the assumptions are made that flow is truly horizontal and radial at all points in the basin and that the velocity is the same at all points equi-distant from the center of the basin. The velocity, of course, will decrease, as the distance from the center increases, and all particles will settle along curved paths. Particles settling at the same velocity, however, will settle along parallel paths at any distance from the center of the tank.

If the frame of reference is transferred from the settling basin to the liquid moving within the settling zone, the velocity, V, becomes zero, and settling takes place as in still water. In other words, the settling which occurs in a vertical column of water as it moves through the basin is the same as that which occurs in an experimental tube, if all convection and eddy currents and wall effects are eliminated. Hence, experimental studies in tubes are an excellent means for determining the effects of coagulation in a "perfect" basin as defined previously. The difference between the observed concentration and that computed by means of Equation (43) is attributable to flocculation. It should be noted in this connection, that an experimental determination of the velocity analysis curve for discrete particles can be made readily; but no such curve exists for particles that flocculate since their velocities are increasing continuously.

In Fig. 11, the writer has shown a zone at the influent end of the basin for dispersion of the suspension uniformly over the cross-sectional area of the basin, and a similar zone at the effluent end for the collection of the clarified liquor uniformly over the cross-sectional area. It is very important in basin design to recognize the functions of these zones and to design them to perform their functions properly. This is an hydraulic problem which has not been effectively solved in the design of most existing basins. The penalties for inadequate solutions are vertical currents and short-circuiting, the latter being, undoubtedly, one of the major causes of basin inefficiency.

In the development of his theory, Hazen assumed the existence of vertical planes in the basin perpendicular to the direction of flow at which instantaneous decreases in concentration of sediment take place. To these planes, he gave the name, "baffles", and thereafter stated that real baffles such as vertical walls or partitions across the basin so as to divide it partially into two or more sections in series were equivalent in their function to his imaginary baffles. Such is not the case, and it is difficult to conceive of any physical device other than a fine screen or a filter placed in a vertical cross-section of the basin, which will produce a sudden decrease in concentration. All baffles across the direction of flow within the settling zone produce vertical currents

which tend to carry particles upward, produce higher velocities, and produce eddy currents. They are objectionable, therefore, within the zone of settling.

Many reports have been published which indicate improvements in settling efficiency due to baffling. The increases in efficiency were doubtless observed, but the cause had nothing to do with Hazen's theory or the effectiveness of baffles generally in increasing basin efficiency. The cause was an inadvertent lessening by the baffles of the degree of short-circuiting previously present, and a corresponding increase in the flowing-through period. The cause was not that the basin was divided into two or more parts by baffling, but that more of the volume of the basin was made effective for settling. The increase in efficiency could have been made more effectively by improving the design of both influent and effluent zones with the definite aim of minimizing short-circuiting.

HARRY H. HATCH,[10] M. AM. SOC. C. E. (by letter).—The author should be commended for his efforts to derive equations which will eliminate errors in the application of the Hazen formulas on sedimentation. Mr. Hazen applied the behavior of one particle size to an entire material in suspension. Obviously, this application can be justified only when the assumed value of t can satisfy the existing conditions.

In discussing Hazen's paper, "On Sedimentation", Robert Spurr Weston, M. Am. Soc. C. E.,[11] states:

"Mr. Hazen bases a large number of propositions on one value of t. It would be interesting to substitute other values of t,—for instance, infinity. In the latter case, t would be a quantity vastly different from those mentioned in the paper."

Professor Slade has attempted to do this and more.

It would be interesting to know the difference, if any, between "time of settling", "time of sedimentation", and "time of subsidence", as used by the author. If they all mean the same, it would have been better for the sake of clearness to use only one of the expressions throughout the paper.

The plotting on logarithmic scale of observed data for Curve (2), Set 2, Fig. 8, did not result in a simple equation satisfying all the points. Had there been numerous observational data on the same material in suspension, an average condition could have been assumed and expressed easily. If it is absolutely essential to fit a curve that will pass through every observation point (or reasonably so), the graph on the logarithmic scale could be broken up into sections, and a simple equation for each section within the limits could be expressed. However, a logarithmic-probability scale plotting of the data of Curve (2), Set 2, Fig. 8, resulted in a flat and smooth curve passing practically through all the observation values. The experimental value of 48% sludge in suspension at the end of 10 min, falls well on this curve; for which point the author had computed a percentage of 39.6 (see Table 1(*b*)), or a variation of $17\frac{1}{2}\%$ from the observed value.

[10] Engr. in Chg., Cobble Mountain Reservoir, Springfield Water-Works, Springfield, Mass.

[11] *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 77.

With respect to Fig. 9, the author states:

"* * * the distribution function cannot be found from the curve for turbulent sedimentation, so that wherever the writer has applied the general formula, Equation (31), it has been a matter of mere curve fitting."

He then begins with the formidable Equation (31) and reduces it "simply" to Equation (35), which is no less formidable; and then assumes certain unknown values and "by trial and error, or by any other method of curve fitting", arrives at Equation (36), which is cumbersome and far from being simple for practical work. The author further states,

"In a way, of course, this curve-fitting procedure furnishes a means of determining the distribution function (the *B*-values), but since the distribution function is not what one usually wants, no importance should be attached to it."

The question, therefore, is why do all that work?

The following equation was readily obtained by the writer from logarithmic plotting of the observation data given in Fig. 9:

$$Y = \frac{66}{t^{0.156}} \qquad (44)$$

in which Y = turbidity in parts per million, and t = time, in hours. Equation (44) will be near enough for all practical purposes. Its graph will vary slightly from that of Fig. 9 for values of t greater than 4 hr. There is no real justification, or no real objection to the path of the curve on Fig. 9 beyond the fourth hour, where it appears that turbidity does not decrease below 52 ppm, for practical purposes.

The writer really fails to discern any particular advantage of all the work done by the author to obtain Equation (36), when a simple equation answering the purpose could be obtained readily.

The settling time of a particle, practically speaking, depends on its velocity, and the velocity, in turn, depends upon the size of the particle. For the same sample material the sedimentation and gradation curves bear a definite relation. In fact, each depends on the other and one could be obtained from the other. No satisfactory general formula has been obtained for the distribution of particle sizes represented by a gradation curve, because of the complex nature of the material. It has been found more practical to make the necessary number of tests and plot their graphs. These test results are usually plotted on natural, semi-logarithmic, or logarithmic-probability scales. Often an error in observation can be detected in the plotted graph. Logarithmic-probability scale plottings result in a flatter curve and are better for the purpose.

It appears that, practically in all cases, without actual test runs, certain terms or factors of the equations proposed by the author can not be obtained. The author states the necessity of determining numerous constants experimentally before making any practical application of the theories developed in the paper. The characteristics of material in suspension are so complex that general application of any set of constants is questionable. To this uncer-

tainty must be added the tedious work involved and probability of errors in solving complicated equations. The writer questions whether direct tests or simpler methods, similar to gradation curves, would not be more practical in every respect. However, the paper affords a good exercise in mathematics and Equation (27) is an improvement over Equation (24), Hazen's second formula.

HARRY H. MOSELEY,[12] ASSOC. M. AM. SOC. C. E. (by letter).—Much has been written about the design of sedimentation tanks, but the correct design still remains an open question. Professor Slade's paper presents a mathematical approach to this problem. He has attempted to establish a relation between the settling of similar solids in a quiescent basin and in a turbulent basin. He has developed a theory which is dependent upon a group of constants and suggests three sets of constants that effect the solution of his formulas: "(1) Those which represent the characteristics of the sediment; (2) those which represent the characteristics of the settling basin; and (3) those which depend on both the character of the sediment and the degree of agitation of the fluid."

Much experimentation and work has been done and many data have been collected on the constants pertaining to the characteristics of the sediment. The point, it seems, may be raised regarding the density of the solids in the liquid. Was it the author's intention to include this in the characteristics of the sediment and thus affect the first constant by a certain degree? There is a large store of data available for the second set of constants. Any settling tank is a potential source. The information desired probably should include: The type of tank inlet and tank outlet; the length and the width of tanks; the depth or length-depth ratio; the type of sediment-removal equipment; the type of operation of removal equipment; the baffling linear velocity and direction of flow of liquid (average and bottom if possible); the direction of flow; the characteristics of solids in the liquid; and the results obtained by the tank. It is appreciated that many of these data may seem to be superfluous, but they all have a bearing on the results obtained from a basin. In many respects, the third set of constants, may be absorbed by the first two sets. However, in the design of grit chambers, or like structures, this set of constants would have an effect on the solution of the problem.

Much of the information pertaining to settling tanks in sewage treatment works has been obtained by the use of the Imhoff cone. Under which classification would the author place these data? Would it be quiescent, the same as a vertical cylinder, incomplete turbulence, or complete turbulence? These available data in many cases will have to be used in the determination of the second set of constants.

At the end of his paragraph discussing "Stratification of Sediment" Professor Slade states that "at a depth greater than $v_m\ a$ [see Fig. 6], the density will be what it was throughout the basin originally." This statement is based on the fact that the sediment in the basin has variable hydraulic subsidence values ranging from v_m to v_M. With a sediment of constant hydraulic sub-

[12] Asst. Engr., George B. Gascoigne, M. Am. Soc. C. E., Cons. San. Engr., Cleveland, Ohio.

sidence characteristics it is possible after time, a, to have that part of the basin below $a\,v_m$ or $a\,v_x$ ($a\,v_m = a\,v_x$ when the hydraulic subsidence characteristics are constant) of the same density as the original, throughout the basin. Theoretically, all particles of the same hydraulic subsidence characteristics are subsiding at the same rate; hence the absence of any flocculating action of the sediment. However, in a basin filled with sediment of variable hydraulic subsidence characteristics there is a flocculating action or the natural combination of suspended particles into larger aggregates. These larger aggregates also have hydraulic subsiding characteristics which are greater than the original particles and, consequently, settle more rapidly. Therefore, as soon as settling is started in this basin a portion of the liquid will have a density of suspended solids greater than that throughout the basin originally.

This flocculating action, of course, increases as the density of the suspended solids increases, even though the hydraulic subsidence characteristics of the original suspended solids in each case are the same before the settling starts, because there is a greater possibility of the suspended solids combining with each other as they start settling, thereby making larger aggregates. For example, a settling tank having a detention period of 1.5 hr will remove roughly 60% of the suspended solids from a raw sewage of 400 ppm, whereas it will remove approximately 45% from one containing only 100 ppm. It is true that in the raw sewage of 400 ppm, some of the solids will have greater hydraulic subsidence characteristics than in the one of 100 ppm; yet it is very doubtful whether this increase in hydraulic subsidence characteristics of some of the suspended solids is great enough to account for an increase of one-third in the efficiency of the tank. This increase can be accounted for better by the flocculating action of the suspended solids in the tank. It seems that the statement made at the end of the paragraph on "Stratification of Sediment", previously referred to, is true mathematically, but due to the flocculating action of the solids, the actual approaches it only as a limit.

The two examples presented by the author based on his interpretation of the original data substantiate his theory in a marked degree. However, it will require agreement in many actual field tests to prove his theory fully. It is hoped that Professor Slade's paper will further stimulate research in the field of sedimentation.

George J. Schroepfer,[13] Assoc. M. Am. Soc. C. E. (by letter).—An admirable attempt to set up, by means of equations and formulas, some of the factors affecting sedimentation of solids, is contained in this paper. In view of the importance of sedimentation in water purification and sewage treatment, and in the separation and classification of ores and chemicals, all investigations that contribute to the fund of knowledge on this subject are distinctly to be appreciated.

Although this discussion will be limited to the sedimentation of sewage solids, many of the principles of sewage sedimentation to which reference will be made, are equally applicable to the theory of sedimentation in general.

[13] Asst. Chf. Engr., Minneapolis-St. Paul San. Dist., St. Paul, Minn.

The writer is inclined to favor the evaluation and determination of various engineering phenomena by means of formulas, but in the case of sedimentation, especially of sewage solids, the large number of influencing factors makes such a method of attack questionable when applied to an actual and practical situation.

Several times in the course of the paper the author makes reference to the application of his theory to sedimentation of sewage solids. Sewage is an extremely variable material, changing in quantity and quality, and in various characteristics which affect its settleability hourly, daily, and seasonally. The results of the application of a purely theoretical basis of analysis to a particular sewage under certain fixed or assumed conditions is valueless and even misleading when considered in terms of a varying material under varying external influences. A certain degree of control can be exercised over some of the variables, but in case of others it is necessary to accept the material as it exists, amenable to sedimentation, or otherwise.

In considering sewage sedimentation, the writer groups the various influencing factors under four headings, as affected by: (*a*) Characteristics of the liquid; (*b*) characteristics of the solids; (*c*) characteristics of the design; and, (*d*) miscellaneous effects.

(*a*).—The principal characteristics of the liquid which affect the settleability of solids are its specific gravity and viscosity. Of the two, it can be demonstrated that viscosity is the more important factor. With a liquid, such as water, the fluid characteristics, therefore, are closely affected by temperature. From a study of monthly average results at two large plants the writer has found a close correlation between the reduction accomplished and the sewage temperature. The reduction in suspended solids at the two plants closely approximates a 0.65% increase in reduction per degree Fahrenheit of temperature change; and in reduction of bio-chemical oxygen demand, 0.50% for every degree of temperature change. These results closely approximate those expected from purely theoretical considerations.

(*b*).—Under characteristics of the solids can be included such factors as size, shape, specific gravity, concentration of particles, natural flocculation, and artificial coagulation and coalescense. Sewage contains particles varying largely in size, shape, and specific gravity. In specific gravity alone particles vary from less then 1.0 to 2.65, or more. As an example of the importance of this factor as affecting a purely theoretical consideration, the hydraulic subsiding value of a particle 0.50 mm in size and having a specific gravity of 1.1, is 3.3 mm per sec; and 53.00 mm per sec for a particle of the same size having a specific gravity of 2.65.

Concentration of particles also plays an important part in the sedimentation of sewage solids, as evidenced by the fact that a study of the data collected on the effect of this factor indicates that, for a given detention period, a sewage containing 200 ppm of suspended solids will have its solids removal increased approximately 30% when compared with the sewage containing 50 ppm of suspended solids. Flocculation, coagulation, and coalescence exert a variable effect depending upon local conditions.

(*c*).—Under characteristics of the design can be included such factors as detention period, linear velocity of flow, depth and ratio of length and depth, inlet and outlet effects, shape of tank, baffling, and mechanism effects.

The first factor mentioned—namely, detention period—plays a very important part in the removal effected by a settling tank. The writer has collected data from more than forty settling-tank installations throughout the United States, which data, for those who desire to express the results of sedimentation data in the form of a equation, can be stated in the following formula:

$$R = C_1 - \frac{C_2}{t + C_3} \qquad (45)$$

in which R is the normal expectancy, in percentage removal of suspended solids; t is the detention period, in hours; and C_1, C_2, and C_3, are coefficients depending on the characteristics of the sewage and of the settling tanks under the particular conditions existing at that time. In view of the importance of the detention period provided, considerable thought should be given this factor in order to be assured that the desired period of detention is actually secured. Sewage treatment plants investigated indicate that the actual flowing-through time in the tanks may be as low as 10% of the theoretical detention period. This would indicate that, in some plants, a considerable expenditure of funds is, in effect, wasted by reason of inefficient design.

With respect to linear velocity of flow, a considerable variation in thought exists as to the desirable maximum velocities beyond which it is not advisable to go. Although this variation ranges from 4 to 59 mm per sec, the writer is inclined to believe that the linear velocity of flow for average flow conditions should preferably be not more than 2 ft per min (approximately 10 mm per sec), depending, however, on influencing conditions and requirements.

Inlet and outlet effects play a very important part in the length of tank actually effective for settling purposes and, in view of their importance, should be given considerable thought in design.

(*d*).—Under miscellaneous effects might be included such factors as currents caused by wind, eddies, and difference in temperature and biological activities. At one plant investigated the writer observed that with a wind velocity estimated at 25 miles per hr the velocity of the surface sewage in the 90-ft square tank was observed to be such as to cover the distance to the outlet in 2 min. The theoretical detention period in the tank was 1.5 hr. Methods effective in reducing this action consist of baffling, provision of free-boards, and the limitation of the size of tanks. When air and sewage temperatures are materially different, short-circuiting, mixing, and stratification may result.

Realizing the value of such investigations as the author reports, the writer has attempted to point out some of the factors which affect the evaluation of sedimentation data, but which, in the case of sewage solids subsidence, at least, are likely to make the methods of determination suggested by the author uncertain and possibly even misleading.

J. J. SLADE, JR.,[14] ESQ. (by letter).—In the analysis presented in this paper the writer was prompted by the realization that the problem of the settling of solids in suspension may be separated completely from consideration of the very complex relations that exist between the particles and the liquid. Homogeneity of material does not imply uniformity of settling, and it is this fact that led the writer to introduce a distribution function into the analysis. Since this distribution function is a function only of the hydraulic properties of the material, the homogeneity or heterogeneity of the material is irrelevant to the phenomenon of sedimentation considered only from the point of view of bulk that settles out in a given time.

That objections to the writer's development were made in the discussion on the grounds that coagulation takes place is, therefore, very surprising to the writer since it is precisely coagulation that his distribution function takes into account. It appears desirable, therefore, to explain this point in greater detail.

Consider, for instance, a clay suspension so homogeneous that all the particles may be taken as identical in size, shape, and density. These particles will not fall at a uniform rate through the liquid. The statistical-mechanical picture of subsidence will be somewhat as follows: Two particles falling freely will come close together and, because of the ionization potentials surrounding them, they will adhere. After that, they fall as a single particle with a different velocity. Farther down a third particle will adhere to these two and the three will fall together, with a still different velocity. These nuclei may grow to fairly large masses depending on the physico-chemical character and the concentration of the solids. These nuclei are not stable, however. As they go down a collision may disrupt them instead of adding more particles to the mass. This interchange is always going on, but in a large enough sample a statistical equilibrium is established, so that a certain percentage of the particles at any time will be falling singly, a certain percentage will be in pairs, etc. Each one of these groups is characterized by its individual hydraulic value, and it is this distribution of hydraulic values that is given by the writer's distribution function. Obviously, no matter how homogeneous or how complex the material may be, it will always be characterized by some distribution function of its hydraulic values.

The method given by the writer to determine the distribution function takes into account only the hydraulic behavior of the sub-groups into which the material arranges itself and, consequently, it leads to a statement only of the bulk that is removed in a given time; that is, it takes coagulation fully into account.

Professor Camp offers two severe criticisms: First, that it is unfortunate that the theory should be based on Mr. Hazen's work, because his formulas are known to fail; and, second, that in introducing the distribution function the basic assumptions on which the theory is established are completely violated.

These two objections may be answered as one. In the first place, the writer's development is scarcely a theory; it is more in the nature of a truism.

[14] Associate Prof. of Eng. Mechanics, Rutgers Univ., New Brunswick, N. J.

In its more general form it may be stated thus: If the quantity of material which has hydraulic values between v and $v + dv$ is $\phi(t)\,dt$, and, if at the end of time, a, the quantity remaining in suspension is a fraction, $f(a, t)$ of the amount initially there, then for this small range in v the quantity remaining in suspension is $\phi(t)\,f(a, t)\,dt$, and the total quantity is $\int \phi(t)\,f(a, t)\,dt$. The integration extends, of course, over the complete range of values of t. Thus far, this is independent of Mr. Hazen's logic, and it is merely a truism stated in compact symbolic form. This statement is useful or useless, depending on whether or not $\phi(t)$ and $f(a, t)$ can be evaluated.

Consider, then, a particle (or globule of particles cohering as a single body) that is falling freely through the liquid. In this case the function, $f(a, t)$, takes the form of Equation (4). This is simply Hazen's statement of Stokes' law, which is known to be correct well within the errors of experiment. For material that has attained statistical equilibrium of coagulation, Equation (6) is true. It remains only to determine $\phi(t)$ and the writer has shown in detail how this may be done. Therefore this equation is a determinate, complete, and correct statement of sedimentation in a still liquid which takes fully into account, coagulation and every factor pertinent to the problem.

For the condition described as critical turbulence the form of $f(a, t)$ is also known. It is simply $f(a, t) = 1$. This is the condition in which turbulence is so great that the material does not settle out. From no turbulence to critical turbulence there is a steady transition of $f(a, t)$ from $\left(1 - \frac{a}{t}\right)$ to 1. This transition can be determined only through experiment. The writer has suggested the form, Equation (19), but this is really quite general because $k(t)$ must be determined experimentally. There is one particular condition of turbulence, which the writer has called complete, in which he has evaluated the function, $f(a, t)$. This evaluation is given in Equation (27) and in that case explicit use was made of Hazen's theory. Whether or not there does exist a condition of turbulence in which $f(a, t) = e^{-\frac{a}{t}}$, the writer is not qualified to state, but if under some condition of turbulence the suspended material is observed to have a fairly uniform vertical distribution, then this form is quite nearly correct. That this form is not a bad approximation to certain conditions of turbulence is shown by the results obtained by applying it to the experiments of Dilling and Pearse[4]. In view of the explanation that has been given of the distribution function it is seen that the choice of these experiments for illustration is not so unfortunate as Professor Camp considers it. However, except for the form of this particular evaluation, the writer's development is in no way dependent on Hazen's definition of turbulence.

It must be explicitly stated that the writer's development as presented herein holds only for the case in which statistical equilibrium of coagulation occurs in a time that is short compared to the period of retention. This may by no means be the case in practise. As Mr. Schroepfer points out, sewage solids change in character hourly, daily, and seasonally. Formally, this is quite easily taken into account by allowing the distribution function to be

dependent both on a and t; practically, however, no advantage would result from this extension. The theory holds only where statistical equilibrium is obtained throughout the period of retention.

It is far from the writer's intention to offer an exercise in curve fitting in presenting this paper. He quite agrees with Mr. Hatch that if a short formula will do as well as a long one, the short formula is much the more desirable of the two.

In evaluating the constants of Equation (36) the writer desired merely to show that Equation (31) does represent the process accurately. Curve fitting after the process is complete is merely a waste of time. However, if the curve for the performance of a tank can be constructed accurately beforehand, then even a long computation is justified. For instance, if through experiments (such as will be indicated under Items (1) to (4) subsequently) it is possible to assign to a given tank a certain degree of turbulence for some given rate of discharge, and if, from a test-tube sample of the sludge, the distribution function is determined by the process represented in Figs. 4 and 5, the writer's contention is that Fig. 9 may be drawn before the tank is in operation; in other words, that it is possible to predict the performance of a tank for any rate of discharge and for any material that may be put through it.

If this is true, it is certainly possible to design a tank to operate in a given manner for a particular type of sludge, and to predict its operation for other types that may be put through it.

Mr. Moseley is quite right in stating that there already exists a vast amount of information regarding the operation of settling tanks. However, it is not the amount of information that is lacking, but the kind of experiments required to evaluate the constants presented in this paper.

Since the principal outcome of this investigation is the suggestion of a unified experimental procedure and standardization of terms, and since it is not likely that the writer will have the opportunity in the near future to undertake the experiments himself, he should like, in closing, to suggest an outline of what he thinks could be done to correlate this theory with practise:

(1) A standard set of materials should be selected for experimental purposes. Each material should be selected for the uniformity of its hydraulic behavior, and as many materials should be in this group as will give a fair range of hydraulic values.

(2) A standard cylinder should be adopted for these experiments. These cylinders should be large enough so that the walls will not appreciably modify the hydraulic behavior of the suspended solids and so that a sample will be able to attain the statistical equilibrium it reaches in a full-sized tank. These cylinders should be equipped with mechanical rotors. By means of these rotors it is possible to give turbulence precise values. For instance, the value, 1, may be assigned to the turbulence produced by a standard rotor in a standard cylinder of water when it rotates at the rate of 1 rpm, the value, 2, when it rotates at the rate of 2 rpm, etc.

(3) The hydraulic behavior of the standard materials of Item (1) may then be studied when subjected to various standard degrees of turbulence and, in this manner, the variations of the function, $f(a, t)$, may be determined for each.

(4) By the use of some suitable material of Item (1) a tank of standard design may be calibrated. Thus, for a given rate of discharge, the material will settle out in one or the other of the various ways determined in Item (3), so that, for that particular rate of discharge, the tank will have assigned to it one of the degrees of turbulence standardized in Item (2). Interpolations, of course, will be necessary.

When data such as Items (1) to (4) have been collected, it will be possible to make use of the theory presented in this paper. This is certainly a formidable set of experiments which requires a fine technique, but, in the writer's opinion, this suggestion represents only a small fraction of the work that has been done in the past and is now in progress in the field; and it has the advantage of a reasonable theory to unify the results. The much more difficult problem of taking into account slow time changes in the material may then be considered.

WIND STRESSES IN REINFORCED CONCRETE ARCH BRIDGES

By A. A. Eremin[1], Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Leon Blog, Fang-Yin Tsai, Paul Andersen, Louis Blume, and A. A. Eremin.

Synopsis

Ordinarily, the effect of wind forces is slighted in the design of arch bridges despite the fact that wind stresses in these structures are often considerable. In the Ammer Arch Bridge,[2] near Echelsbach, Germany, with a span of 426 ft, the stresses due to wind constitute about 55% of the total, including live load, dead load, and temperature changes. On the other hand, the excessively heavy wind-bracing sometimes built into reinforced concrete arch bridges results in an uneconomic and unsightly design.

Introduction

The usual assumptions made in designing reinforced concrete rigid frames have been adopted in this paper. For example, the concrete was assumed to be elastic within the range of working stresses, from which it follows that strain is proportional to stress. The effect of plastic flow on the distribution of stress was not considered.

Notation.—The notation of this paper is defined where first introduced and summarized for reference, in the Appendix. A definition of the torsion factor, F, has been stated by J. Charles Rathbun, M. Am. Soc. C. E.[3] in the following form:

$$F = \frac{b^3\, t^3}{3.58\,(b^2 + t^2)} \qquad (1)$$

in which b is the width, and t is the thickness of the arch rib measured radially.

Note—Published in December, 1935, *Proceedings*.

Arch Rib Without Bracing

Obviously, the single arch rib, fixed at the abutments and subjected to lateral forces, is statically indeterminate and requires six equations for its solution. In the case of a symmetrical structure, however, the computation of wind stresses is simplified, and, furthermore, the effects of shear and direct stresses in the rib may be neglected without introducing serious error.

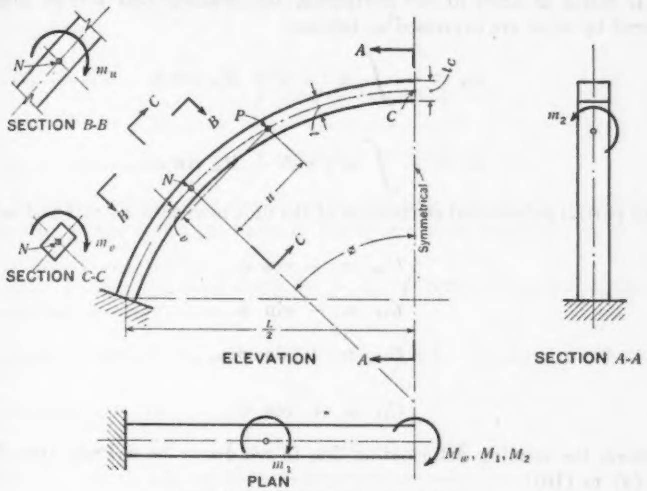

Fig. 1.—Symmetrical Arch Rib.

If the temperature of the arch is assumed constant the internal work due to elastic formation is expressed as,

$$W = \frac{1}{2}\int\left(\frac{m^2_u}{EI} + \frac{m^2_v}{GF}\right) ds \text{ .... (2)}$$

Applying Castigliano's theorem, the virtual displacement at some point, N (Fig. 1), may be derived from Equation (2) as follows:

$$\theta = \int (m_u\, C_{1m} + \gamma\, m_v\, C_{1t})\, dw \text{ .... (3)}$$

and,

$$\tau = \int (m_u\, C_{2m} + \gamma\, m_v\, C_{2t})\, dw \text{ .... (4)}$$

in which $\dfrac{ds}{EI} = dw$ and C_{1m} and C_{1t} are, respectively, the partial differential coefficients representing the moment and torsion produced by a unit moment, $m_1 = 1$, applied at Point P, and C_{2m} and C_{2t} are, respectively the partial differential coefficients representing the moment and torsion produced by a unit moment, $m_2 = 1$ at Point P.

Professor E. Mörsch has shown[4] that, when a symmetrical arch rib is exposed to symmetrical lateral wind forces, such as an ideal uniform wind, the only bending moment that occurs at the crown is M_w about the vertical axis. It is obvious that the torsion and shear stresses at this point are equal to zero, as are the bending moments about the horizontal axis, since the direct stresses are assumed to be negligible. Consequently, for the structure in Fig. 1, which is fixed at the springing, the bending and torsion moments produced by wind are expressed as follows:

$$m_u = -\int w\, t\, u\, ds + M_w \cos\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

and,

$$m_v = +\int w\, t\, v\, ds - M_w \sin\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

The partial differential coefficients of the unit moments, $m_1 = 1$ and $m_2 = 1$, are:

$$C_{1m} = + \cos\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

$$C_{1t} = - \sin\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

$$C_{2m} = + \sin\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

and,

$$C_{2t} = + \cos\phi \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Therefore, the bending deformation due to wind may be written, from Equations (4) to (10):

$$\theta_w = -\int \left(\cos\phi \int w\, t\, u\, ds + \gamma \sin\phi \int w\, t\, v\, ds\right) dw$$

$$+ M_w \int (\cos^2\phi + \gamma \sin^2\phi)\, dw \quad \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

and the torsion deformation will be:

$$\tau_w = -\int \left(\sin\phi \int w\, t\, u\, ds - \gamma \cos\phi \int w\, t\, v\, ds\right) dw$$

$$+ M_w \int (1 - \gamma) \sin\phi \cos\phi\, dw \quad \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

The tangent at the crown does not move when a symmetrical arch rib is subjected to uniformly distributed lateral forces. Therefore, by equating the bending deformation at the crown to zero, M_w may be expressed:

$$M_w = \frac{\int \left(\cos\phi \int w\, t\, u\, ds + \gamma \sin\phi \int w\, t\, v\, ds\right) dw}{\int (\cos^2\phi + \gamma \sin^2\phi)\, dw} \quad \ldots\ldots (13)$$

[4] *Beton und Eisen*, 1923, p. 53.

In a similar manner the equations for bending and torsion deformations and the moment at the crown produced by the symmetrical moments, $m_1 = 1$, may be written:

$$\theta_1 = \int (\cos^2 \phi + \gamma \sin^2 \phi)\, dw + M_1 \int (\cos^2 \phi + \gamma \sin^2 \phi)\, dw \quad (14)$$

$$\tau_1 = \int (1 - \gamma) \sin \phi \cos \phi \, dw + M_1 \int (1 - \gamma) \sin \phi \cos \phi \, dw \quad (15)$$

and,

$$M_1 = - \frac{\int (\cos^2 \phi + \gamma \sin^2 \phi)\, dw}{\int (\cos^2 \phi + \gamma \sin^2 \phi)\, dw} \quad (16)$$

In a similar manner the equations for bending and torsion deformations, and moment at the crown produced by the symmetrical moments, $m_2 = 1$, are:

$$\theta_2 = \int (1 - \gamma) \sin \phi \cos \phi \, dw + M_2 \int (\cos^2 \phi + \gamma \sin^2 \phi)\, dw \quad (17)$$

$$\tau_2 = \int (\sin^2 \phi + \gamma \cos^2 \phi)\, dw + M_2 \int (1 - \gamma) \sin \phi \cos \phi \, dw \quad (18)$$

and,

$$M_2 = \frac{\int (\gamma - 1) \sin \phi \cos \phi \, dw}{\int (\cos^2 \phi + \gamma \sin^2 \phi)\, dw} \quad (19)$$

The numerators of Equations (16) and (19) must be integrated from the points of application of the unit moments, m_1 and m_2, to the springing and the denominator from the crown to the springing section.

Braced Arch Ribs

Reinforced concrete arch bridges are generally constructed with lateral braces between the ribs. Each of these braces adds six more unknowns to the system of forces in the rib. When the structure is symmetrical, however, the number of unknowns is reduced; but in order to derive simple expressions for stresses in the bracing, certain assumptions are necessary. For example, it is assumed that each rib carries the same wind load. Furthermore, the intersections of the braces with the rib are assumed to be fixed in space and, therefore, the points of contraflexure in the braces will be at the mid-point in each case, and will also be fixed in space.

One-half of one arch rib is analyzed by substituting for the remainder of the structure the forces, R_1 and R_2, as shown in Fig. 2. Direct stresses in the members are neglected. Forces R_1 and R_2, therefore, will keep the mid-point of the brace fixed in position and the equations for these reactions can be developed by an application of Maxwell's theorem.

Two increments of displacement in the arch rib and bracing are considered: First, that produced by wind pressures on the half arch rib in Fig. 2, without the reactions, R_1 and R_2; and, second, that produced by the forces, R_1 and R_2, in order to translate the mid-point of the cross-brace back to its original position.

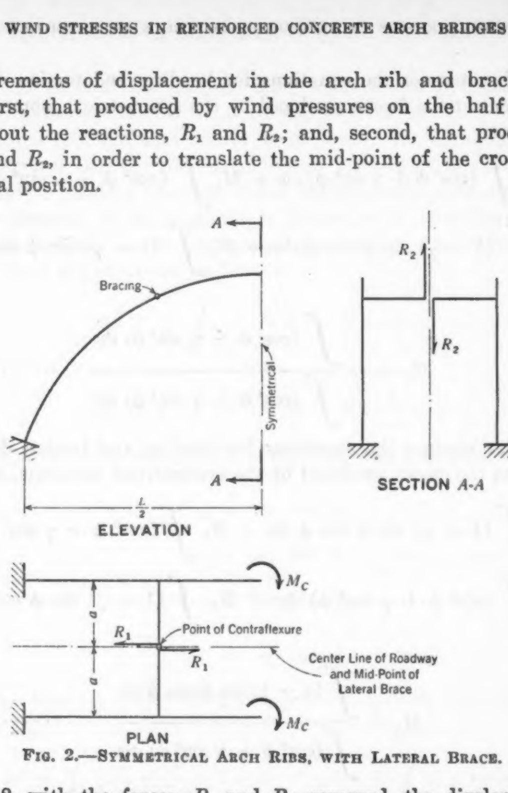

FIG. 2.—SYMMETRICAL ARCH RIBS, WITH LATERAL BRACE.

In Fig. 2, with the forces, R_1 and R_2, removed, the displacement in the direction of the force, R_1, is $\theta_w a$, and in the direction of R_2, $\tau_w a$. If, instead of the uniform lateral wind load, the half arch in Fig. 2 were loaded with the force, R_1, the deflections would be, respectively, in the direction of R_1 $\left(\text{since the deflection of a cantilever beam is } \frac{R_1 a^3}{3 E I_a}\right)$:

$$\Delta = R_1 \, a \left(\theta_1 \, a + \frac{a^2}{3 E I_a}\right) \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

and, in the direction of R_2;

$$\Delta = R_1 \, a \, \tau_1 \, a \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

in which the products, $R_1 a$ and $R_2 a$, are moments of the forces, R_1 and R_2, about the intersection of the cross-brace and the arch rib.

If, instead of the reaction, R_1, the arch is loaded with the reaction, R_2, the corresponding displacements are:

In the direction of R_1:

$$\Delta = R_2 \, a \, \theta_2 \, a \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

and, in the direction of R_2:

$$\Delta = R_2\, a \left(\tau_2\, a + \frac{a^2}{3\, E\, I_b} \right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

Consequently, according to Maxwell's theorem, the displacements may be expressed as follows:

$$\theta_w = R_1 \left(a\, \theta_1 = \frac{a^2}{3\, E\, I_a} \right) + R_2\, a\, \theta_2 \ldots\ldots\ldots\ldots\ldots (24)$$

and,

$$\tau_w = R_1\, a\, \tau_1 + R_2 \left(a\, \tau_2 + \frac{a^2}{3\, E\, I_b} \right) \ldots\ldots\ldots\ldots\ldots (25)$$

Equations (24) and (25) were simplified by dividing through by the length, a. The deformations, θ and τ, are computed by means of Equations (11) to (18), inclusive, and with these values substituted in Equations (24) and (25), simultaneous solutions will yield the values of R_1 and R_2. Removing the right half of the arch has the effect of substituting a moment at the crown of the remaining left half equal to,

$$M_c = M_w + M_1\, R_1\, a + M_2\, R_2\, a \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

The bending moment and torsion at any other section of the rib can be computed by statics. Formulas similar to Equations (24) and (25) may be written for any number of braces between the arch ribs.

Illustrative Example

In order to illustrate the application of the foregoing equations, the wind load stresses in the arch shown in Fig. 3 will be computed. The ribs are fixed at the springing and braced at a distance of 26.28 ft measured hori-

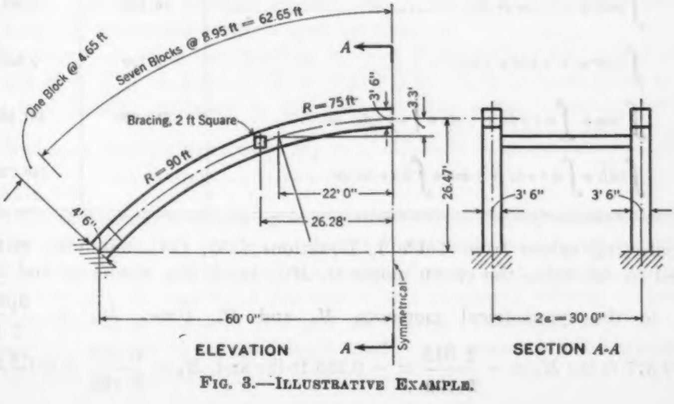

FIG. 3.—ILLUSTRATIVE EXAMPLE.

zontally from the crown. The theoretical span of the arch is 120 ft and the thickness of the arch rib varies according to the formula,

$$t = t_c\,(1 + 0.446\,\phi^2) \quad \text{......................(27)}$$

in which t_c equals the thickness of the rib at the crown and ϕ equals the angle between the radial line and the vertical through the crown. Since the lateral cross-brace is 2 by 2 ft in section, $I_a = I_b = 1.33$ ft^4, and,

$$\frac{a^3}{3\,E\,I_a} = \frac{a^3}{3\,E\,I_b} = \frac{56.26}{E} \quad \text{..................(28)}$$

The steel reinforcement is not taken into consideration in computing the moment of inertia. Such precision would be useless because the theory of wind load distribution on exposed surfaces is still so inadequate that extreme refinements in other factors are inconsistent.

Although the complete computations for this numerical example are not recorded herein, it is believed that they are given in sufficient detail for the guidance of those who are familiar with the design of arch bridges.

A wind load of $w = 45$ lb per sq ft is assumed to act horizontally and at right angles to the plane of the arch rib. In order to integrate the elastic and geometric properties, the rib was divided into eight blocks as indicated in Fig. 3, the values being given in Table 1. The modulus of elasticity of concrete in compression was assumed equal to 2.5 G, the modulus of elasticity of concrete in shear.

TABLE 1.—VALUES OF INTEGRATIONS IN TERMS OF $\frac{1}{E}$

Integrals	For half arch rib	From springing to bracing
$\int (\gamma - 1) \sin\phi \cos\phi \frac{dw}{2}$	0.543	0.374
$\int (\sin^2\phi + \gamma \cos\phi)\,dw$	6.542	3.461
$\int (\cos^2\phi + \gamma \sin^2\phi)\,dw$	5.199	3.043
$\int (\cos\phi \int w\,t\,u\,ds + \gamma \sin\phi \int w\,t\,v\,ds)\,dw$	516 660	481 360
$\int (\sin\phi \int w\,t\,u\,ds + \gamma \cos\phi \int w\,t\,v\,ds)\,dw$	....	246 720

Selecting values from Table 1, Equations (13), (14), and (19) may be solved to determine the crown moments, M_w, due to the wind load and those due to the symmetrical moments, M_1 and M_2, thus: $M_w = \frac{516\,660}{5.199} = 99\,377$ ft-lb; $M_1 = -\frac{3.043}{5.199} = -0.585$ ft-lb; and, $M_2 = \frac{0.374}{5.199} = 0.072$ ft-lb.

The angular deformations $\left(\text{multiplied by } \frac{1}{E}\right)$ are computed by means of Equations (11) to (18), as follows:

$$\theta_w = -\ 481\,360 + 99\,377 \times 3.043 = -\ 178\,956$$

$$\tau_w = -\ 246\,720 + 99\,377 \times 0.374 = -\ 209\,652$$

$$\theta_1 = +\quad 3.043 - 0.585 \times 3.043 = +\ 1.263$$

$$\tau_1 = -\quad 0.374 + 0.585 \times 0.374 = -\ 0.155$$

$$\theta_2 = -\quad 0.374 + 0.072 \times 3.043 = -\ 0.155$$

and,

$$\tau_2 = +\quad 3.461 - 0.072 \times 0.374 = +\ 3.434$$

It follows from Maxwell's theorem, furthermore, that $\tau_1 = \theta_2$. The bending moment and the torque were considered positive in the direction indicated in Fig. 1. The same is true of the angular deformations. The forces in the lateral cross-brace may be derived from Equations (24) and (25) by substituting the necessary angular deformations; thus:

$$(56.25 - 0.16 \times 15)\ R_1 + 3.434 \times 15\ R_2 = 209\,652 \ldots\ldots (29)$$

and,

$$1.263 \times 15\ R_1 + (56.26 - 0.16 \times 15)\ R_2 = 178\,956 \ldots\ldots\ldots (30)$$

which, solved simultaneously, yield $R_1 = 1.074$ lb and $R_2 = 2.946$ lb.

The bending moment about the vertical axis at the crown is computed by Equation (26), thus: $M_c = 99.377 - 0.585 \times 1.074 \times 15 + 0.072 \times 2\,946 \times 15 = 92\,785$ ft-lb. Therefore, the maximum unit compressive stress in the arch rib at the crown, produced by a wind-load bending moment, M_c, will be, $f_c = \frac{M}{S} = \frac{6 \times 92\,785 \times 12}{42 \times 42 \times 42} = 90.5$ lb per sq in., which is about 9% of the maximum compressive working stress (1 000 lb per sq in.) generally used in the design of reinforced concrete arch bridges.

The maximum wind-load bending moment at the end of the lateral cross-brace is $M = R_2 A = 2\,946 \times 15 = 44\,190$ ft-lb, which is about 126% of the dead load bending moment in the brace at that point. For comparison, the dead load bending moment is $M_d = \frac{D(2a - b)}{12} = \frac{600 \times 26.5 \times 26.5}{12} = 35\,113$ ft-lb.

When this problem occurs in connection with a through bridge, hangers may be assumed flexible enough so that their influence on the rigidity of the rib may be neglected. If the roadway is poured monolithic with the abutment, it will transmit its own wind pressure to the abutment without materially affecting stresses in the arch ribs and the braces. Therefore, only the wind pressure on the side of the arch itself needs to be assumed to be carried by the ribs and the bracing.

The foregoing development may lead some readers to criticize the paper for lack of precision. However that may be, the illustrative example is offered merely for the purpose of demonstrating the application of the formulas developed in this paper. The relative accuracy can be controlled by the designer himself.

Conclusion

Although the wind stresses computed in this paper have not been verified by tests, the formulas were developed from the well-known elastic equations. Furthermore, the method of computing the torsion factor and the influence of torque on the deformation of an arch have been successfully proved by tests of skew arches reported in 1928 by Professor Rathbun.[5]

The effects of lateral wind forces on the forces in the plane of the arch rib are so slight as to be negligible and, therefore, the lateral forces may be treated separately.

In the case of arches subjected to unsymmetrical lateral forces, the equations in this paper may be modified as the particular case demands. Forces inclined to the plane of the arch rib may be resolved into their components. Furthermore, the eccentric forces applied to the arch through the roadway deck may be divided into components of force acting in the plane of the arch rib and a torque equal to the vertical force times eccentricity. In this case, the torque may also be treated as a moment produced by horizontal lateral forces.

It is important to study the practical application of the elastic equation to problems in which forces in space occur. Such study may eliminate many obsolete assumptions in time, thus resulting in further economic and æsthetic improvements in the design of such structures.

APPENDIX

Notation

The following notation is adopted for use in this paper:

- a = one-half the length of a lateral csoss-brace, measured from its intersection with the axis of the arch rib; as a subscript, a denotes "vertical axis";
- b = breadth; width of arch rib; as a subscript, b denotes "horizontal axis";
- c = a subscript denoting "concrete";
- d = a subscript denoting "dead load";
- f = unit stress; f_c = unit compressive stress in concrete;
- m = moment component; m_u = a component of the moment acting in a tangential plane through Point N (Fig. 1); m_v = a component of the moment acting in a radial plane through Point N.
- ds = length of an element of the arch rib = $E\,I\,dw$;
- t = thickness of the arch barrel, measured radially;

[5] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 135.

u = a co-ordinate of any point, P, measured at right angles to a radial line through Point N; as a subscript, u refers to a plane perpendicular to a radial line through Point N;

v = a co-ordinate of any point, P, referred to a Point N, measured parallel to the radial line through Point N (see Fig. 1); as a subscript, v refers to a radial plane;

w = uniformly distributed, lateral, wind load; $dw = \frac{ds}{EI}$; as a subscript, w denotes "due to wind load";

$\gamma = \frac{EI}{GF}$; or, if $E = 2.5\,G$, $\gamma = \frac{2.5\,I}{F}$;

C = a partial differential coefficient; C_{1m} and C_{2m} = bending moment coefficients corresponding to $m_1 = 1$ and $m_2 = 1$ applied at Point P; C_{1t} and C_{2t} = torque coefficients corresponding to moments, $m_1 = 1$ and $m_2 = 1$, applied at Point P; as a subscript, C denotes "at the crown";

D = total dead load;

E = modulus of elasticity of concrete in tension and compression;

F = a torsion factor;

G = modulus of elasticity of concrete in shear;

I = moment of inertia of the cross-section area of the arch cut by a radial plane; I_a = moment of inertia of a section of a cross-brace, about a vertical axis through the center of gravity; I_b = moment of inertia of a section of bracing about a horizontal axis through the center of gravity;

L = span length;

M = bending moment; M_C = bending moment at the crown; M_w = bending moment due to wind load; M_1 = bending moment at the crown due to the symmetrical moments, $m_1 = 1$; M_2 = bending moment at the crown due to the symmetrical moments, $m_2 = 1$; M_d = dead load bending moment;

R = reaction; R_1 = horizontal force applied to the center of a wind-brace; R_2 = vertical force applied to the center of a wind-brace;

S = section modulus;

T = torsion; T_1 = torque corresponding to a unit moment, $m_1 = 1$, applied at Point P;

W = internal work due to the elastic deformation of the arch rib;

Δ = displacement;

θ = bending deformation at Point N, about the vertical axis; θ_w = bending deformation produced by the wind; θ_1 = bending deformation produced by $m_1 = 1$; θ_2 = bending deformation produced by $m_2 = 1$;

τ = torsion deformation at Point N about the horizontal axis; τ_w = deformation produced by wind; τ_1 = deformation produced by $m_1 = v$; τ_2 = deformation produced by a moment $m_2 = 1$;

ϕ = central angle locating any point, N, on the arch axis with relation to a radius through the crown.

DISCUSSION

LEON BLOG,[6] ASSOC. M. AM. SOC. C. E. (by letter).—An elegant method of analyzing an arch subjected to lateral stresses is presented in this paper which the author has explained by an application to a reinforced concrete arch loaded by horizontal wind forces. This method is elegant because it weaves together the theorems of Castigliano and Maxwell, but it is not so simple as the method devised by Professor Maurice Levy[7] who solved the problem by a graphic solution based upon a rigorous mathematical analysis. By his method an arch can be solved in one day at as many sections as desired and, furthermore, the section of the arch at which a strut subject to the least bending or torsion should be located, aside from the question of æsthetics, is clearly indicated. The author's method is not that speedy nor can the physical behavior of the arch be visualized without considerable work supplementary to the analysis for various sections.

Arch Ribs Without Bracing.—Although the introduction of so many types of moments is perfectly natural due to the use of the Castigliano and Maxwell theorems, the visualization of the contribution of each toward the solution of the problem is difficult. The use of the designation, "deformation", for the values, θ and τ, is confusing. Although an angular change in the position of a section is, in a sense, a deformation, the ordinary use of the term is to describe changes of length. It is only when the reader comes to the paragraph following Table 1 that he learns that θ and τ are angular changes unless he happens to recall that the basis of the terms in the parentheses of Formula (2) (which leads to the internal work, W) is that the angular change at any section of a member subjected to bending is the derivative of the internal work with respect to the external bending moment and the angular change has the same sign as that of the moment, that is,

$$\theta \text{ or } \tau = \frac{dW}{dM} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

By virtue of its derivation Equation (31) involves the concept that the angular change occurs either in the same plane, or in a plane parallel to the actuating bending moment. Although the accuracy of Equation (2) is admitted, it is not obvious to the writer that the torsional moment, m_v, contributes anything to the value of θ, or that the bending moment, m_u, contributes anything to the value of τ. If these views are correct, there will be no partial differential coefficients, Equations (3) and (4) will be modified, and Equations (7) to (10), inclusive, will be superfluous.

The formula for the angular rotation about the normal to the tangent at any section of an arch rib in terms of an external bending moment is,

$$\theta = -\int \frac{M_b\, ds}{E\, I_n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

[6] Asst. Chf. Structural Engr., Div. of Bridges and Structures, City of Los Angeles, Los Angeles, Calif.

[7] "La Statique Graphique", Pt. III, by Maurice Levy.

and that about such a tangent is,

$$\tau = + \int \frac{M_t \, ds}{G \, I_t} \qquad (33)$$

in which M_b and M_t are, respectively, the external bending and torsional moments at the section; ds is a small piece of the arch axis; E and G, respectively, are the moduli of elasticity in tension; and, in shear, I_n and I_t are the rectangular moment of inertia about the normal and the polar moment of inertia about the tangent, respectively.

The limits of the definite integrals are the springing line and the distance from it to the section of the arch rib measured along its geometric axis. The sign convention is that of the author, θ and τ are independent variables along the rib and are proved to be so by Professor Levy[8] from simple geometric considerations.

Assume for the moment that the torsional moment, m_v, has some effect upon θ and that the bending moment, m_u, has some effect upon τ. Then, C_{1m} is obtained by partial differentiation of Equation (5) with respect to m_u, which amounts to finding the first derivative of cos ϕ, which is $-$ sin ϕ. Likewise, C_{1t}, the first derivative of sin ϕ, is $+$ cos ϕ, allowing M_w to retain its negative sign. Similarly, C_{2m} and C_{2t} are, respectively, $-$ sin ϕ and $-$ cos ϕ. When substituted in Equations (11) to (13), inclusive, these values will alter their form. Equation (16), being derived from Equation (14), reveals that $M_1 = -1$ always, whereas its evaluation from Equation (15) would also $= -1$. Equations (14) and (15) express the fact that θ_1 always equals τ_1, which is doubtful. Similar doubt exists as to M_2 from Equations (17) to (19) which would yield two different values of M_2.

A statement should be made as to the evaluation of the lateral shear in the rib. In 1918, Professor Levy[9] stated that, for an arch with symmetrical shape and loading, the torsion and shearing stresses are zero at the crown. He also stated that the total external shear at any section is equal to the algebraic sum of all the lateral forces between the crown and the section in question. This external shear results in internal shearing stress at the section, which must be combined properly with similar stresses due to the torsional moment and the vertical shear due to gravity loads.

The author closes the development of the first caption with a statement as to the limits of the integrations for Equations (16) to (19). It would assist those not so familiar with the method if this were done for the formulas preceding Equation (16).

Before closing the discussion of the subject under the caption, "Arch Ribs Without Bracing", the writer directs attention to the statements by the author that direct stress is induced by wind in the rib. Since the arch subjected to lateral forces acts as a beam which is subjected to bending, torsional shear, and ordinary beam shear, and has no curvature in the horizontal plane, the writer does not see how direct stress without a prerequisite arch thrust can occur.

---

[8] "La Statique Graphique", p. 183 *et seq.*

[9] *Loc. cit.*, Pt. III, p. 199, Paragraph *b*.

Another statement of theory which must be questioned is the second paragraph of the author's "Conclusion." Professor Levy[10] shows that the action of gravity forces leaves the vertical neutral plane undeformed, whereas the lateral forces produce displacements normal to that plane, and "each of these kinds of forces produce the same displacements as if the other did not exist." Therefore, the lateral wind forces can have absolutely no effect on the forces in the plane of the arch rib.

Braced Arch Ribs.—The author's assumption that each rib is subjected to the same wind load happens to fit in nicely with the development of his bracing theory for two symmetrical arches, but what would he do if the bridge were on a curve with one arch longer and thicker than the other? If there were three or more ribs in the bridge unequally spaced, or of different dimensions, or both? The correct guess as to wind-load distribution between the ribs would be difficult. Professor Levy has shown[11] how to treat this problem with only the generally accepted assumptions.

By Equations (29) and (30), the values of R_1 and R_2 are approximately 3 150 lb and 2 018 lb, which corresponds with the writer's experience that the horizontal bending moment and the shear it causes in the brace are more serious than the torsional bending moment and its resultant shear. The combined bending and direct wind stress is equal to $\pm$ 528 lb per sq in., which indicates a large factor of safety for the 24 by 24-in. brace. However, the brace should always be analyzed for shear due to bending and for other column considerations. If the underlying assumptions are accurate, this method of analysis is an elegant one.

Professor Levy's Method.—Professor Levy has presented analyses of arches subjected to lateral loads for all shapes and degrees of fixation, but the writer will merely touch upon the symmetrical shape and loads to indicate the rapidity, and the ease of visualizing the structure during such analyses. Fig. 4 shows a pair of such ribs in plan, and the elevation of the rib shows all the work required for the determination of the bending moment and the torsional moment at any section. The leeward rib receives its wind loads at Points 10, 8, 6, 4, and 2, and these loads are laid off in order, to yield the force polygon, P–M–N. For convenience, the pole distance, P–M, was taken as the sum of the loads, M–N, and the equilibrium polygon, e–f, was drawn through the Load Points 10 to 2. The closing line, u–v, of the arch considered as a fixed-ended beam is located by laying off from Line g–f the arithmetic mean of all the ordinates through Points 10 to 0 between the line, g–f, and the polygon, e–f, taken to the dimension scale of the layout. Then, the ordinate, v_a, between Lines e–f and u–v, multiplied by the pole distance, P–M, is the bending moment at Point 5 about the vertical plumb-line, y–y.

By drawing another force polygon for the same loads laid off on the half-chord, N'–S, and drawing an equilibrium polygon through horizontals drawn through the load points, 10, 8, 6, 4, and 2, the torsional moment about the horizontal through Point 5 is equal to h_a times the pole distance for the force

[10] "La Statique Graphique", Pt. III, p. 190, Lines 29 to 31.
[11] *Loc. cit.*, Pt. III, p. 211.

polygon. These two values correspond in direction to the values obtained by the author when he multiplies R_1 by one-half the brace length in the problem and does the same with R_2.

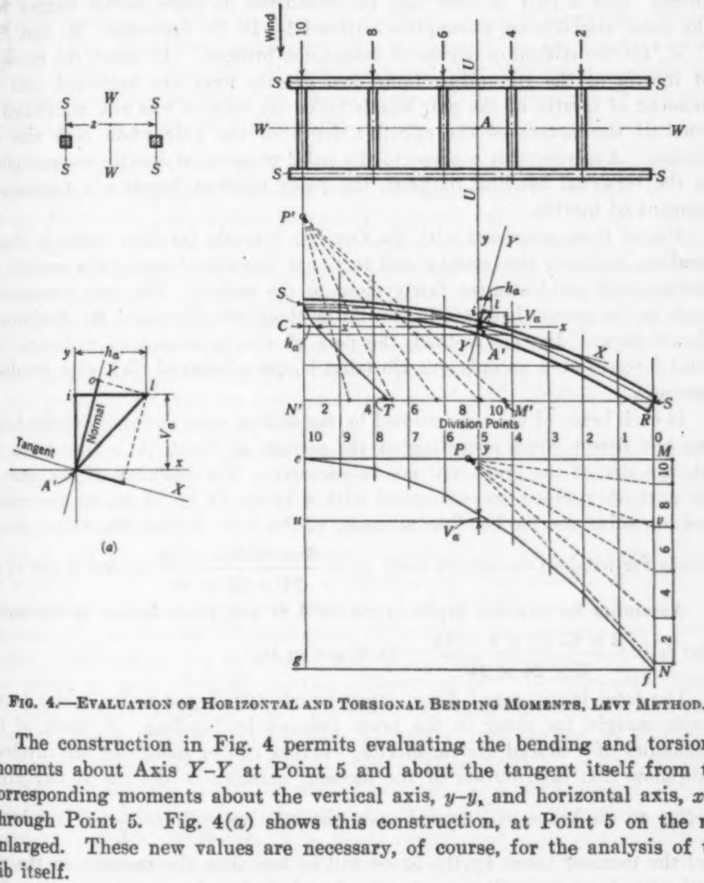

FIG. 4.—EVALUATION OF HORIZONTAL AND TORSIONAL BENDING MOMENTS, LEVY METHOD.

The construction in Fig. 4 permits evaluating the bending and torsional moments about Axis $Y-Y$ at Point 5 and about the tangent itself from the corresponding moments about the vertical axis, $y-y$, and horizontal axis, $x-x$, through Point 5. Fig. 4(a) shows this construction, at Point 5 on the rib, enlarged. These new values are necessary, of course, for the analysis of the rib itself.

Most of the groundwork for this analysis having already been done in solving the problem of the gravity load, the solution of the arch for wind is rapid. The concepts of loads and force polygons are familiar to most engineers; relative magnitudes can be compared, and it is seen that the point where the polygon, $e-f$, crosses the line, $u-v$, is the point of minimum bending. It is also a point of relatively small torsional moment.

Rational Method for Analyzing a Braced Arch System.—The author's development of formulas and his "Illustrative Example" show clearly what he means by the assumption that each rib is subjected to the same wind load;

that is, the leeward rib of the system resists the same amount of wind as the windward rib. This assumption, made in order to arrive at a solution, penalizes the system too severely and is entirely unnecessary. Professor Levy has shown[12] that a pair of ribs may be considered as plate girder flanges with the same simplifying assumption utilized by D. B. Steinman, M. Am. Soc. C. E., for the stiffening trusses of suspension bridges.[13] In short, the moments of inertia of the ribs about their own gravity axes are neglected, and the moment of inertia of the pair equals twice the area of one rib, multiplied by one-half the square of the effective depth of the pair when both ribs are similar. Applying this concept to the polar moment of inertia corresponding to the torsional bending moment, the polar moment becomes a rectangular moment of inertia.

Use of these constants with the familiar formula for fiber stress in simple bending, utilizing the bending and torsional moments found for a specific rib section, will yield stresses fairly close to the actual. The only assumption made in the process has been held valid by those who discussed Mr. Steinman's classic paper. In this method, the pair of ribs is caused to withstand the wind force coming on only one rib (that is, the windward rib), with resultant economy.

If each brace of the type studied by the author were designed for the bending and direct stress occurring at the section at which it is framed to the rib, the size of the brace will not be excessive. For instance, if the arch in the author's problem were supplied with a brace, 24 by 24 in., at the crown, and his value for the bending moment, 92 785 ft-lb (which the writer checks closely for wind on one rib) is used, $f_b = \dfrac{6 \times 92\,785 \times 12}{24 \times 24 \times 24} = 485$ lb per sq in.

Assuming an average depth of rib of 4 ft and three braces in the entire rib: $f_c = \dfrac{2 \times 67.30 \times 4 \times 45}{3 \times 24 \times 24} = 24$ lb per sq in.

The total bending and direct stress equals 509 lb per sq in., which leaves ample margin for shear in the brace induced by bending. A study of the mechanics of a braced system of ribs, whether two or more ribs are involved, will show that distribution of the moment existing in the rib at any given section to the brace will depend upon the relative stiffness, $\dfrac{I}{L}$, of the brace, and the moment taken by the brace will be less than the moment in the rib. Esthetics, however, will not permit of a brace section commensurate with the stresses therein, so that the writer's severe but simple method used in connection with Professor Levy's method, will not result in excessively large braces.

The writer finds the bending moment at the crown to be 99 700 ft-lb; that in the rib at the brace, 44 700 ft-lb; and the torsional moment in the rib at the brace, 21 000 ft-lb. The values found by the author in the rib at the

[12] "La Statique Graphique", p. 211 *et seq.*

[13] "A Generalized Deflection Theory for Suspension Bridges", *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1223, Lines 10–12.

crown, were 92 785 ft-lb, and with corrected formulas the bending in the brace would be 47 250 ft-lb, with a torsional moment in the brace of 30 270 lb. The writer believes the author's values for the braces are too high.

Mr. Eremin has opened a discussion of the treatment of the simplest types of arch-rib bridges in which the ribs and the loading are symmetrical. When either of these items is unsymmetrical, the solution is not as simple as the author's conclusion indicates. It is to be hoped that still other methods of analyzing structures subjected to lateral loads will be developed, which are simpler, easier to grasp, and more rapid.

FANG-YIN TSAI,[14] ASSOC. M. AM. SOC. C. E. (by letter).—The problem of wind stresses in reinforced concrete arch bridges is similar to that of bow girders, which have been treated previously by many authors[15], the only difference being that the former are fixed-end beams, curved in vertical plan, and subjected to horizontal loads, whereas the latter are fixed-end beams curved in horizontal plan, and subjected to vertical loads. However, the part of the paper under the heading, "Braced Arch Ribs", seems to be quite original. Although the solution of the problem has been indicated previously by some authors[16], the scant attention which the problem has received thus far, as well as the tendency to increase the span lengths of such bridges, makes the presentation of this paper very timely.

It is most unfortunate that the demonstrations are rather too brief and also not very clear. There is also quite a number of ambiguities which cause considerable confusion when one wishes to follow the demonstrations closely. For example, as stated by the author, Equations (3) and (4) are derived from Equation (2) by applying Castigliano's theorem. It may be noted that, for computing displacements, the application of Castigliano's theorem is advantageous only in cases where there is a load at the point and also in the direction of the desired displacement. Otherwise, an arbitrary load must be first introduced at the said point and in the said direction, and then the load is set to zero after the partial differentiation[17]. Consequently, there is a considerably long step from Equation (2) to Equations (3) and (4). However, if the method of work with a dummy unit loading as developed by Maxwell, Mohr, and the late George Fillmore Swain[18], Past-President and Hon. M., Am. Soc. C. E., is used, Equations (3) and (4) can be written directly with the dummy unit moments, $m_1 = 1$ and $m_2 = 1$, applied, successively, at Point P. Therefore, it is much simpler and more straightforward than the application of Castigliano's theorem. Of course, the two methods differ only in conception and operation, and they give identical results.

It must be also noted that the quantities, m_u and m_v, in Equation (2) are not the same as those in Equations (3) and (4). Whereas, those in Equation

[17] See "Statically Indeterminate Stresses", by J. I. Parcel and G. A. Maney, Members Am. Soc. C. E., John Wiley, New York, First Edition, 1926, pp. 37-39.

[18] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-1920), p. 622.

(2) are, respectively, the bending and torsion moments at Point N due to both the actual load (wind, m_1 or m_2, as the case may be) and the dummy moments, m_1 and m_2, applied at Point P in the horizontal and profile planes, those in Equations (3) and (4) are, respectively, the bending and torsion moments at Point N due to the actual load only. The values of m_u and m_v, due to the actual load, to be substituted in Equations (3) and (4), will be, respectively, those given by: (a) Equations (5) and (6) for deriving Equations (11) and (12) due to wind load; (b) $+ \cos \phi + M_1 \cos \phi$ and $- \sin \phi - M_1 \sin \phi$, for deriving Equations (14) and (15), due to the symmetrical moments, $m_1 = 1$; and (c) $+ \sin \phi + M_2 \cos \phi$ and $+ \cos \phi - M_2 \sin \phi$, for deriving Equations (17) and (18) due to symmetrical moments, $m_2 = 1$. The foregoing distinction must be noted carefully in following the derivation of all the aforementioned equations in order to avoid confusion. Again, the complications in applying Castigliano's theorem to the problem are evident.

Following Equation (25) the author states that Equations (24) and (25) may be expressed by Maxwell's theorem. Apparently, he refers to the principle of superposition, which is not due to Maxwell, as pointed out elsewhere[19] by the writer.

Table 1 gives only the numerical results of the various terms of integration, without showing the detailed method of computing them. The writer hopes that, in his closing discussion, the author will show the detailed computations for all the terms in tabulated forms as A. J. S. Pippard[20], M. Am. Soc. C. E., did in solving a problem of bow girder. Such an example of tabulated computations will not only facilitate the application of the method, but will also help in understanding the various terms of integration. It will be certainly welcomed by all those who wish to use the method in practice.

PAUL ANDERSEN,[21] ASSOC. M. AM. SOC. C. E. (by letter).—This paper is a valuable contribution to the theory of arch design. It is incomplete to the extent that it makes no mention of stresses in barrel arches with spandrel walls. Although the bending stresses, due to wind load, in an earth-filled arch are of no consequence, torsional stresses at the springing line may become quite large.

Using the author's notation and applying the principles of statics, the maximum torsional moment, M_T, which occurs at the springing line can be determined from,

$$M_c \cos \alpha + M_T = \int w\, t\, n\, ds \qquad (34)$$

in which α = the angle between the horizontal line and the tangent to the earth axis at the springing line; and n = the distance from the arch element to this tangent.

Using the values from the illustrative example in Fig. 3, Equation (34) becomes, $92\,785 \times 0.715 + M_T = 99\,470$; and $M_T = 33\,130$ ft-lb.

[19] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 130.

[20] "Strain Energy Methods of Stress Analysis", by A. J. S. Pippard, Longmans, Green & Co., London, 1928, pp. 133–135.

[21] Balboa Heights, Canal Zone.

This moment produces a maximum shearing stress, at the center of the wide side, of $\dfrac{33\,129 \times 12}{0.225 \times 54 \times 42^2} = 19$ lb per sq in. To this stress should be added the shearing stress due to dead load and live load.

In case of an arch with a rigidly connected superstructure (Fig. 5), the arch rib will transmit to the springing lines considerably more stress than the wind load acting upon the rib itself. If the arch is of the barrel type with spandrel walls, a large area is exposed to lateral wind pressure and the arch section, although possessing high resistance to horizontal bending, has comparatively low torsional strength. Shearing stresses for this type of structure will be considerably greater than 19 lb per sq in.

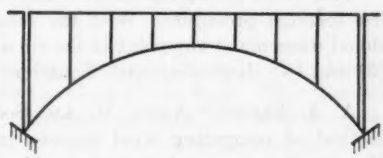

FIG. 5

It is unfortunate that the author chose the symbol, *w*, to indicate load intensity and *dw* to represent elastic weight; integration limits in the deflection terms and moment equations would also have been helpful.

LOUIS BLUME,[22] ESQ. (by letter).—Under the heading, "Arch Rib Without Bracing", the author presents an analysis that appears to lead to correct results. However, careful examination indicates that the method of approach is such as to involve superfluous work. To illustrate this, the following treatment of Equations (2), (5), and (6), is presented: Equation (2) can be written,

$$W = \frac{1}{2}\int m^2_u \, dw + \frac{\gamma}{2}\int m^2_v \, dw \quad \text{.............(35)}$$

Applying the principle of least work:

$$\frac{dW}{dM_w} = \int m_u \frac{dm_u}{dM_w} \, dw + \gamma \int m_v \frac{dm_v}{dM_w} \, dw = 0 \quad \text{.......(36)}$$

From Equations (5) and (6), $\dfrac{dm_u}{dM_w} = + \cos\phi$ and $\dfrac{dm_v}{dM_w} = - \sin\phi$.

By substitution:

$$\frac{dW}{dM_w} = \int M_w \cos^2\phi \, dw - \int \left[\cos\phi \, dw \int_c^N w\, t\, u\, ds \right]$$

$$+ \gamma \int M_w \sin^2\phi - \gamma \int \left[\sin\phi \, dw \int_c^N w\, t\, v\, ds \right] = 0 \quad \text{......(37)}$$

[22] Structural Engr., City Engr.'s Office, Los Angeles, Calif.

Solving for M_w:

$$M_w = \frac{\int \left[\cos \phi \int_c^N w \; t \; u \; ds + \gamma \sin \phi \int_c^N w \; t \; v \; ds \right] dw}{\int [\cos^2 \phi + \gamma \sin^2 \phi] \; dw} \quad ..(38)$$

This value of M_w agrees with that of Equation (13) but is obtained by a less tortuous procedure. With the value of M_w found, the bending and torsional moments at any point in the rib may be obtained by means of Equations (5) and (6), dispensing with Equations (16) and (19).

A. A. EREMIN,[28] ASSOC. M. AM. SOC. C. E. (by letter).—An interesting method of computing wind stresses in arch bridges, devised by Professor Maurice Levy[7], was described by Mr. Blog who, in discussing its various advantages, has not shown its serious limitations. Equations for wind stresses developed by Professor Levy may be applied only to a single arch rib. In the numerical example of wind-stress computations in an arch bridge with two steel ribs, braced with San Andreas cross-braces, as solved by Professor Levy, it was assumed that the bracings were absolutely stiff and two arch ribs were considered as a single arch rib. A similar method of analyzing wind stresses in reinforced concrete arch ribs with elastic braces, such as that shown in Fig. 3, would involve a serious error.

The graphical construction for computing wind stresses in a symmetrical arch rib shown by Mr. Blog, was devised by Professor Levy for a case in which the product of the moment of inertia of the arch rib and the cosine of the angle between a tangent to the arch axis and the horizontal, is a constant. A similar graphical construction of moments in the arch rib in Fig. 3 would require complicated computations for locating the line, u-v, in Fig. 4. In this case, analytical computations are much shorter. With a mechanical calculating machine the coefficients in Table 1 may be computed in a few hours. Furthermore, they may be computed with a slide-rule with reasonable accuracy for practical purposes.

Mr. Blog could not understand why the torsion moment, m_v, contributes anything to the value of θ, or that the bending moment, m_u contributes anything to the value of τ. This may be proved with reference to the similarity between forces and deformations in the plane of the arch rib. Vertical forces in this plane produce vertical and horizontal displacements. Likewise, horizontal forces also produce vertical and horizontal displacements. Therefore, Equations (32) and (33) are incorrect if applied to arch ribs.

In evaluating the coefficients, C_{1m} and C_{1t}, Mr. Blog erroneously considers the angle, ϕ, as a variable, which precludes the possibility of verifying the writer's equations. Contrary to Mr. Blog, wind pressures do have an effect on direct stresses in arch ribs. Such stresses in Equation (2) were not considered because they are negligible. In straight beams with ends fixed, which sustain transverse loads the direct stresses are never considered. However,

[28] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

it does not indicate that, in a beam completely fixed at the ends, transverse forces have absolutely no effect on direct stresses. Mr. Blog cites the writer's assumption that, in the braced arch ribs in Fig. 3, both arch ribs resist the same amount of wind pressure, stating that this condition penalizes the system severely. The writer does not agree since, by means of rigid braces, wind forces from the windward rib are transferred to the leeward rib in such a manner as to involve both arch ribs equally. For all practical purposes this assumption is correct and facilitates the location of the points of contraflexure in the braces.

Professor Tsai states that in developing Equations (3) and (4) by means of Castigliano's theorem, the writer failed to show all the steps. This theorem is described in standard textbooks on strengths of materials[24] sufficiently to reveal all the steps between Equations (2) and (3). The method involving the idea of a "dummy" unit force at a displacement point also follows from Castigliano's theorem.

The values in Table 1 were computed by the method of approximate summation. The arch rib was divided into voussoirs as shown in Fig. 3. The physical properties of the voussoirs were computed at their centers of gravity. The limits of integration are shown in Table 1; and, for the half arch rib, the limits are from the springing to the crown section.

Mr. Andersen's Equation (34) is similar to Equation (5) developed for a single arch rib. It is to be noted that, in the braced arch rib shown in Fig. 3, Equation (34) cannot be used for computing the bending moment at the springing. From Equations (5) and (6) the bending moment, M_B, and the torsion moment M_T, at the springing, in a single arch rib, are:

$$M_B = -\int w\ t\ u\ ds + M_w \cos \alpha \ldots\ldots\ldots\ldots\ldots (39)$$

and,

$$M_T = +\int w\ t\ v\ ds - M_w \sin \alpha \ldots\ldots\ldots\ldots\ldots (40)$$

The bending moment, M_{BS}, and the torsion moment, M_{TS}, at the springing of the braced arch rib in Fig. 3 are:

$$M_{BS} = -\int w\ t\ u\ ds + M_c \cos \alpha - R_1\ a \sin \alpha + R_2\ a \cos \alpha \ldots. (41)$$

and,

$$M_{TS} = +\int w\ t\ v\ ds - M_c \sin \alpha + R_1\ a \cos \alpha - R_2\ a \sin \alpha \ldots. (42)$$

Equations (39) to (42) may be used for computing wind stresses in filled or spandrel open arch bridges such as that shown in Fig. 5, as stated by Mr. Andersen. Fig. 6 shows a symmetrical spandrel filled arch bridge, subjected to a wind pressure, P, on a vertical strip, dx. In this case,

$$P = w\ H\ dx \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (43)$$

[24] Interesting information regarding Castigliano's theorem and the originality of Maxwell's theorem may be found in "Strength of Materials", Pt. I, by S. Timoshenko.

The force, P, is concentrated at the center of the strip but it may be transferred to the arch axis as a force, P, and an overturning moment, thus:

$$M_P = P\,e = w\,H\,e\,dx \qquad (44)$$

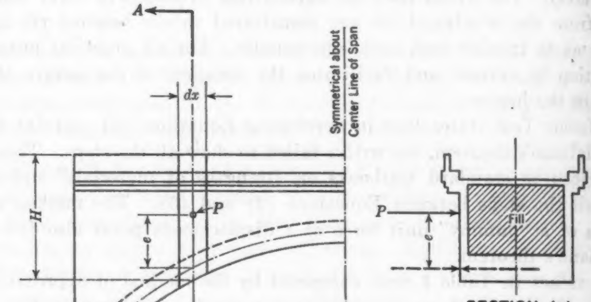

FIG. 6.—SPANDREL FILLED ARCH BRIDGE.

Therefore, the wind stresses in the arch rib in Fig. 6 are equal to the sum of the stresses computed with concentrated forces, P, acting along the arch axis, and the overturning moments, M_P. Wind stresses and deformations produced by Force P may be computed by means of Equations (1) to (13). The deformations and stresses in an arch rib sustaining overturning moments, M_P, may be developed by means of Equations (3) and (4).

The moments, m_u and m_v, in the arch rib due to an overturning moment, M_P, are:

$$m_u = -\int M_P \sin\phi\, ds + M_{mw}\cos\phi \qquad (45)$$

and,

$$m_v = +\int M_P \cos\phi\, ds + M_{mw}\sin\phi \qquad (46)$$

in which M_{mw} is the bending moment at the crown due to the symmetrical overturning moments, M_P. From Equations (45) and (46) and Equations (7) to (10), the deformations in an arch rib sustaining symmetrical moments, M_P, are found to be:

$$\theta_{mw} = -\int\left[\cos\phi\int M_P \sin\phi\, ds + \gamma\sin\phi\int M_P\cos\phi\, ds\right] dw$$

$$+ M_{mw}\int(\cos^2\phi + \gamma\sin^2\phi)\, dw \qquad (47)$$

and,

$$\tau_{mw} = \int \left[\sin \phi \int M_P \sin \phi \, ds - \gamma \cos \phi \int M_P \cos \phi \, ds \right] dw$$

$$+ M_{mw} \int (I - \gamma) \sin \phi \cos \phi \, dw \ldots\ldots\ldots\ldots\ldots (48)$$

In an arch rib with symmetrical wind pressures, the deformation, θ_{mw}, at the crown is equal to zero. Therefore, from Equation (47), the bending moment at the crown is:

$$M_{mw} = \frac{\int \left[\cos \phi \int M_P \sin \phi \, ds + \gamma \sin \phi \int M_P \cos \phi \, ds \right] dw}{\int (\cos^2 \phi + \gamma \sin^2 \phi) \, dw} \ldots (49)$$

For integrating Equations (47) to (49), the overturning moment, M_P, should be expressed as a continuous function. However, in practice the integration may be performed as an approximate summation without serious error. The arch rib is divided into a convenient number of vertical strips and forces, P, with overturning moments, M_P, computed for each strip. Strips that intersect the arch rib are considered as arch voussoirs and are treated in the manner shown in the illustrative example given in the paper (see Fig. 3).

Evidently, in the summation, the wind forces, P, the moments, M_P, and the physical properties of an arch rib must be considered at the centers of gravity of the voussoirs. An approximate method of summation is especially convenient in open spandrel arch bridges, in which wind-stress pressures vary abruptly along the arch axis, at the spandrel column.

Mr. Blume has shown the intermediate steps in developing Equation (13) from Equation (2). However, he was incorrect in considering the ratio, γ, to be constant. Obviously, it varies, along the arch axis, with the moment of inertia, I, and the torsion factor, F.

Paper No. 1962

SUCCESSIVE ELIMINATION OF UNKNOWNS IN THE SLOPE DEFLECTION METHOD

By John B. Wilbur[1], Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. C. A. Willson, Paul Andersen, R. W. Stewart, Adolphus Mitchell, Fang-Yin Tsai, A. Floris, A. W. Fischer, L. E. Grinter, L. T. Wyly, and John B. Wilbur.

Synopsis

A method of applying the usual slope deflection equations[2] is presented in this paper, which by successively expressing all the unknown elements in terms of a few unknowns makes an exact solution possible without the formal solution of a large number of simultaneous equations.

The method is described by showing its application to three types of structures: Continuous beams, building frames with shallow wind-bracing, and the Vierendeel truss. Certain principles are then enumerated, which may be extended to other structures that may be solved by the slope deflection method.

Notation

Throughout this paper, it will be assumed that the reader is familiar with the slope deflection theory. The usual slope deflection notation will be used, as follows:

d = relative deflection measured normal to the axis of a member, between the ends of the member;

h = height of a column, or distance between floors; story height;

p = panel length;

Note.—Published in December, 1935, *Proceedings*.

[1] Asst. Prof., Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.

[2] "Analysis of Statically Indeterminate Structures by the Slope Deflection Method", by W. M. Wilson, F. E. Richart, and Camillo Weiss, Members, Am. Soc. C. E., *Bulletin 108*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.

C = fixed-end moment at Point B on Beam BC, due to any load, P; a resisting moment;
E = modulus of elasticity in tension and compression;
I = moment of inertia;
K = ratio of the moment of inertia, to the length of a structural member;
M = moment of an external couple; M_{AB} = moment at End A, of Beam AB, etc. (see, also, C);
P = a concentrated load;
R = ratio of the increment in horizontal deflection occurring in a story, to the story height, the floors being identified by subscripts;
θ = a change in the slope of the tangent to the elastic curve of a member.

Continuous Beams

For a slope deflection solution of the structure shown in Fig. 1(a), there are five unknowns: θ_A, θ_B, θ_C, θ_D, and θ_E. For the order of using the slope deflection equations to be outlined, θ_A will be termed the permanent unknown, since all the other values of θ will be expressed, successively, in terms of θ_A, which will then be evaluated. The slope deflections, θ, at the remaining supports will be termed the temporary unknowns.

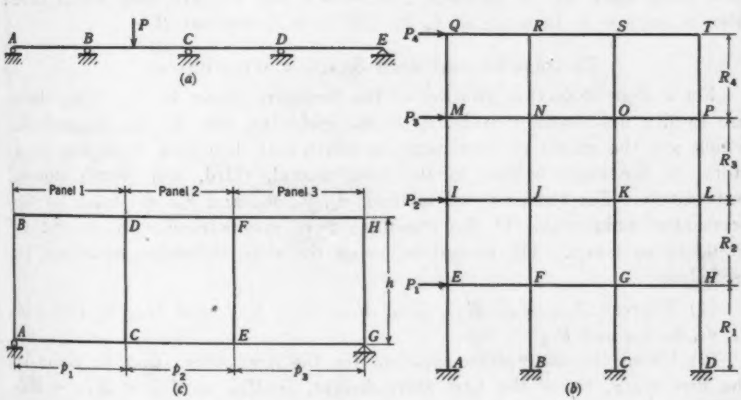

Fig. 1.

At either end support of a continuous beam, a known element exists; either the moment or the slope is zero, or the moment is known, as when the beam is a cantilever beyond the support. In Fig. 1(a) the moment at each end is zero. Thus, taking θ_A as the permanent unknown:

(1) Express θ_B in terms of θ_A by writing,

$$M_{AB} = 2\,E\,K_{AB}\,(2\,\theta_A + \theta_B) = 0 \ldots\ldots\ldots\ldots\ldots (1)$$

or,

$$\theta_B = -2\ \theta_A \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

(2) Express θ_C in terms of θ_A by writing $M_{BA} + M_{BC} = 0$, in which,

$$M_{BA} = 2\ E\ K_{AB}\ (2\ \theta_B + \theta_A) = 2\ E\ K_{AB}\ (-\ 3\ \theta_A) \ldots\ldots (3)$$

and,

$$M_{BC} = 2\ E\ K_{BC}\ (2\ \theta_B + \theta_C) \pm C = 2\ E\ K_{BC}\ (-\ 4\ \theta_A + \theta_C) \pm C. (4)$$

in which C is the fixed-end moment at Point B on Beam BC due to any load, P.

(3) Similarly, by $M_{CB} + M_{CD} = 0$ (that is, $\Sigma M = 0$ at Support C), express θ_D in terms of θ_A.

(4) Similarly, by $\Sigma M = 0$ at Support D, express θ_E in terms of θ_A.

(5) The fact that $M_{ED} = 0$ enables a solution for θ_A since $M_{ED} = E\ K_{DE}\ (2\ \theta_E + \theta_D) = 0$, in which θ_E and θ_D are functions of θ_A.

(6) With θ_A known, and all other values of θ in terms of θ_A, the moments in the beam are easily determined by the slope deflection equation.

Thus, the continuous beam shown in Fig. 1(*a*) is analyzed without the formal solution of simultaneous equations. This fact is not dependent upon the number of spans. Had the beam been fixed at Point A, θ_B would have been taken as the permanent unknown, and the first step would have been to express θ_C in terms of θ_B by $\Sigma M = 0$ at Support B.

Building Frames with Shallow Wind-Braces

For a slope deflection solution of the structure shown in Fig. 1(*b*), there are twenty unknowns, namely, θ_E to θ_T, inclusive, and R_1, R_2, R_3, and R_4, which are the ratios of increment in horizontal deflection occurring in a story, to the story height, in the first, second, third, and fourth stories, respectively. For the proposed method, θ_E, θ_F, θ_G, and θ_H, are taken as the permanent unknowns. If the structure were symmetrical only θ_E and θ_F would be so taken. The procedure, using the slope deflection equations, is, as follows:

(1) Express M_{AE}, M_{EA}, M_{BF}, M_{FB}, M_{CG}, M_{GC}, M_{DH}, and M_{HD} in terms of θ_E, θ_F, θ_G, θ_H, and R_1;

(2) Using the shear-story equation for the first story (that is, shear in the first story, times the first story height, $+ M_{AE} + M_{EA} + M_{BF} + M_{FB} + M_{CG} + M_{GC} + M_{DH} + M_{HD} = 0$), express R_1 in terms of θ_E, θ_F, θ_G, and θ_H;

(3) At Joint E, write $\Sigma M = 0$, where all moments may now be written in terms of θ_E, θ_F, θ_G, θ_H, θ_I, and R_2; from this equation express θ_I in terms of θ_E, θ_F, θ_G, θ_H, and R_2. Similarly, working from $\Sigma M = 0$ at Joints F, G, and H express θ_J, θ_K, and θ_L, respectively, in terms of θ_E, θ_F, θ_G, θ_H, and R_2;

(4) The moments in the ends of the second-story columns may now be written in terms of θ_E, θ_F, θ_G, θ_H, and R_2, and the application of the shear-story equation to the second story, enables the designer to express R_2, and, hence, θ_I, θ_J, θ_K, and θ_L, in terms of the permanent unknowns;

(5) Working progressively up the building in this manner, express all θ-values and all R-values in terms of the permanent unknowns; four equations, one for each unknown, will still be available, namely, $\Sigma M = 0$ at Joints Q, R, S, and T. The formal solution of these four simultaneous equations yields values of θ_E, θ_F, θ_G, and θ_H; and,

(6) With all the R-values and all the temporary θ-values previously expressed in terms of the permanent unknowns, the moments in the structure are easily determined by the slope deflection equation.

Thus, the building frame shown in Fig. 1(*b*) is solved with the formal solution of only four simultaneous equations, one equation for each row of columns. This fact is independent of the number of stories. Symmetry would further reduce the labor since for the structure shown in Fig. 1(*b*), $\theta_E = \theta_H$ and $\theta_F = \theta_G$. Thus, a twenty-story, four-column, symmetrical bent[8] could be analyzed with the formal solution of only two simultaneous equations.

Illustrative Problem

To demonstrate the application of the proposed method to the case of building frames with shallow wind-braces, the structure shown in Fig. 2 may be solved, as follows: The shear-story equation applied to the first floor yields:

$$2\,[2\,E\,(2\,\theta_A - 3\,R_1)$$

$$+ 2\,E\,(\theta_A - 3\,R_1)] + 20\,(20) = 0$$

or,

$$3\,R_1 = 1.5\,\theta_A + \frac{100}{2\,E}$$

For the condition, $\Sigma M = 0$ at Joint A:

$$2\,\theta_A - 1.5\,\theta_A - \frac{100}{2\,E}$$

$$+ 3\,\theta_A + 2\,\theta_A + \theta_C - 3\,R_2 = 0$$

or,

$$\theta_C = 3\,R_2 + \frac{100}{2\,E} - 5.5\,\theta_A$$

Applied to the second floor, the shear-story equation yields:

$$2\,[\,2\,E\,(3\,\theta_A + 9\,R_2 + \frac{300}{2\,E}$$

$$- 16.5\,\theta_A - 6\,R_2)] + 10 \times 20 = 0$$

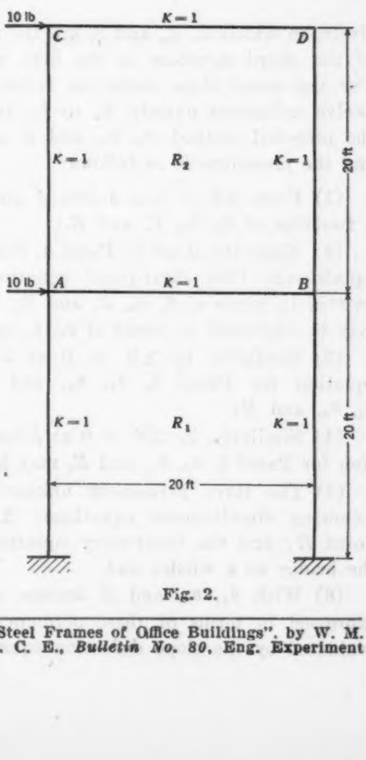

Fig. 2.

[8] For example, see "Wind Stresses in the Steel Frames of Office Buildings", by W. M. Wilson and G. A. Maney, Members, Am. Soc. C. E., *Bulletin No. 80*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill., 1915.

or,

$$3\ R_2 = 13.5\ \theta_A - \frac{400}{2\ E};\ \text{and,}\ \theta_C = 8\ \theta_A - \frac{300}{2\ E}$$

Similarly, for the condition, $\Sigma M = 0$ at Joint C:

$$2\left(8\ \theta_A - \frac{300}{2\ E}\right) + \theta_A - 13.5\ \theta_A + \frac{400}{2\ E} + 3\left(8\ \theta_A - \frac{300}{2\ E}\right) = 0$$

and $\theta_A = \dfrac{40}{2\ E}$. Therefore, the deflection ratio, R_1, is expressed by $3\ R_1 = \dfrac{160}{2\ E}$; and the moment at the column base is $M = 2\ E\left(\dfrac{40}{2\ E} - \dfrac{160}{2\ E}\right) = -\ 120$ ft-lb, the minus sign denoting that the couple, M, acts contra-clockwise on the column.

Vierendeel Truss

For the structure shown in Fig. 1(*c*), let $R = \dfrac{d}{h}$, in which d is the relative horizontal deflection between the top and bottom of any of the vertical members of the truss. Let R_1, R_2, and R_3 equal $\dfrac{d_1}{p_1}$, $\dfrac{d_2}{p_2}$, and $\dfrac{d_3}{p_3}$, respectively, in which d_1, d_2, and d_3 are the relative vertical deflections of the ends of the chord members in the first, second, and third panels, respectively. For the usual slope deflection solution of this structure, there would be twelve unknowns namely, θ_A to θ_H, inclusive, and R, R_1, R_2, and R_3. For the proposed method, θ_A, θ_B, and R are taken as the permanent unknowns, and the procedure is as follows:

(1) From $\Sigma M = 0$ at Joints A and B, express θ_C and θ_D, respectively, as a function of θ_A, θ_B, R, and R_1;

(2) Since the shear in Panel 1, times p_1 plus $M_{AC} + M_{CA} + M_{BD} + M_{DB}$, equals zero (the shear-panel equation), and all these moments may be written in terms of θ_A θ_B, R, and R_1, it follows that R_1 and, thus, θ_C and θ_D may be expressed in terms of θ_A, θ_B, and R;

(3) Similarly, by $\Sigma M = 0$ at Joints C and D, and the shear-panel equation for Panel 2, θ_E, θ_F, and R_2 may be expressed in terms of θ_A, θ_B, and R;

(4) Similarly, by $\Sigma M = 0$ at Joints E and F, and the shear-panel equation for Panel 3, θ_G, θ_H, and R_3 may be expressed in terms of θ_A, θ_B, and R;

(5) The three permanent unknowns may now be evaluated from the following simultaneous equations: $\Sigma M = 0$ at Joint G; $\Sigma M = 0$ at Joint H; and the shear-story equation applied to the vertical members of the bridge as a whole; and,

(6) With θ_A, θ_B, and R known, and the temporary unknowns already expressed in terms of these permanent unknowns, the moments are easily evaluated by the slope deflection equation.

Remarks

The foregoing examples show that it is necessary to take as permanent unknowns only one θ-value for each row of members parallel to the direction in which the solution is to progress across a structure, plus one R-value for each panel between such rows (if there is more than one row), whenever the construction is such that these R-values do not equal zero. For the formal solution of simultaneous equations, there will be as many equations as there are permanent unknowns. It should be evident that solution in this manner does not actually avoid the solution of simultaneous equations, but, rather, provides a means of eliminating the unknowns progressively. The usual slope deflection equations could be written simultaneously, and if solved in the order described in this paper, would lead to the same solution. It seems to the writer, however, that there is little likelihood of this being done without purposely following the line of reasoning herein outlined.

A portion of the underlying research which forms the basis of this paper was submitted to Massachusetts Institute of Technology by the writer in 1933 in partial fulfillment of the requirements for the degree of Doctor of Science. Other phases of the broader subject have been published elsewhere under the titles, "A New Method for Analyzing Stresses Due to Lateral Forces in Building Frames[4]", and "Distribution of Wind Loads to the Bents of a Building[5]."

DISCUSSION

C. A. WILLSON,[e] M. AM. SOC. C. E. (by letter).—The slope deflection method of analyzing statically indeterminate structures is recognized by structural engineers as a valuable working tool. It is especially useful in the analysis of a complicated unsymmetrical framework. However, it is a fact that the solution of a large number of simultaneous equations can become very tiresome. Therefore, the method outlined by Professor Wilbur should be of real service to designing engineers who find it advisable to make complete analyses of structural frames.

The writer has found it convenient and sufficiently accurate in many cases to determine the bending moments in the members meeting at a particular joint by a consideration of sixteen members that radiate from it. In such a layout there are five unknown deflection angles, the one at the joint in question and four others. The writer has used the same idea advanced by Professor Wilbur of successive elimination of unknowns in the development of a simple solution.

The sixteen-member framework is preferable to the smaller frameworks frequently used because greater accuracy is obtained and because the effect of loading and unloading a number of members in the vicinity of the joint in question can be determined quickly.

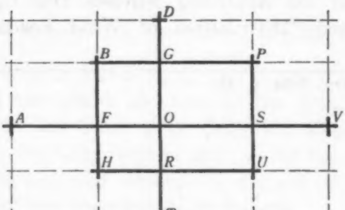

FIG. 3.

Let Fig. 3 represent a part of a building framework composed of beams and columns of different lengths, moments of inertia, and loadings. Assume that bending moments are to be determined at Joint O because of the unsymmetrical conditions that surround that joint. Assume fixed-end terminals at a distance of two joints removed from Joint O in all directions. The resulting partial structure of sixteen members is indicated by heavy lines in Fig. 3. To summarize, fixed ends are assumed at A, B, D, P, V, U, T, and H, and bending moments are to be determined at Joint O.

The moments in members meeting at Joint R will be as follows:

$$M_{RT} = 4\ E\ \theta_R\ K_{RT} \qquad (5)$$

$$M_{RH} = 4\ E\ \theta_R\ K_{RH} + C_{RH} \qquad (6)$$

$$M_{RO} = 2\ E K_{OR}\ (2\ \theta_R + \theta_O) \qquad (7)$$

and,

$$M_{RU} = 4\ E\ \theta_R\ K_{RU} - C_{RU} \qquad (8)$$

[e] Structural Engr., State Archt.'s Office, Madison, Wis.

Let $C_R = C_{RH} - C_{RU}$ and let $\Sigma K_R = K_{RT} + K_{RH} + K_{RO} + K_{RU}$. With $\Sigma M = 0$ at Joint R:

$$0 = 4 E \theta_R \Sigma K_R + 2 E \theta_O K_{OR} + C_R \quad \text{.............. (9)}$$

Then,

$$E \theta_R = -\frac{2 E \theta_O K_{OR} + C_R}{4 \Sigma K_R} \quad \text{.................. (10)}$$

Similarly,

$$E \theta_F = -\frac{2 E \theta_O K_{OF} + C_F}{4 \Sigma K_F} \quad \text{.................. (11)}$$

$$E \theta_G = -\frac{2 E \theta_O K_{OG} + C_G}{4 \Sigma K_G} \quad \text{.................. (12)}$$

and,

$$E \theta_S = -\frac{2 E \theta_O K_{OS} + C_S}{4 \Sigma K_S} \quad \text{.................. (13)}$$

The moments in members meeting at Joint O will be as follows:

$$M_{OR} = 2 E K_{OR} (2 \theta_O + \theta_R) = 4 E \theta_O K_{OR} - \frac{E \theta_O (K_{OR})^2}{\Sigma K_R} - \frac{C_R K_{OR}}{2 \Sigma K_R} \quad \text{.. (14)}$$

$$M_{OF} = 2 E K_{OF} (2 \theta_O + \theta_F) + C_{OF} = 4 E \theta_O K_{OF} - \frac{E \theta_O (K_{OF})^2}{\Sigma K_F}$$

$$- \frac{C_F K_{OF}}{2 \Sigma K_F} + C_{OF} \quad \text{...................... (15)}$$

$$M_{OG} = 2 E K_{OG} (2 \theta_O + \theta_G) = 4 E \theta_O K_{OG} - \frac{E \theta_O (K_{OG})^2}{\Sigma K_G} - \frac{C_G K_{OG}}{2 \Sigma K_G} \quad \text{.. (16)}$$

and,

$$M_{OS} = 2 E K_{OS} (2 \theta_O + \theta_S) - C_{OS} = 4 E \theta_O K_{OS} - \frac{E \theta_O (K_{OS})^2}{\Sigma K_S}$$

$$- \frac{C_S K_{OS}}{2 \Sigma K_S} - C_{OS} \quad \text{...................... (17)}$$

With $\Sigma M = 0$ at Joint O and $\Sigma K_O = K_{OR} + K_{OF} + K_{OG} + K_{OS}$:

$$E_O \left[4 \Sigma K_O - \frac{(K_{OR})^2}{\Sigma K_R} - \frac{(K_{OF})^2}{\Sigma K_F} - \frac{(K_{OG})^2}{\Sigma K_G} - \frac{(K_{OS})^2}{\Sigma K_S} \right]$$

$$= \frac{C_R K_{OR}}{2 \Sigma K_R} + \frac{C_F K_{OF}}{2 \Sigma K_F} + \frac{C_G K_{OG}}{2 \Sigma K_G} + \frac{C_S K_{OS}}{2 \Sigma K_S} - C_O \quad \text{....... (18)}$$

and,

$$E\,\theta_O = \frac{\dfrac{C_R\,K_{OR}}{2\,\Sigma K_R} + \dfrac{C_F\,K_{OF}}{2\,\Sigma K_F} + \dfrac{C_G\,K_{OG}}{2\,\Sigma K_G} + \dfrac{C_S\,K_{OS}}{2\,\Sigma K_S} - C_O}{4\,\Sigma K_O - \dfrac{(K_{OR})^2}{\Sigma K_R} - \dfrac{(K_{OF})^2}{\Sigma K_F} - \dfrac{(K_{OG})^2}{\Sigma K_G} - \dfrac{(K_{OS})^2}{\Sigma K_S}} \quad \ldots\ldots\ldots(19)$$

When the value of the deflection angle at Joint O is determined by Equation (19), the values of the other four unknown deflection angles (Equations (10) to (13)) can be found easily. Then, with known values of the five deflection angles, it is a simple matter to calculate the desired bending moments.

PAUL ANDERSEN,[7] ASSOC. M. AM. SOC. C. E. (by letter).—A clear and interesting method of setting up the slope deflection equations necessary for the analysis of continuous structures, is contained in this paper. It should be noted, however, that the method of reducing the number of unknown quantities, as presented by the author, is one which suggests itself immediately after all the "joint" and "bent" equations are written, and as such the idea is not unknown to designers. Professor Wilbur's procedure is to eliminate unknown quantities as the equations are set up rather than afterward. In all cases the author's final equations can be derived by writing the total number of slope deflection relations and proceeding as outlined in the paper. Furthermore, designers who make use of the slope deflection method are not, as a rule, objecting to the large number of simultaneous equations; a careful tabulation and the use of two or three successive approximations will yield results which are very close to the actual rotations.

In the case of secondary stress analysis the author's method will involve more work than the usual process, the permanent and the temporary unknowns being the rotations of bottom chord joints and top chord joints, respectively.

Professor Wilbur's method can be used to advantage in dealing with a continuous beam; the slope deflection equations for this type of structure are so simple and few that much unnecessary writing is avoided by choosing one permanent unknown. It is interesting to note, however, that an application of the same principle to the theorem of three moments results in a still larger saving. Thus, referring to Fig. 1(*a*):

$$2\,M_B\left(\frac{1}{K_{AB}} + \frac{1}{K_{BC}}\right) + \frac{M_C}{K_{BC}} = A_{BC} \quad \ldots\ldots\ldots\ldots(20)$$

in which A_{BC} can be computed from the position and magnitude of the load, P, and K_{BC}. Express M_C in terms of M_B.

Applying the three-moment theorem to $B\,C\,D$:

$$\frac{M_B}{K_{BC}} + 2\,M_C\left(\frac{1}{K_{BC}} + \frac{1}{K_{CD}}\right) + \frac{M_D}{K_{CD}} = A_{CB} \ldots\ldots\ldots(21)$$

[7] Balboa Heights, Canal Zone.

in which A_{CB} likewise is known. After substituting for M_C the value in Equation (20), it is seen that from Equation (21), M_D is obtained in terms of M_B.

Applying the three-moment theorem to $C\,D\,E$:

$$\frac{M_C}{K_{CD}} + 2\,M_D\left(\frac{1}{K_{CD}} + \frac{1}{K_{DE}}\right) = 0 \qquad (22)$$

In Equation (22) substitute the values of M_C and M_D in terms of M_B, and solve for M_B.

The application of the theorem of three moments has the advantage of leading directly to the bending moments without computing first the changes of slope in which the designer is generally not interested.

R. W. Stewart,[8] M. Am. Soc. C. E. (by letter).—Systemization is the essence of slope deflection and this is recognized in the author's paper. However, it appears that one opportunity for better systemization has been overlooked; that is, improvement in the rules for signs in the use of the fixed-end moment constants.

The author's Equation (4) terminates with the term, $\pm C$. Authoritative treatises[9] would invert this double sign, making it $\mp C$. A study of several available expositions of these sign rules has convinced the writer that the use of a single minus sign for the fixed-end moments throughout all the standard equations will operate more satisfactorily than the double sign usually published, or the alternate plus and minus signs sometimes used.[10] Furthermore, the usual explanatory statements can be curtailed with greater resulting clarity. To illustrate this in an introductory manner the following solution of the author's Fig. 1 is offered, assigning numerical values to the load, its position, and the relative stiffnesses $\left(\frac{I}{L}\text{-values}\right)$ of the members. In this illustration the fixed-end moments are considered as the activating moments which a loaded span would exert on its end joints if these joints were fixed.

The following rules of signs are offered as completely covering all conditions: (1) Clockwise rotations are taken as positive, the reverse as negative; (2) moments that tend to produce clockwise rotation are considered positive, the reverse negative; and (3) deflections that produce clockwise rotations are considered positive, the reverse negative. Any further statements the writer feels to be dangerous and likely to cause confusion, except that the reader may be asked to observe the obvious fact that a moment or a deflection at a point in a beam which tends to cause the beam on one side of it to rotate in a clockwise direction will tend to cause the part on the other side to rotate in a

[8] Engr. of Bridge and Structural Design, City of Los Angeles, Los Angeles, Calif.

[9] *Bulletin 108*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.; also, *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 75.

[10] "Modified Slope Deflection", by L. T. Evans, Assoc. M. Am. Soc. C. E., *Journal*, Am. Concrete Inst., October, 1931.

contra-clockwise direction. This is analogous to the shear changing from positive to negative under the load when a simple beam is loaded with a single concentrated load.

In the author's program for solving Fig. 1, the solution is carried from the left end of the beam to the right, thereby necessitating carrying the constants for the fixed-end moments through the equations for the two unloaded spans, CD and DE. An easier program will be to work from right to left, as is done in the following solution, thereby carrying these constants through the equations for a lesser number of spans. The fixed-end moments with proper signs and directional arrows are, in accordance with the foregoing conventionality, indicated on Fig. 4. The standard equations used are the same as those in the various existing texts except that in all standard equations the fixed-end moment constants are preceded by a minus sign only—not a double sign, nor alternating plus and minus signs. Relative stiffness or $\frac{I}{L}$-values are indicated. Referring to Fig. 4:

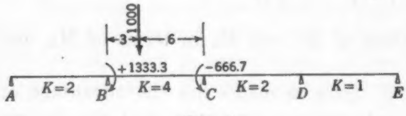

FIG. 4.

$$M_{ED} = 2\,(2\,\theta_E + \theta_D) = 0 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(23)$$

and, $\theta_D = -2\,\theta_E$;

$$M_{DE} + M_{DC} = 0 = 2(-4\,\theta_E + \theta_E) + 2 \times 2\,(-4\,\theta_E + \theta_C) \;\ldots(24)$$

and, $\theta_C = 5.5\,\theta_E$;

$$M_{CD} + M_{CB} = 0 = 2 \times 2\,(11\,\theta_E - 2\,\theta_E) + 2 \times 4\,(11\,\theta_E + \theta_B) + 666.7 \;..(25)$$

and, $\theta_B = -15.5\,\theta_E - 83.33$;

$$M_{BC} + M_{BA} = 0 = 2 \times 4\,(-31\,\theta_E - 166.7 + 5.5\,\theta_E)$$
$$-1\,333.3 + 2 \times 2\,(-31\,\theta_E - 166.7 + \theta_A) \;\ldots\ldots\ldots\ldots(26)$$

and, $\theta_A = 82\,\theta_E + 833.3$;

$$M_{AB} = 0 = 2 \times 2\,(164\,\theta_E + 1\,666.7 - 15.5\,\theta_E - 83.33) \;\ldots\ldots.(27)$$

and, $\theta_E = -10.67$.

Comments.—In Equation (25) the fixed-end moment has the plus sign because it is negative in Fig. 4 and is preceded by a minus sign in the standard equation, and $- \times - = +$. The fixed-end moment of 1 333.3 is plus in Fig. 4 and minus in the standard equation making it $+ \times - = -$ in Equation (26).

If the load acted upward, the signs in Fig. 4 would be reversed, thereby reversing the signs for these terms in Equations (25) and (26) and yielding $\theta_E = +10.67$. Likewise, the constant, H_{AB}, familiar to users of slope deflection, may always be preceded by the minus sign only in the standard equations

provided it is delineated on the diagram in accordance with the convention stated.

The author's numerical solution of Fig. 2, using θ_A and the first-story R-value as the permanent unknowns, is of interest in that, apparently, it displays the full possibilities of slope deflection for this problem, which involves side-sway and is not so conveniently solved by end-moment distribution.

However, it is of interest and probably useful to show the following solution for this problem in which the phenomena of flexure are so treated as to eliminate the R-terms (deflection terms) which are necessary in the author's solution, and, otherwise, to simplify and reduce materially the work.

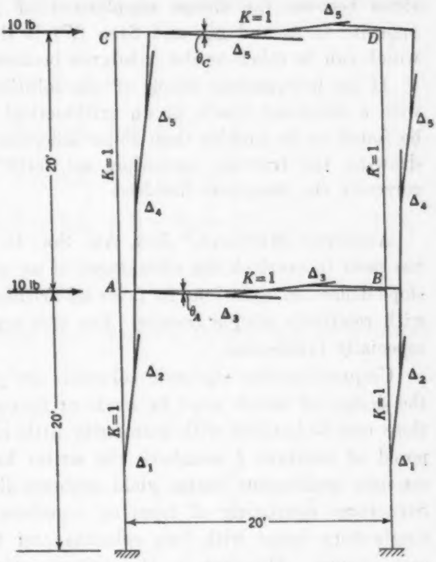

FIG. 5.

Referring to Fig. 5:

$$(A)\ldots.2\,(2\,\Delta_1 + 2\,\Delta_2) = 20 \times 20$$

and, $\Delta_1 = 100 - \Delta_2$;

$$(B)\ldots.\theta_A = 100 - \Delta_2 - \Delta_2 \ldots\ldots\ldots\ldots\ldots\ldots\Delta_2 = 50 \quad - \quad 0.5\ \theta_A$$

$$(C)\ldots.2\,(2\,\Delta_4 + 2\,\Delta_5) = 10 \times 20$$

and, $\Delta_5 = 50 - \Delta_4$;

$$(D)\ldots.\theta_A = \tfrac{1}{3}\,(50 - \Delta_4) + 50 - \Delta_4 - \Delta_4 \ldots\ldots\Delta_4 = 28.6 - \ 0.43\ \theta_A$$

$$(E)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots - \Delta_3 = \qquad - \ 3.0\ \theta_A$$

$$(F)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \Sigma\,\Delta = 0 = 78.6 - \ 3.93\ \theta_A$$

and, $\theta_A = \dfrac{20}{E}$. The moment at the column base $= 2(100 - 50 + 10) = 120$.

Comments.—Since the stiffness factors of all members are equal and may be taken as unity, each moment will be double its corresponding Δ.

In Step (A), the sum of the internal moments is equated to the external moment for the first story; in Step (B), the column angles of the left lower column are added to obtain an expression for θ_A; Step (C) is the same as Step (A), except that it is for the second story; Step (D) is the same process as Step (B), except that it is for the left upper column; Step (E) is written directly from the geometry of the figure[11] and the terms are given negative

[11] "An Improved Method of Finding Beam Deflections", *Civil Engineering*, February, 1934, p. 88; also "Analysis of Continuous Structures by Traversing the Elastic Curves", *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 105.

signs because the obtuse supplement of Δ_3 indicates rotational activation opposite to Δ_3 and Δ_4; and Step (F) is the moment balance about Joint A which can be taken as the Δ-balance because all K-factors are equal.

If an independent check of the solution is desired, the traverse method with a graphical check, or an arithmetical angle summation check, will also be found to be simpler than slope deflection for Fig. 4. If the procedure for drawing the traverse heretofore set forth[12] is followed, it is easy to draw correctly the diagrams involved.

ADOLPHUS MITCHELL,[13] JUN. AM. SOC. C. E. (by letter).—The recent trend has been to overlook the advantages of an algebraic procedure of applying the slope-deflection equations in favor of arithmetical methods even when dealing with relatively simple frames. For this reason Professor Wilbur's ideas are especially interesting.

Unquestionably, algebraic solutions are preferable when analyzing frames, the design of which must be made at frequent intervals, whenever the equations can be handled with reasonably little effort. Among the structures composed of constant I members, the writer has found that triple culverts and six-span continuous beams yield without difficulty to the algebraic solution. Structures consisting of tapering members are more difficult to solve, but single-story bents with two columns and three-span continuous beams are easy enough. However, in the writer's opinion, a skeleton type of building frame, such as that described by the author, should, unhesitatingly, be solved by fixation factors[14], or by moment distribution.[15] If the slope-deflection method is applied, the use of Gauss' normal equations[16] will be found valuable as it affords many checks as the solution proceeds.

The importance of arranging the solution so as to produce the greatest degree of accuracy cannot be over-emphasized. Although in the schoolroom it is sufficient to gain the principles involved, in the design office, the quantitative results must be correct as well. In the treatment of continuous beams and frames of limited complexity it is best to consider all members loaded and to solve the problem in such a manner that a symmetry of form in the equations is preserved throughout the analysis. One will soon find this an inestimable aid to accuracy.

Consider the problem of a continuous beam over five supports and with equal spans, as shown in Fig. 6. Let $A = -C_{1,2}$; $B = C_{2,1} - C_{2,3}$; $C = C_{3,2} - C_{3,4}$; $D = C_{4,3} - C_{4,5}$; and $E = +C_{5,4}$; and notice that for uniform loading over all spans the loading

FIG. 6.

[14] "Structural Frameworks", by T. F. Hickerson, M. Am. Soc. C. E., Univ. of North Carolina Press., Chapel Hill, N. C.

[15] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

[16] "Secondary Stresses in Bridges", by Cecil von Abo, Assoc. M. Am. Soc. C. E. *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 107; also, "Method of Least Squares", by Merriman, N. Y., John Wiley & Sons.

factors, B, C, and D, equal zero. Next, write the equation for each support, omitting EK for simplicity; thus:

$$M_{1,2} = 0 = 2\,\theta_1 + \theta_2 + A$$

$$M_{2,1} + M_{2,3} = 0 = 4\,\theta_2 + \theta_3 + \theta_1 + B$$

$$M_{3,2} + M_{3,4} = 0 = 4\,\theta_3 + \theta_4 + \theta_2 + C$$

$$M_{4,3} + M_{4,5} = 0 = 4\,\theta_4 + \theta_5 + \theta_3 + D$$

and,

$$M_{5,4} = 0 = 2\,\theta_5 + \theta_4 + E$$

To eliminate the unknowns, begin simultantously at each end, as indicated by the arrows:

$$\theta_1 = -\frac{1}{2}\,\theta_2 - \frac{1}{2}\,A$$

$$\frac{7}{2}\,\theta_2 + \theta_3 + B - \frac{1}{2}\,A = 0; \text{ or } \theta_2 = -\frac{2}{7}\,\theta_3 - \frac{2}{7}\,B + \frac{1}{7}\,A$$

$$\frac{26}{7}\,\theta_3 + \theta_4 - \frac{2}{7}\,B + \frac{1}{7}\,A + C = 0;$$

$$\text{or, } \theta_3 = -\frac{7}{26}\,\theta_4 - \frac{7}{26}\,C + \frac{2}{26}\,B - \frac{1}{26}\,A$$

$$\theta_3 = \frac{2}{26}\,\theta_3 + \frac{2}{26}\,D - \frac{1}{26}\,E - \frac{7}{26}\,C + \frac{2}{26}\,B - \frac{1}{26}\,A \longrightarrow \theta_3$$

$$= \frac{1}{24}\Big[-A + 2\,B - 7\,C + 2\,D - E\Big]$$

$$\frac{7}{2}\,\theta_4 + \theta_3 + D - \frac{1}{2}\,E = 0; \text{ or } \theta_4 = -\frac{2}{7}\,\theta_3 - \frac{2}{7}\,D + \frac{1}{7}\,E$$

$$\theta_5 = -\frac{1}{2}\,\theta_4 - \frac{1}{2}\,E$$

Finally:

$$\theta_2 = \frac{1}{84}\,[13\,A - 26\,B + 7\,C - 2\,D + E]$$

$$\theta_4 = \frac{1}{84}\,[A - 2\,B + 7\,C - 26\,D + 13\,E]$$

$$\theta_1 = -\frac{1}{168}[97\,A - 26\,B + 7\,C - 2\,D + E]$$

and,

$$\theta_5 = -\frac{1}{168}[A - 2B + 7C - 26D + 97E]$$

Substituting in the fundamental equations.

$$M_{2,1} = 2\theta_2 + \theta_1 + C_{2,1} = \frac{1}{56}[-15A - 26B + 7C - 2D + E] + C_{2,1}$$

$$M_{3,2} = 2\theta_3 + \theta_2 + C_{3,2} = \frac{1}{56}[+4A - 8B - 28C + 8D - 4E] + C_{3,2}$$

and,

$$M_{4,5} = 2\theta_4 + \theta_5 - C_{4,5} = \frac{1}{56}[+A - 2B + 7C - 26D - 15E] - C_{4,5}$$

Notice the symmetry preserved in each step. The writer now wishes to justify his claim that "it is best to consider all members loaded." There are almost always limiting cases for which the solution of a problem can be found. In this problem it is the condition of uniform load over all spans, which may be used as a check. For this case, $A = -\frac{1}{12}wL^2$; $B = 0$; $C = 0$; $D = 0$; $E = +\frac{1}{12}wL^2$; and $M_{3,2} = \frac{1}{56}\left(\frac{1}{12}wL^2\right)(-4 - 4) + \frac{1}{12}wL^2 = \frac{2}{28}wL^2$, which value can be found in any handbook. Although this check does not necessarily indicate that every part of a solution is correct, failure to obtain it does reveal that a mistake has been made. The thoroughness of this method of checking depends upon the number of known cases available. If there is a case requiring the retention of each loading term, the check may be regarded as absolute.

If the reader would write out a solution carrying θ_1 as the unknown throughout the evaluation of the rotations as suggested by the author, he would more readily appreciate the foregoing procedure

FANG-YIN TSAI,[17] ASSOC. M. AM. SOC. C. E. (by letter).—By a simple process the method presented by Professor Wilbur can be adjusted to apply to the case of continuous structures with variable moments of inertia.

Slope-deflection equations for the case of variable moments of inertia have been presented by L. T. Evans[18], Jun. Am. Soc. C. E., and also by the writer[19], both results being almost identical. These equations involve certain coefficients known as angle changes which express the effect of variable moment of inertia, and the forms of these equations are rather cumbersome, and, therefore, inconvenient for use in this method. The writer has deduced the

following equations, using the various constants of the method of moment distribution developed by Hardy Cross[20], M. Am. Soc. C. E.:

$$M_{ab} = S_a\,[\theta_a + C_{ab}\,\theta_b - (1 + C_{ab})\,R] \mp M_{Fa}\ldots\ldots\ldots(28)$$

and,

$$M_{ba} = S_b\,[\theta_b + C_{ba}\,\theta_a - (1 + C_{ba})\,R] \pm M_{Fb}\ldots\ldots\ldots(29)$$

in which C_{ab} and C_{ba} are factors to carry over the moment applied at Ends a and b, respectively, to the other ends, b and a, which are assumed fixed; S_a and S_b are stiffness factors when a unit moment is applied at the designated end with the other end fixed; and M_{Fa} and M_{Fb} are fixed-end moments at the designated ends, due to loading, with both ends fixed. For a member of which the moment of inertia varies symmetrically with respect to its center line:

$$C_{ab} = C_{ba} = C\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(30)$$

and,

$$S_a = S_b = S\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(31)$$

For a member of constant cross-section,

$$C = \frac{1}{2}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(32)$$

and,

$$S = 4\,E\,K\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(33)$$

in which E and K are the same as the notation of the paper. With the values of C and S from Equations (32) and (33) substituted in Equations (28) and (29), the well-known ordinary slope-deflection equations for the case of constant moment of inertia are derived.

It may be noted that, according to the usual sign convention for moment adopted in the slope-deflection method, the carry-over factors, C_{ab} and C_{ba}, will always be positive, which is just opposite to that adopted in the method of moment distribution.

The determination of the values of the various constants in Equations (28) and (29) for members with moments of inertia varying in any manner and under any loading, the method of moment area, as shown by G. E. Large[21], Assoc. M. Am. Soc. C. E., will be found the most expedient. For certain special cases, there are many sets of tables and diagrams which give directly the values of those constants. Hence, with Equations (28) and (29) available, the application of this method to the case of variable moment of inertia will involve no difficulty or inconvenience.

A. Floris,[22] Esq. (by letter).—This ingenious method of analyzing statically indeterminate structures by means of the slope-deflection equation reduces, considerably, the number of the unknowns arising in such problems.

---

[20] "Analysis of Continuous Frames by Distributing Fixed-End Moments", by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

[21] *Bulletin No. 66*, Ohio State Univ., Columbus, Ohio, November, 1932.

[22] Dipl.-Ing., Los Angeles, Calif.

It is elegant, direct, and does not involve approximations. Thus far, there are several methods available which render the analysis of structures with high redundancy comparatively easy. From the point of view of practical expediency simultaneous equations should be avoided, or their solution, at least, should be facilitated by special devices.

The avoidance of simultaneous equations by means of the moment distribution leads to tedious and indirect, if not difficult, processes. On the other hand, the method of iteration applied to the solution of simultaneous equations of a special kind, although convenient, is nevertheless time-consuming.

The author's method is a valuable contribution to the analysis of complicated structures. In principle, it is preferable to many widely used methods. However, whether it will replace them in practice is another matter. The question can be decided only by actual experience or comparative calculations.

A. W. FISCHER,[23] ESQ. (by letter).—The author has contributed a method for solving indeterminate structures by the slope-deflection method by what he terms "successive elimination", which seems to solve the simple examples he gives in a very short time. For solving secondary stresses in trusses by the slope-deflection method, however, the writer doubts if the author's method is any shorter than the use of a systematic table for solving the simultaneous equations.

Much has been written concerning the solution of rectangular frames by the slope-deflection method, but not much has been offered in regard to the solution of a symmetrical frame with inclined legs, supporting unsymmetrical loads. Consider, for example, the top story of the Kinzua Viaduct[24] with a horizontal load at the top (see Fig. 7). Assume the bases to be fixed and then compare the results with those that are obtained by the method of least work, which gives correct results. This bent is symmetrical and, using the author's method, sufficient equations can be written to solve it.

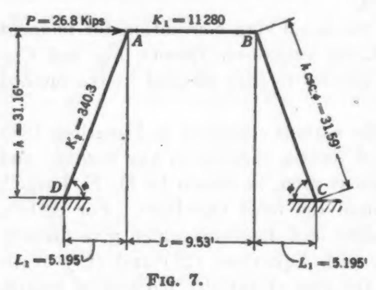

FIG. 7.

The change of length of members is considered zero; and, since the bent is symmetrical, $\theta_A = \theta_B$, $\theta_C = \theta_D = 0$. The horizontal movement at the top of Members AD and $BC = Rh$, and is to the right; the fall of Joint $A = R\,L_1$; and the rise of Joint $B = R\,L_1$. Therefore, the R-value of $A\,B = \dfrac{2R\,L_1}{L} = \dfrac{10.39}{9.53} = 1.09\,R$.

Of the two unknowns, θ_A and R, let θ_A be the permanent unknown. As E is constant, it can be assumed equal to unity, which will shorten the equations.

[23] Care, Pennsylvania Sugar Co., Philadelphia, Pa.

[24] "The Kinzua Viaduct of the Erie Railroad Company", by the late Carl Robert Grimm, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. XLVI (1901), p. 21.

For the condition, $\Sigma M = 0$, at Joint A, $M_{AD} + M_{AB} = 0$. Therefore, $2 \times 340.3\,(2\,\theta_A - 3\,R) + 2 \times 11\,280\,(3\,\theta_A + 3.27\,R) = 0$; from which,

$$R = -0.9625\,\theta_A \ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

A second true equation can be developed by considering the equilibrium of Member AB. Let s_1 and s_2 be the direct stresses of Members AD and BC; then:

$$s_1 \sin\phi + \frac{680.6\,(3\,\theta_A - 6\,R)\cos\phi}{h\csc\phi} - \frac{22\,560\,(6\,\theta_A + 6.54\,R)}{L} = 0 \ldots (35)$$

$$s_2 \sin\phi - \frac{680.6\,(3\,\theta_A - 6\,R)\cos\phi}{h\csc\phi} + \frac{22\,560\,(6\,\theta_A + 6.54\,R)}{L} = 0 \ldots (36)$$

and,

$$s_1\cos\phi - \frac{680.6\,(3\,\theta_A - 6\,R)\sin\phi}{h\csc\phi} - 26.8 - s_2\cos\phi$$
$$- \frac{680.6\,(3\,\theta_A - 6\,R)\sin\phi}{h\csc\phi} = 0 \ldots\ldots\ldots\ldots (37)$$

From Equation (35),

$$s_1 = \frac{22\,560\,(6\,\theta_A + 6.54\,R)}{L\sin\phi} - \frac{680.6\,(3\,\theta_A - 6\,R)\cos\phi}{h} \ldots\ldots (38)$$

and, from Equation (36),

$$s_2 = \frac{680.6\,(3\,\theta_A - 6\,R)\cos\phi}{h} - \frac{22\,560\,(6\,\theta_A + 6.54\,R)}{L\sin\phi} \ldots (39)$$

Substituting the values from Equations (38) and (39) in Equation (37) and reducing:

$$\frac{66.30\,(6\theta_A + 6.54\,R)\cos\phi}{L\sin\phi} - \frac{2\,(3\,\theta_A - 6\,R)}{h} - \frac{26.8}{680.6} = 0 \ldots (40)$$

Equation (40) also expresses the simple relation:

$$2\,M_{AD} + 2\,M_{DA} + \frac{4\,L_1}{L}\,M_{AD} + 26.8\,h = 0 \ldots\ldots\ldots (40a)$$

Substituting the value of R from Equation (34) and $\sin\phi$ and $\cos\phi$ from Fig. 7, and reducing: $\theta_A = -0.04343$; and, then, from Equation (34), $R = +0.04180$.

From the foregoing values of θ_A and R:

$$M_{AD} = 2 \times 340.3\,(-0.08686 - 0.12540) = -144.5 \text{ ft-kips}$$

$$M_{AB} = 2 \times 11\,280\,(-0.08686 - 0.04343 + 0.13670) = 144.6 \text{ ft-kips}$$

and,

$$M_{DA} = 2 \times 340.3\,(-0.04343 - 0.12540) = -114.9 \text{ ft-kips}$$

For the upper story, with fixed bases, Mr. Grimm[24], found that,

$$M_{AB} = 4.765 \times 30.4 = +144.9 \text{ ft-kips}$$

$$M_{AD} = -144.9 \text{ ft-kips}$$

and,

$$M_{DA} = 9.69 \times 30.4 - 31.16 \times 13.4 = -114.7 \text{ ft-kips}$$

On comparing the foregoing results it can be seen that the two different methods practically check. (All calculations in this discussion were made with a 20-in. slide-rule.)

The general equations for solving a symmetrical bent with inclined legs, fixed bases, and various loads derived by "relative deflections"[25] and modified to solve the foregoing example are:

$$M_{AD} = -\frac{P\,L\,n\,h\,(3\,L + 4\,L_1)}{2\left\{L^2\,(1 + 6\,n) + 12\,L\,L_1\,n + 8\,n\,L_1^2\right\}} \quad \ldots\ldots\ldots\ldots(41)$$

and,

$$M_{DA} = -\frac{P\,L\,h\left\{L\,(1 + 3\,n) + 2\,L_1\,n\right\}}{2\left\{L^2\,(1 + 6\,n) + 12\,L\,L_1\,n + 8\,n\,L_1^2\right\}} \quad \ldots\ldots\ldots\ldots(42)$$

in which $n = \dfrac{K_1}{K_2}$. Substituting the values given in Fig. 7 in Equations (41) and (42), and reducing: $M_{AD} = -144.7$ ft-kips; and, $M_{DA} = -115.1$ ft-kips. These values, again, practically agree with those determined by Mr. Grimm[24].

If $L_1 = 0$, Equations (41) and (42) can be used to solve a symmetrical rectangular bent fixed at the bases and a horizontal load, P, at the top.

The author's method can be used for solving many problems in indeterminate structures, but to the writer it is just one tool, of many, which solves such simple examples as those given by the author in a very short time. A problem such as the analysis of a Vierendeel truss, with inclined top chord, however, is not so simple, and if the author would analyze a three-panel Vierendeel truss with an inclined top chord, the analysis might supply additional data for solving indeterminate structures with inclined members.

L. E. Grinter,[26] Assoc. M. Am. Soc. C. E. (by letter).—There is no question but that the author has made an excellent case for his procedure of automatically eliminating the unknowns in the slope-deflection equations. In fact, Professor Wilbur has hit upon a major reason why the slope-deflection method has lost some of its original popularity. The lack of a standard procedure for solving the simultaneous equations involved had led to considerable dissatisfaction with the method itself. The truth is that a confused sign convention and the difficulties involved in the solution of the simultaneous equations are the major objections that have been offered to its use. A

[25] "Stresses in Statically Indeterminate Structures", by Prof. H. Yu, National Wuhan Univ., Wuchang, Hupeh, China, Second Edition, 1935, pp. 471–474.

[26] Dept. of Civ. Eng., Armour Inst. of Technology, Chicago, Ill.

physical picture of the relation of moment, sign, and curvature will eliminate the confusion in regard to signs, and the automatic procedure of eliminating unknowns suggested by Professor Wilbur will aid in simplifying the solution of the simultaneous equations.

Physical Significance of Signs.—The question of signs naturally is involved in the illustrative example presented in the paper. This example ends with the statement, "and the moment at the column base is $M = 2\,E\left(\frac{40}{2\,E} - \frac{160}{2\,E}\right)$ $= -120$ ft-lb, the minus sign denoting that the couple, M, acts contra-clockwise on the column." This statement without further explanation will not be understood by many readers. The signs of the end moments of an unloaded member will be made clear by Fig. 8. Such end moments are calculated by the standard slope-deflection equation, $M_{AB} = 2\,E\,K\,(2\,\theta_A + \theta_B - 3\,R)$. Evidently, therefore, the sign of the moment will be dependent upon the signs and relative magnitudes of θ_A, θ_B, and R.

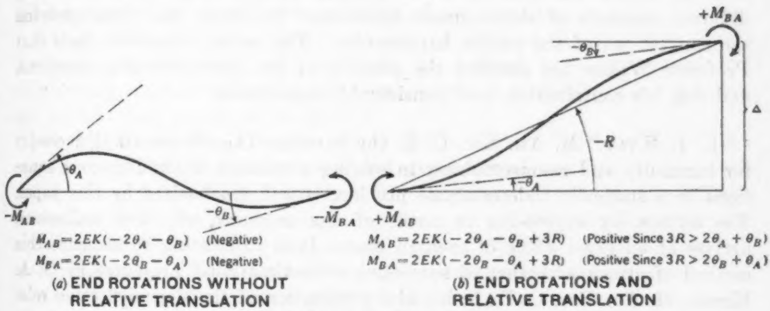

Fig. 8.—Signs of End Moments.

For the ordinary case of reversed curvature shown in Fig. 8(*a*), in which the value of R is zero, the sign of M is the same as the sign of the end slopes, θ_A and θ_B. The end rotations are counter-clockwise (negative) for the case illustrated, so that both the end moments, M_{AB} and M_{BA}, must be negative. Accordingly, the end moments represented by M_{AB} and M_{BA} must be the negative resisting moments external to the beam itself. Similarly, in Fig. 8(*b*), the geometry of the configuration determines the signs of the end moments. For the configuration shown, the value of $3\,R$ must be larger than $2\,\theta_A + \theta_B$ or $2\,\theta_B + \theta_A$. This is merely a geometric fact that any one can prove by attempting to re-sketch the diagram, assuming the reversed inequality. (For instance, when $3\,R = 2\,\theta_A + \theta_B = 2\,\theta_B + \theta_A$, the elastic line would be straight and the end moments would be zero.) Hence, for the case illustrated in Fig. 8(*b*), the end moments are of the same sign as the sign of R in the slope-deflection equations; that is, positive. Again, these end moments must be the resisting moments that act externally to the beam itself in order to agree with these signs.

Advantages of a Routine Procedure.—The usefulness of Professor Wilbur's procedure for the successive elimination of unknowns will depend very largely upon the number of simultaneous equations involved in the standard solution; that is, upon the number of unknowns. The continuous beam illustrated in Fig. 1(*a*) of the paper is indeterminate only to the third degree. The three simultaneous equations in any standard analysis can be solved so simply and conveniently that the successive elimination of unknowns would offer little advantage. However, the wind frame of Fig. 1(*b*) is a highly indeterminate structure the analysis of which would require the solution of twenty simultaneous equations, a tedious and wholly objectionable task. Certainly, there could be no justification of the use of the slope-deflection method for the analysis of this frame, unless some automatic procedure, such as that suggested by the author, was to be used.

Undoubtedly, many engineers have been applying the procedure suggested by the author, but in a rather haphazard fashion. The writer has found his students quite confused by the fact that different members of the class would seem to obtain the solution for a problem such as Fig. 1(*a*) by solving different numbers of simultaneous equations. In effect, they were applying the suggestions of the author haphazardly. The writer, therefore, feels that Professor Wilbur has clarified the solution of the slope-deflection equations, and that his contribution is of considerable importance.

L. T. Wyly,[27] M. Am. Soc. C. E. (by letter).—The oft-remarked necessity for ingenuity and resourcefulness in solving a number of simultaneous equations in a statically indeterminate problem is well emphasized by this paper. The author, by expressing in terms of one unknown all other unknowns, arrives at an exact value of each in turn. It is interesting to compare this method of attack with that of successive approximations[28] presented by G. A. Maney, M. Am. Soc. C. E., in his first publication of the slope-deflection relation, and with the moment-distribution method[29] presented by Hardy Cross, M. Am. Soc. C. E. In these latter procedures, the simultaneous solution of the equations is avoided and, by methods of approximations, the unknowns at each joint in succession are determined to any desired degree of refinement, the ultimate values, of course, being exactly the same as those obtained by the author in his exact solution of all equations simultaneously.

In order to compare the relative merits of these different methods of solution of the slope-deflection relation, it may be well to review, briefly, the history of the development of this very useful and general method of analysis. The essential steps are as follows:

(1) The first publication of the slope-deflection relation was in 1893 by Otto Mohr who used the method for the solution of secondary stress problems[30]. The form used by Mohr was limited to this type of problem; that is, to frames without loads between the joints.

[27] With Bureau of Bridges, Div. of Highways, Springfield, Ill.

[28] Eng. Studies, *Bulletin No. 1*, Univ. of Minnesota, March, 1915.

[29] "Analysis of Continuous Structures by Distributing Fixed-End Moments," *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

[30] *Zivilingenieur*, December, 1892–January, 1893.

(2) In May, 1914, Axel Bendixsen published in Denmark a monograph entitled, "Die Methode der Alpha-Gleichungen zur Berechnung von Rahmenkonstructionen", which gives the first general statement of the slope-deflection relation for any type of loading. This publication appears to have been generally overlooked even in Europe until about 1923 when Professor A. Ostenfeld amplified it somewhat[31].

(3) In 1914, Professor Maney evolved and, in March, 1915, published the first general statement of the slope-deflection relation to appear in America[26]. Professor Maney's work was original with him, as at this time he did not know of the work of Mohr and of Bendixsen on this problem. This presentation included any type of loading between joints and expressed the end moments of members in terms of the fixed-end moments, modified by the addition of moments arising from rotations and deflections of the joints. This method was not extended to members with variable moments of inertia at this time. Problems both in wind stresses in building frames and in secondary stresses in bridge trusses were solved; and, for the latter problem, a method of successive approximations was presented, which method did not require the simultaneous solution of the equations.

(4) In 1914, Professor Maney and W. M. Wilson, M. Am. Soc. C. E., developed, and, in June, 1915, published, the solution of wind stresses in a twenty-story office building by the slope-deflection method[32]. This solution was by the exact simultaneous method.

(5) In 1915 to 1918, Professor Maney and J. I. Parcel, M. Am. Soc. C. E., completed their analytical solution and experimental research in the field, and, in 1922, published their study of the secondary stresses on the Kenova Bridge[33]. This solution was made by the use of influence lines for the secondary stresses and involved the solution of forty-three equations for each case considered. The method of successive approximations was again used here in all cases. Eight cases were solved.

(6) In 1918 there was published by Professor Wilson, F. E. Richart, and C. Weiss, Members, Am. Soc. C. E., a bulletin giving general formulas for a large number of types of structures by the slope-deflection method[34].

(7) In 1923 Professor Ostenfeld published an amplification of Bendixsen's work, the presentation covering all cases for which solution is made for deformations rather than stresses[31].

(8) In 1930 Professor Cross published his moment-distribution method which he had been teaching for several years previously[29]. The Cross method also follows the general procedure of assuming fixed-end moments at ends of members and correcting them by a method of approximations that can be carried to any desired degree of refinement.

(9) In 1931, L. T. Evans, Assoc. M. Am. Soc. C. E., published a modification of the slope-deflection formulas, taking into account the variable moment of inertia of members for a number of typical cases[35].

---

[31] "Die Deformationsmethode", by A. Ostenfeld, *Der Bauingenieur*, January 31, 1923.
[32] *Bulletin 80*, Eng. Experimental Station, Univ. of Illinois, June, 1915.
[33] Eng. Studies, *Bulletin No. 4*, Univ. of Minnesota, 1922.
[34] *Bulletin 108*, Eng. Experiment Station, Univ. of Illinois, 1918.
[35] *Journal*, Am. Concrete Inst., October, 1931.

The method of successive elimination of unknowns in the solution of secondary stress problems was used at least as early as 1911 by David A. Molitor, M. Am. Soc. C. E.[36] Mr. Molitor solved twenty-two equations for twenty-two moments, all expressed in terms of the first two unknown moments.

It is thus seen that, in America, a remarkable development has followed Professor Maney's derivation of the general method of slope deflection in 1914. E. J. Mehren, M. Am. Soc. C. E., lists slope deflection and moment distribution as the two analytical instruments which have vitally affected the advance of concrete structures in America.[37]

In order to compare the methods of approximate solution with the exact solution by successive elimination of unknowns illustrated by the author, attention is directed to the continuous girder of four spans illustrated in Fig. 1(*a*) of the paper. Assume the loading shown in the illustration, or any other loading. By Maney's method of approximations, the procedure is as follows:

(*a*) Fixed-beam end moments are computed on the assumption that all spans are fixed at the ends. Denote these moments as M_{FAB}, M_{FBC}, M_{FBA}, etc. Let ΣM_{FA} designate the sum of all fixed-beam moments at A.

(*b*) The first approximation of joint rotation values at a given joint are obtained by assuming that all joints at the far ends of the members in question have zero rotation. For purposes of illustration consider Joint B, Fig. 1(*a*). Then,

$$\theta_B = \frac{M_{FBA} + M_{FBC}}{2\,K_{BA} + 2\,K_{BC}} \qquad (43)$$

or, in general,

$$\theta_B = \frac{\Sigma M_{FB}}{2\,\Sigma K_B} \qquad (44)$$

Also,

$$\theta_C = \frac{M_{FCB} + M_{FCD}}{2\,K_{CB} + 2\,K_{CD}} \qquad (45)$$

or, in general,

$$\theta_C = \frac{\Sigma M_{FC}}{2\,\Sigma K_C} \qquad (46)$$

Substituting these values as found in the joint equations, a new and closer set of values for the joint rotations is obtained, and this can be continued as often as necessary, seldom more than three approximations being necessary.

(*c*) Placing the values of joint rotations as determined by Equations (44) and (46) in the joint equations, solution is made for the resulting end moments. As has been noted, this process consists in adding algebraically the end moments induced by the joint rotations to the fixed-beam end moments assumed at the start.

[36] "Kinetic Theory of Engineering Structures", by David A. Molitor, 1911, p. 232 *et seq.*

[37] "Concrete, Yesterday, Today and Tomorrow", *Journal*, Am. Concrete Inst., March-April, 1935; also, *Proceedings*, Am. Concrete Inst., Vol. 31, p. 345.

By the Cross' moment-distribution method of approximations, the procedure is very similar. If the values of joint rotation, obtained by Equations (44) and (46), are substituted in the moment equation for a given member,

$$M_{BC} = M_{FBC} = \left(\frac{K_{BC}}{\Sigma K_B}\right) \Sigma M_{FB} - \frac{1}{2}\left(\frac{K_{BC}}{\Sigma K_C}\right) \Sigma M_{FC} \ldots\ldots (47)$$

It is seen at once that the second term on the right-hand side of the equality sign represents the "distribution factor" and that the third term is the "carry-over" factor. Distribution and carrying-over are continued until all unbalanced moments at the joints become negligible, or disappear, which is a parallel process to arriving at successively closer values of true joint rotations. Indeed, it is noteworthy that the reason the moment-distribution process converges so rapidly, is that a rotation at Joint A, say, will induce only one-half as much end moment at Joint B as at Joint A, etc. This relation is evident at once on inspection of the slope-deflection equation. By Maney's procedure, one solves for closer and closer values of the joint rotations, or deflections, and then obtains final moments from final values of the joint rotations. By Cross' procedure, one distributes moment differences until all unbalanced moments are negligible or disappear. A very interesting development in this regard was made in 1934 by C. E. Morgan, M. Am. Soc. C. E.[38]. Pursuing moment distribution to its logical conclusion mathematically, Mr. Morgan expressed the end moments in terms of a geometric series, and arriving at the limit of the series, obtained the true values of the moments—that is, the same values that would be obtained by Professor Wilbur's exact method of solution. In 1936, Mr. Morgan published formulas for moments for a four-span continuous structure similar to Fig. 1(*a*). These formulas were derived by Mr. Morgan's series method[38].

For frames such as those illustrated in Fig. 1(*b*) and Fig. 1(*c*), the procedure is essentially the same, and the relations between the foregoing methods of attack are similar. Methods of solution by approximations of these frames were published[39] by Professor Maney and J. E. Goldberg, Jun. Am. Soc. C. E., in 1932. In 1931, there was also published[40] a method of solving secondary stresses by moment distribution by L. S. Thompson and R. W. Cutler, Jun. Am. Soc. C. E.

With regard to the method of procedure for a given case, naturally the designer's preference will vary. Where not too many unknowns or joints are involved, it will frequently be desirable to use a procedure similar to that illustrated by the author. Where a large number of unknowns are involved, however, it is the writer's belief that most engineers will prefer one of the approximate methods. It should be noted in this connection that there is a difference in procedure between the slope-deflection method of approximation and the moment-distribution method. In both, any variation in the con-

[38] "Designing Concrete Girder Bridges for Continuity", *Engineering News-Record*, April 23, 1936, pp. 604–606.

[39] "Simplified Methods for Analysis of Multiple Joint Rigid Frames", *Bulletin No. 7*, Northwestern Univ., October 17, 1932.

[40] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 108.

vergence indicates that an error has been made. In the moment-distribution method, however, it is possible to carry over an initial unbalanced moment of incorrect value, and it will be distributed and no check will appear. In the slope-deflection method, a complete set of static and elastic equations is set up, and when the true values of the unknowns are obtained, by whatever means, these unknowns must satisfy all equations simultaneously, and, hence, must be correct. In many cases the moment distribution method is undoubtedly most expeditious. On the other hand, it is the writer's belief, based upon a certain amount of observation, that there is a tendency for the designer to lose sight of the actual significance of each step of the process with moment distribution, and that this is not so likely to occur with slope deflection. Furthermore, in a number of cases, such as where correction is to be made during construction, it is necessary to know the computed value of the joint rotations or deflections, and in this case slope deflection is plainly necessary.

In conclusion, it may be said that the progressive use of indeterminate structures seems to have been dependent, largely, upon the development of expeditious methods of solving simultaneous equations. This has probably been true—not because of the difficulties of the problem—but because simultaneous solution of a considerable number of equations has required more time than the procedure of most designing offices allows. This paper is of definite value in that it calls attention to means of expediting this analytical process.

JOHN B. WILBUR,[41] ASSOC. M. AM. SOC. C. E. (by letter).—The valuable additions that have been contributed by the discussers of this paper are appreciated. In one general respect the method of presenting the solution of a continuous beam by successive elimination of unknowns was unfortunate in that it was included as a pedagogical step in leading the reader gradually into the more complicated problem of a building frame, in which it was believed the proposed expedient might be of value. The writer agrees with those who suggest that other methods of solution are likely to be superior in analyzing continuous beams.

A method of determining, approximately, the bending moments in the members meeting at a particular joint of a building frame, is presented by Mr. Willson. He assumes that there is no side-sway in the building. Under loadings where side-sway would occur, his Equation (19) would be incorrect unless revised to include this effect. Such revision would seem to lead to a more cumbersome expression.

Mr. Andersen believes that the method of eliminating unknowns suggested by the writer would immediately suggest itself to one setting up the solution of a problem by the slope deflection method. Judging from his own experience, the writer is forced to disagree on this point. Mr. Andersen states moreover, that, in his opinion, designers do not object to the solution of simultaneous equations. Although this may be true, those who pay for the designer's time must certainly have an opposite point of view, especially if a large number of unknowns are involved.

[41] Asst. Prof. Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.

The necessity of understanding the sign convention fully in using the slope deflection method, is emphasized by Mr. Stewart, who gives an excellent statement of these conventions. Professor Grinter likewise shows, with examples, the conventions which the writer has followed. Both these discussions should be of value to those who may have difficulty with this important aspect. The modification of the writer's method as applied to a building frame, which Mr. Stewart suggests, is of genuine interest. Professor Grinter stresses the need of a physical conception of structural problems; and with this belief, the writer is in full accord.

Mr. Mitchell states that office practice should be such that, in so far as is practicable, it is self-checking. There can be no dispute on this point. Longer methods which have this advantage are often preferable to shorter approaches which leave one in doubt as to the accuracy of one's result. The method suggested by the writer, however, is self-checking. It yields certain values of R and θ, so that the solution corresponds to a possible deformation of the structure. The solution is thus consistent elastically. If the moments from these functions are in static equilibrium with the external forces acting on the structure, the solution is also consistent statically, and must be correct.

The equations contributed by Professor Tsai which take into account beams of variable moment of inertia, are of value in the general slope deflection solution and, of course, aid in the particular technique of solution suggested by the writer.

Mr. Fischer raises an interesting problem with respect to the solution by slope deflection of a frame with inclined legs. Inasmuch as the treatment of this problem as given in certain engineering literature is incorrect, in the writer's opinion, the treatment by Mr. Fischer is valuable.

The outline of the development of the slope deflection method given by Mr. Wyly is excellent, and will be of value to those investigating this field.

REINFORCED CONCRETE MEMBERS UNDER DIRECT TENSION AND BENDING

By D. B. Gumensky[1], Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. A. W. Fischer, William E. Wilbur, F. C. Snow, Ralph E. Byrne, Jr., Carl H. Heilbron, Jr., F. E. Turneaure, H. E. Warrington, William A. Larsen, B. Kovediaeff, A. Floris, David B. Hall, Odd Albert, and D. B. Gumensky.

Synopsis

The combination of compression and bending stresses is a common occurrence in design and has been very well treated in standard books on reinforced concrete. However, the combination of direct tension and bending is a problem that has received less attention from authors of engineering texts. This problem is met with in the design of Vierendeel trusses or particularly in the design of closed water conduits under pressure, where the conduit barrel is horizontal and acts as a complete elastic ring. The following presentation is an attempt to analyze the stress distribution in reinforced concrete members subjected to a combined stress due to direct tension and bending, and to suggest an easy method of solving these problems.

Assumptions

The assumptions used in the derivation of the formulas are the same as those generally accepted for the derivation of working formulas for reinforced concrete. They are as follows: (1) A straight-line distribution of stress; (2) concrete is an elastic substance; (3) tension is resisted entirely by steel; (4) bond between concrete and steel is perfect; (5) there are no initial stresses in concrete or steel; (6) the symbols denote only a numerical value of the quantities they represent; (7) vertical distances measured downward from the axis of a member are negative and upward distances are

Note.—Published in December, 1935, *Proceedings*.

[1] With Metropolitan Water Dist. of Southern California, Los Angeles, Calif.

positive; (8) forces acting from right to left are positive and forces acting from left to right are negative; and (9) moments of forces about a point acting in a counter-clockwise direction are positive.

Notation.—The mathematical symbols are defined where they first appear in the paper and are summarized, for reference, in the Appendix.

Analysis and Solution Related to the Geometrical Axis of the Cross-Section of the Member

In analyzing indeterminate structures, the resultant moment, M, the direct pull, T, and the eccentricity of direct stress, $e\left(=\dfrac{M}{T}\right)$, at any one point, are usually related to the geometrical axis of the elastic ring or frame. This relation is maintained in the following presentation. It is generally accepted that the combination of an axial load and a couple will produce the same stresses as an equivalent eccentrically applied pull. In this paper, the latter will be used for the derivation of formulas. There are two distinct cases of stress distribution: (1) That in which the entire section is under tension; and (2) that in which part of the section is under compression.

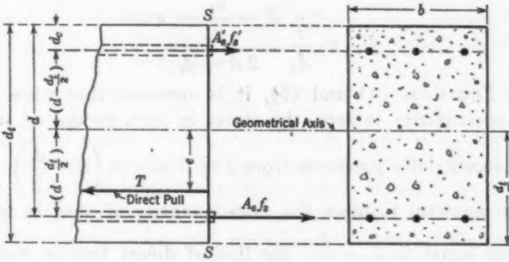

FIG. 1.

Case 1.—The Entire Section Under Tension.—This case has been excellently, but briefly, treated by Messrs. Taylor, Thompson, and Smulski.[3] Section *S-S*, Fig. 1, is subjected to direct tension, T, and a bending moment, M, which is produced by the eccentricity, $e = \dfrac{M}{T}$. Since concrete cannot resist tension, the only stresses in the section are those in the steel. For equilibrium, the algebraic sum of all forces acting on the section must equal zero. Therefore,

$$T = A_s f_s + A'_s f'_s \quad\text{..........................(1)}$$

Taking moments about the center of the upper steel rods,

$$A_s f_s = T\,\frac{\left(d - \dfrac{d_t}{2} + e\right)}{2\,d - d_t} \quad\text{....................(2)}$$

[3] "Concrete, Plain and Reinforced", by F. W. Taylor, S. E. Thompson, and Edward Smulski, Vol. 1, Edition 4, N. Y., John Wiley & Sons, Inc., 1925, p. 137.

In the same manner, taking moments about the center of the lower steel rods:

$$A'_s f'_s = T \frac{\left(d - \frac{d_t}{2} - e\right)}{2\,d - d_t} \quad \text{.....................(3)}$$

Equations (1), (2), and (3) are used to determine the stresses in the two groups of steel. However, since there are, altogether, four unknowns—A, f_s, A'_s, and f'_s—and only three equations, it is necessary to make an additional assumption before these equations can be solved. Many designers arbitrarily make the area of steel in the upper and lower groups the same; or (which would be more economical), the unit stress in the steel of the upper and lower groups may be assumed to be equal.

If $A_s = A'_s$, the required area of steel in one group will be governed by the maximum allowable tensile stress in steel; thus:

$$A_s = \frac{T}{f_s} \frac{d - \frac{d_t}{2} + e}{2\,d - d_t} \quad \text{.....................(4)}$$

in which f_s is the maximum allowable stress in the steel. In the other group the steel will be under-stressed; thus:

$$f'_s = \frac{T}{A_s} \frac{d - \frac{d_t}{2} - e}{2\,d - d_t} \quad \text{.....................(5)}$$

Comparing Equations (4) and (5), it is apparent that when the pull is axial and the eccentricity is zero, the stress in both groups of steel rods is equal. As the eccentricity increases from $e = 0$ to $e = \left(d - \frac{d_t}{2}\right)$, it becomes more and more wasteful to place the same quantity of steel in both groups. When e becomes equal to $d - \frac{d_t}{2}$, the line of direct tension coincides with one group of steel rods, the stress in the other group equals zero, and there is no need of placing the two groups. In such case, or when e nearly equals $d - \frac{d_t}{2}$, the use of two equal groups of steel will make the total reinforcement in a member almost twice as great as if the steel had been designed for $f_s = f'_s$.

Should the same unit stress be used in both groups of bars (that is, $f_s = f'_s$), A_s is the same as would be determined by Equation (4), and A'_s becomes:

$$A'_s = \frac{T}{f_s} \frac{d - \frac{d_t}{2} - e}{2\,d - d_t} = A_s \frac{d - \frac{d_t}{2} - e}{d - \frac{d_t}{2} + e} \quad \text{...........(6)}$$

Again, when $e = d - \frac{d_t}{2}$, the line of direct pull coincides with one group of rods, and no steel is required in the other group. When e is greater

than $d - \frac{d_t}{2}$, Equations (1) to (6) are not applicable because part of the concrete begins to act in compression, and, if two groups of steel are used, one group also is in compression.

Case 2.—Part of the Section Under Compression.—This condition is created when the line of direct pull falls outside the steel reinforcement in the member.

The steel may be placed either in the tension face alone, or in both the tension and the compression faces of the member. By placing it only on the tension side, a design is produced in which steel acts in tension and concrete in compression, the combination that usually results in greatest economy.

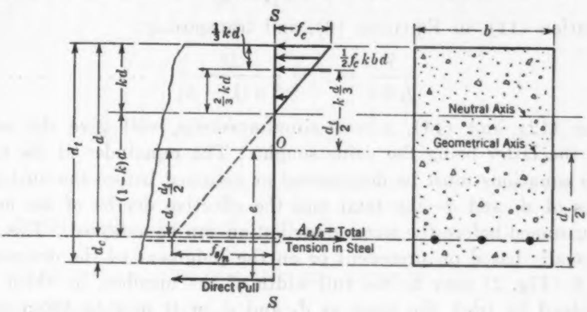

FIG. 2.

A thin section of concrete beam, *S-S*, in Fig. 2 (an independent structural element), is acted upon by the internal forces of compression in the concrete, the tension in the steel, and the external force of direct pull applied at a distance, *e*, from the geometrical center of the section.

Since Section *S-S* is in static equilibrium, the sum of the moments of all forces acting upon that section must be equal to zero. Taking moments about Point *O*:

$$A_s f_s\left(d - \frac{d_t}{2}\right) - T e + \frac{1}{2} f_c k b d \left(\frac{d_t}{2} - \frac{1}{3} k d\right) = 0 \quad \ldots\ldots(7)$$

The sum of all horizontal forces acting on the section must equal zero:

$$T - A_s f_s + \frac{1}{2} f_c k b d = 0 \quad \ldots\ldots(8)$$

Multiplying Equation (8) by *e* and equating to Equation (7):

$$A_s f_s \left(d - \frac{d_t}{2}\right) - T e + \frac{1}{2} f_c k b d \left(\frac{d_t}{2} - \frac{1}{3} k d\right)$$

$$= A_s f_s e - T e - \frac{1}{2} f_c k b d e \quad \ldots\ldots(9)$$

Substituting in Equation (9):

$$f_s = n f_c \frac{1-k}{k} \quad \ldots\ldots(10)$$

and,

$$A_s = p\ b\ d \qquad \text{.........................(11)}$$

and solving for $\frac{e}{d}$:

$$\frac{e}{d} = \frac{2\,p\,n(1-k)\left(1-\frac{d_t}{2\,d}\right)+k^2\left(\frac{d_t}{2\,d}-\frac{k}{3}\right)}{2\,p\,n\,(1-k)-k^2} \qquad \text{.......(12)}$$

Substituting,

$$f_c = f_s\,\frac{k}{n\,(1-k)} \qquad \text{.........................(13)}$$

and Equation (11), in Equation (8), and transposing:

$$\frac{T}{f_s\,b\,d} = p - \frac{k^2}{2\,n(1-k)} \qquad \text{...................(14)}$$

Equations (12) and (14), solved simultaneously, will give the values of k and p, the latter being the value sought. The remainder of the values in these two equations must be determined or assumed before the final solution.

Values of d_t and d—the total and the effective depths of the member—must be assumed before the stress distribution can be analyzed. This assumption is usually based on precedent or on the judgment of the designer. The value of b (Fig. 2) may be the full width of the member, in which event it is determined by trial, the same as d_t and d, or it may be taken as a unit width, usually 1 ft. Values of T and e are found from the analysis of stress distribution in the structure, thus, $e = \frac{M}{T}$.

The value of n which designates the ratio between the modulus of elasticity of steel and the modulus of elasticity of concrete, depends on the quality of concrete. Normally, it is assumed to vary between $n = 8$ and $n = 15$, which corresponds to $E_c = 3\,750\,000$ and $2\,000\,000$ lb per sq in., respectively. The value of f_s is determined by the grade of steel used and the purpose for which the structural member is designed, allowing an adequate factor of safety.

The two unknowns remaining are k and p. For any given condition of loading, dimensions, and stress distribution, the required amount of steel can be determined. However, the solution of Equations (12) and (14) is laborious, and, for this purpose, the writer has devised a set of diagrams, an example of which is reproduced on Fig. 3 for discussion. These diagrams were based on values of n equal to 15 and 10, respectively. In solving design problems by means of such curves the procedure is, as follows:

(1) Determine the bending moment, M, and the direct pull, T, for the member in question;
(2) Select trial values for d_t and d, unless they were tentatively chosen previously;
(3) Determine the value of $e = \frac{M}{T}$;

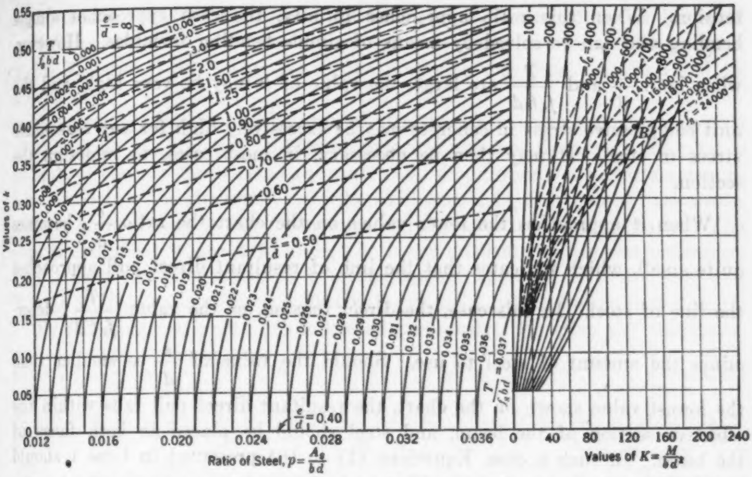

FIG. 3.—ECCENTRICITY, e, MEASURED FROM GEOMETRICAL CENTER OF CROSS-SECTION.

(4) Find the value of $\frac{e}{d}$;

(5) Assume a value of f_s, the unit stress in steel;

(6) Find the value of $\frac{T}{f_s\, b\, d}$;

(7) Find the ratio, $a = \frac{d_c}{d}$, of depth of cover on the steel to the effective depth of the beam;

(8) From a set of diagrams, such as Fig. 3, with the value of n in the problem, find the set of curves for a, closest to the value determined in Step (7);

(9) On Fig. 3 find the intersection of the two curves representing the values of $\frac{e}{d}$ and $\frac{T}{f_s\, b\, d}$ found in Steps (3) and (5);

(10) Directly below read the ratio of steel, p, to use for this particular condition; and

(11) Determine the area of steel, $A_s = p\ b\ d$, in section.

Incidentally, the value of k is determined by the same point of intersection as that found in Step (9). In order to find the unit compressive stress in concrete, follow a horizontal line from the point of intersection (found in Step (9)) to the right until its intersection with a curve representing the value of f_s assumed in Step (5). Finally, read or interpolate the value of f_c.

In most cases, the intersection of the curves for $\frac{e}{d}$ and $\frac{T}{f_s\, b\, d}$ will fall on the chart, which will give a definite solution of the problem. When the ratio, $\frac{e}{d}$, is very large the bending moment is very large in respect to direct

tension. When this ratio approaches infinity, the case approaches simple bending and can be solved by means of simple bending formulas. However, when both $\frac{e}{d}$ and $\frac{T}{f_s b d}$ are large, the value of k may be very high, and the unit compressive stress in concrete may be excessively high for any reasonable stress in steel. It may then be necessary, in most cases, to re-design the section.

When it approaches the lower values on the chart the ratio, $\frac{e}{d}$, becomes quite small, which indicates that the line of resultant direct pull approaches the line of steel. In this case, the direct tension, or the value, $\frac{T}{f_s b d}$, determines the amount of steel to use. Should the value of $\frac{e}{d}$ be smaller than the lowest value shown on the chart, the resultant direct pull falls within the effective section of the beam, and steel should be placed in both faces of the beam. In such a case, Equations (1) to (6) presented in Case 1, should be applied.

Should the intersection of the two curves fall outside the limits of the chart, it would mean that the case is of an unusual character as far as the percentage of steel or the relationship of stresses is concerned and that further analyses or re-designing may be necessary.

Returning, again, to Equations (12) and (14): When $k = 0$, there is no stress in the extreme compression fiber of the concrete. Substituting $k = 0$ in Equation (12):

$$\frac{e}{d} = 1 - \frac{d_t}{2\,d} \qquad \text{(15)}$$

or,

$$e = d - \frac{d_t}{2} \qquad \text{(16)}$$

In other words, this condition occurs when direct pull coincides with the steel reinforcement (see Fig. 2). Substituting $k = 0$ in Equation (14):

$$\frac{T}{f_s b d} = p \qquad \text{(17)}$$

or,

$$T = f_s\, p\; b\; d = f_s A_s \qquad \text{(18)}$$

that is, the quantity of steel is determined by the direct pull and the unit stress.

When the direct pull is zero, Equation (14) may be written thus:

$$k = \sqrt{2\,p\,n + (p\,n)^2} - p\,n \qquad \text{(19)}$$

which is a familiar relationship in the case of simple bending, when the eccentricity equals infinity, and the left side of Equation (12) is obviously

equal to infinity; the right-hand expression of Equation (12) can be equal to infinity only in case the denominator is equal to zero, which again yields Equation (19). The use of the diagrams may best be illustrated by an example.

Example 1.—Determine the area of steel to use in a precast concrete pipe of 12.0-ft inside diameter. Under an internal pressure the top of the pipe is to be 10 ft beneath the surface and water will flow through it under a pressure head of 50 ft. The thickness, t, of the shell equals 12 in.; the steel reinforcement is covered with 2 in. of concrete, and the effective depth is 10 in. The pipe is embedded in concrete along the lower quadrant of its circumference. The severest condition of stress is at the bottom where $M = 19\,230$ ft-lb and $T = 16\,530$ lb. Assume $E_c = 2\,000\,000$ lb per sq in., which means that $n = 15$.

By following the procedure indicated previously: By Step (3) the eccentricity, $e = \frac{M}{T} = \frac{19\,230}{16\,530} = 1.163$ ft $= 14$ in.; and by Step (4), $\frac{e}{d} = \frac{14}{10} = 1.40$; in the case of combined bending and tension where concrete is under compression, select $f_s = 18\,000$ lb per sq in. (Step (5)). Then by Step (6), $\frac{T}{f_s b d} = \frac{16\,530}{18\,000 \times 12 \times 10} = 0.0076$; by Step (7), $a = \frac{d'}{d} = \frac{2}{10} = 0.20$. Steps (8), (9), (10), and (11) require the use of Fig. 3 for the case, $a = 0.200$, and $n = 15$. In this case (a member subjected to bending and direct tension, combined), the eccentricity, e, is measured from the geometrical center of the gross section. The intersection of two curves (Step 9), $\frac{e}{d} = 1.40$ and $\frac{T}{f_s b d} = 0.0076$, is at Point A, Fig. 3. Directly below the intersection (Step (10)) read the ratio of steel, $p = 0.016$. The area of transverse steel is $A_s = 0.016 \times 12 \times 10 = 1.92$ sq in. per lin ft (Step (11)).

The value of k for this condition is approximately 0.395. Following the horizontal line from Point A to the right until its intersection with the curve, $f_s = 18\,000$, $f_c = 795$ lb per sq in. at Point B, Fig. 3. Should it be desirable to use steel reinforcement in both the compression and the tension faces of the member, the compression steel will help the concrete under compression. Steel reinforcement could be used in the compression side to reduce the compression stress in the concrete or in order to provide for possible reversal of stresses.

Analysis and Solution Related to the Center of Steel Reinforcement in Tension Face

The foregoing example, depending for quick solution on sets of diagrams of the type of Fig. 3, refers to the geometrical axis of the beam as the center of moments. This leads to consideration of a depth of cover on the steel and necessitates a number of charts for various ratios of the depth of cover on steel to the effective depth of beam.

It may be considered that the centroid of the tension steel is the true center of stress in the beam subjected to tension and bending. This considera-

tion eliminates the necessity for several charts, but changes the value of eccentricity by an amount equal to $d - \frac{d_t}{2}$.

Fig. 4 illustrates a condition similar to that of Case 2, in which part of the section is under compression and steel is placed in the tension face only. All the notation and assumptions previously mentioned will apply in this case with one exception, namely, the eccentricity is measured from the center line of the steel in the tension face and is designated e'.

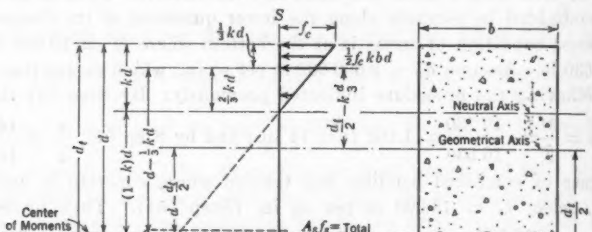

FIG. 4.

Taking moments about the centroid of the tension steel, for condition of equilibrium:

$$T\,e' = \frac{1}{2} f_c\, k\, b\, d \times \left(d - \frac{1}{3} k\, d\right) \ldots\ldots\ldots\ldots\ldots\ldots (20)$$

Since the sum of all horizontal forces must be equal to zero:

$$T - A_s f_s + \frac{1}{2} f_c\, k\, b\, d = 0 \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Solving for $\frac{e'}{d}$ after transpositions and substitutions:

$$\frac{e'}{d} = k^2 \frac{\left(1 - \frac{k}{3}\right)}{2\,p\,n\,(1-k) - k^2} \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

Equation (21), with substitutions and transpositions similar to those of Case 2, could be rewritten:

$$\frac{T}{f_s\, b\, d} = p - \frac{k^2}{2\,n\,(1-k)} \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

A simultaneous solution of Equations (22) and (23) will give the values of k and p.

A complete set of curves such as that shown in Fig. 5 obviates the necessity of laborious solutions and, similarly, to diagrams such as Fig. 3, gives a quick and accurate method of determining the percentage of steel

reinforcement in a member subjected to combined tension and bending moment. The writer has constructed diagrams for values of n equal to 8, 10, 12, and 15. Only one set of curves is necessary for the solution of a problem, but one must be careful to use eccentricity relative to the center of reinforcement in tension. Following standard procedure, Steps (1), (2), (3), (5), (6), (10), and (11) are exactly as before.

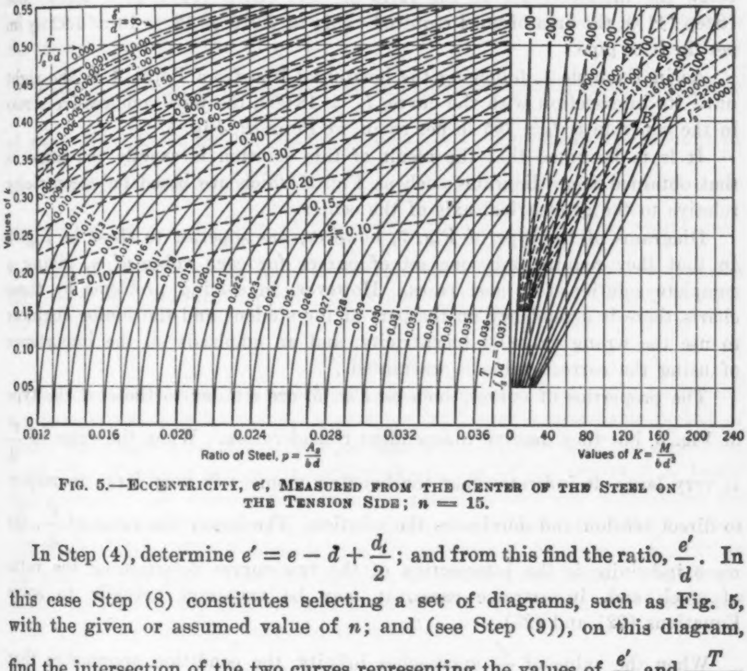

FIG. 5.—ECCENTRICITY, e', MEASURED FROM THE CENTER OF THE STEEL ON THE TENSION SIDE; $n = 15$.

In Step (4), determine $e' = e - d + \frac{d_t}{2}$; and from this find the ratio, $\frac{e'}{d}$. In this case Step (8) constitutes selecting a set of diagrams, such as Fig. 5, with the given or assumed value of n; and (see Step (9)), on this diagram, find the intersection of the two curves representing the values of $\frac{e'}{d}$ and $\frac{T}{f_s\, b\, d}$ found in Steps (4) and (6). The value of k and the unit compressive stress in the concrete are determined precisely as in Case 1.

Example 2.—Using the same problem as in Example 1, $M = 19\,230$ ft-lb; $T = 16\,530$ lb; $n = 15$; $d_t = 12$ in.; $d = 10$ in.; and $d_c = 2$ in. As before, the eccentricity relative to the geometrical center of the section (Step (3)) is $e = \frac{M}{T} = \frac{19\,230}{16\,530} = 1.163$ ft $= 14$ in. The eccentricity relative to the center of the steel reinforcement in tension (Step (4)) is $e' = e - d + \frac{d_t}{2} = 14 - 10 + 6 = 10$ in.; and, consequently, $\frac{e'}{d} = \frac{10}{10} = 1$. Assume a unit tensile

stress in steel (Step (5)) of $f_s = 18\,000$ lb per sq in.; find the value, $\frac{T}{f_s\,b\,d}$ (Step (6)) $= \frac{16\,530}{18\,000 \times 12 \times 10} = 0.0076$; on Fig. 5 (Step (9)), find the intersection of two curves, $\frac{e'}{d} = 1.00$ and $\frac{T}{f_s\,b\,d} = 0.0076$ at Point A; directly below the intersection read the ratio of steel (Step (10)), $p = 0.016$; and (Step (11)), the area of steel required $= A_s = 0.016 \times 12 \times 10 = 1.92$ sq in. per lin ft of pipe.

As in Example 1, following the horizontal line from Point A to the right until its intersection with the curve, $f_s = 18\,000$, the unit compressive stress in the concrete is $f_c = 795$ lb per sq in. at Point B, Fig. 5.

It is to be noted that the result of this solution is exactly the same as that obtained from diagrams such as Fig. 3 which are based on eccentricity relative to the geometrical axis of the center.

Diagrams of the type of Fig. 5, however, are superior to those of Fig. 3 in that they require only one set of curves for each value of n, giving a complete solution for most cases. However, in solving problems by these charts there is a tendency on the part of the student and the junior engineer to use the wrong value of eccentricity, and an emphasis on the importance of using the correct value is warranted.

The properties of curves, such as Fig. 5, are similar to those of the type of Fig. 3, but they deserve independent consideration. When the value of $\frac{e'}{d}$ is very large, it indicates that the bending moment is very large in respect to direct tension and dominates the solution. The larger the value of $\frac{e'}{d}$, the more indefinite is the intersection of the two curves determining the ratio of steel, and, in extreme cases, it may be necessary actually to solve Equations (22) and (23).

When the value of $\frac{e'}{d}$ approaches infinity, the condition approaches that of simple bending moment, and the problem is solved either by the formulas or by the diagrams. In order to solve a case of simple bending moment by means of diagrams such as Fig. 5, proceed as follows: Having determined the value of the bending moment, M, the width, b, and the effective depth, d, of the member in question, determine the auxiliary value, $K = \frac{M}{b\,d^2}$. Enter the right side of the diagram for the proper value of n with the value of K found in the previous step. Follow the vertical line to its point of intersection with the desirable or assumed stress lines for f_c and f_s, or with the limiting stress as the case may be. From this point of intersection follow the horizontal line to the left to its intersection with the curve, $\frac{T}{f_s\,b\,d} = 0.$

Vertically below the last intersection read the steel ratio, p. Determine the area of steel, $A_s = p\,b\,d$. No example is necessary to illustrate this case.

When $\frac{e'}{d}$ and $\frac{T}{f_s\,b\,d}$ are both relatively large, the value of K may be very high and the unit compressive stress in concrete may be excessively high for any reasonable stress in the steel. In most cases, it would be necessary to re-design the section by increasing the over-all dimensions, b and d, of the member, or by placing steel in the compression side in order to relieve the stress in the concrete, or both.

When $\frac{e'}{d}$ is small it means that the line of direct pull approaches the line of steel. The direct tension, or the value, $\frac{T}{f_s\,b\,d}$, determines the amount of steel to use. It may happen that the value of e' is negative, which is possible when the value of e, by Step (3), is smaller than $d - \frac{d_t}{2}$. This would indicate that the line of direct pull falls within the effective section and that the two layers of steel are needed. Equations (1) to (6) in Case 1 provide the solution.

Conclusion

A full appreciation of the advantages of the procedure outlined herein, can be obtained only by using, in practice (and over a reasonable period of time), the complete set of curves upon which the arguments of the paper are based. In offering a condensed outline description of the curves it is hoped that discussion will develop their value in principle and that suggestions for their improvement, for example, such as the desirable intervals of the n-curves, will be advanced. If it is conceded that complete sets of curves such as those described in this paper, would be valuable to structural designers in this field, should they be of the type demonstrated by Fig. 3, or Fig. 5? These and other questions could be answered in discussion.

APPENDIX

Notation

The symbols introduced in the paper are summarized herein, for convenience of reference, as follows:

$a = \frac{d_c}{d}$ = ratio of the depth of cover on the steel, to the effective depth of the beam;

b = breadth of beam;

c = distance from the neutral axis of a beam to the extreme fiber in compression; as a subscript, c denotes "concrete";

d = depth; effective depth of a beam, or the depth from the extreme fiber in compression, to the centroid of the steel reinforcement on the tension side of the beam; d_t = total depth of a beam; d_c = depth of cover on the steel reinforcement, measured from the centroid of the rods; $k\,d$ = distance from the extreme fiber in compression, to the neutral axis;

e = eccentricity of the resultant force, T, in respect to the geometrical axis of the entire section $\left(e = \dfrac{M}{T}\right)$;

f = unit stress; f_c = unit compressive stress in the extreme fiber of a concrete section; f_s = unit tensile stress in steel; f'_s = unit stress in the upper steel rods;

k = ratio of the depth of the neutral axis from the extreme fiber in compression to the effective depth of the beam; $k\,d$ = the distance from the extreme fiber in compression to the neutral axis;

n = the ratio of the moduli of elasticity, $\left(n = \dfrac{E_s}{E_c}\right)$;

p = ratio of steel area to the effective area of a beam, $\left(p = \dfrac{A_s}{b\,d}\right)$;

s = a subscript denoting "steel";

t = thickness; as a subscript, t denotes "total";

A = area; A_s = cross-sectional area of steel ($A_s = p\,b\,d$); A'_s = cross-sectional area of the steel in the upper part of a beam;

C = a subscript denoting "depth of cover";

E = modulus of elasticity; E_c for concrete and E_s for steel;

I = rectangular normal of inertia;

K = a constant, $\left(K = \dfrac{M}{b\,d^2}\right)$;

M = moment; bending moment at the section under consideration;

T = total tension; resultant pull due to external forces.

DISCUSSION

A. W. FISCHER,[3] ESQ. (by letter).—The method of designing concrete members under direct tension and bending, as presented by the author, gives correct results. However, since values must be ascertained by using either Fig. 3 or Fig. 5 (which appear rather complicated) and generally must be interpolated, it seems that a more direct method can be used for solving such simple examples.

When e' is negative the author's method is as simple as any that the writer knows, but the suggested solution is not so simple when e' is positive. Consider Example 2 and Fig. 4 of the paper. Taking the center of moments about the centroid of the tension steel and solving for K, by Equation (20), $K = \frac{Te'}{bd^2} = \frac{16\,530 \times 10}{12 \times 10 \times 10} = 137.75$. Referring to a diagram in a standard textbook[4], with $n = 15$, $f_s = 18\,000$ lb per sq in., and $K = 137.75$; then, f_c is found to be equal to 796 lb per sq in. which practically agrees with the value derived by Mr. Gumensky. Furthermore, $k = \frac{n f_c}{f_s + n f_c} = \frac{796}{1\,200 + 796} = 0.3988$ (use 0.399), making $k\,d = 3.99$ in. The value of k can also be read directly from a diagram.[4]

Taking moments about the centroid of the compression area of the concrete (which is $\frac{1}{3}\,k\,d$ below the top of the beam in Fig. 4) the amount of tension steel required will be:

$$\frac{16\,530\left(e' + d - \dfrac{1}{3}\,k\,d\right)}{18\,000\left(d - \dfrac{1}{3}\,k\,d\right)} = \frac{16\,530\,(10 + 10 - 1.33)}{18\,000\,(10 - 1.33)} = 1.978 \text{ sq in. per lin ft,}$$

which corresponds with the results obtained by Equation (21).

If the stresses had been limited to $f_s = 18\,000$ lb per sq in., $n = 15$, and $f_c = 700$ lb per sq in., some compression steel would need to be added and, in that case, since the value of $K = 113.1$, the resisting moment in the concrete can be computed, and the remainder must be taken by compression steel.[5]

It seems to the writer that the foregoing procedure is more in line with that ordinarily used in beam design. The results can be derived very readily and all that is needed is a diagram giving the values of K and k, which are given in any standard textbook on reinforced concrete. All calculations have been made with a 20-in. slide-rule.

WILLIAM E. WILBUR,[6] M. AM. SOC. C. E. (by letter).—It is a fact, frequently unnoticed by writers on structural design, that in determining the fiber stresses in a section of a beam to resist bending, the center of moments

[3] Care, Pennsylvania Sugar Co., Philadelphia, Pa.

[4] See, for example, "Structural Members and Connections", by Hool and Kinne, p. 467.

[5] "Data on Design of Concrete", by A. W. Fischer, *Civil Engineering*, March, 1935, p. 180.

[6] Asst. Engr., Harrington & Cortelyou, Kansas City, Mo.

may be taken at any convenient point in the depth of the beam, and need not be at the neutral axis or at the geometrical axis. In a concrete beam, as the author shows in discussing his Case 2, it is advantageous to take the moment center at the location of the tensile steel. Using the nomenclature of Fig. 4, consider a beam subject to any bending moment, M, without direct stress, and take moments about the tensile steel; thus:

$$M = \frac{1}{2} f_c\, b\, k\, d \left(d - \frac{1}{3} k\, d\right) \qquad \text{(24)}$$

which is the ordinary formula for beams subject to bending only. When the bending moment is that due to a force, T, with an eccentricity, e', the author's Equation (20) results. By carrying the foregoing analysis further, the author's process may be simplified considerably.

Referring again to Fig. 4, one may, without changing the conditions, add two equal opposite forces, each equal to T, in the plane of the tensile steel. The external forces to be resisted are then a couple, of amount, $T\,e'$, and a direct stress, T, in the plane of the tensile steel. The moment, $T\,e'$, as was demonstrated previously, is resisted in the same manner as a moment due to vertical forces; and the beam may be designed for this moment in the same manner as is the ordinary rectangular beam. This determines the concrete stress, f_c, and the quantity of steel required for moment only. The force, T, acts in the line of the tensile steel, and must be resisted by an additional steel area, $\frac{T}{f_s}$. Then one may write:

$$A_s = p_1\, b\, d + \frac{T}{f_s} \qquad \text{(25)}$$

in which p_1 is the percentage of steel required for moment only; and A_s is the total cross-sectional area of steel. This completes the design. Equation (25) may be readily derived from Equations (20) and (21), if $f_s\, p_1$ is substituted for its equivalent, $\frac{1}{2} f_c\, k$. The value of p_1 is determined readily from any of the ordinary diagrams for rectangular beams given in textbooks on concrete design.[7]

The analysis of a beam subject to bending and direct tension then resolves into the following steps: (1) Determine the moment, $M = T\,e'$, in which e' is the distance from the tensile steel to the applied tension, T; (2) compute $K = \frac{M}{b\,d^2}$; (3) enter the diagram (for rectangular beam design) with the value of K, proceed to the desired value of f_s, and read directly the values of f_c and p_1; and (4) determine the total steel required, by Equation (25). This is seen to be much shorter than the author's method, and to require only the ordinary diagram for rectangular beam design found in textbooks.

[7] For example, "Structural Members and Connections", by Hool and Kinne, p. 467.

To solve the example given by Mr. Gumensky: $T = 16\,530$ lb; $e' = 10$ in.; $n = 15$; $M = T\,e' = 165\,300$ in-lb; and, $K = \dfrac{M}{b\,d^2} = \dfrac{165\,300}{12 \times 10 \times 10} = 137.7$. Entering the diagram with this value of K, and reading at $f_s = 18\,000$, one finds at once, that $f_c = 800$, nearly, and $p_1 = 0.0088$. Then,

$$A_s = p_1\,b\,d = 0.0088 \times 120 = 1.056 \text{ sq in.}$$

$$+\frac{T}{f_s} = \frac{16\,530}{18\,000} = \underline{0.918}$$

$$1.974 \text{ sq in.}$$

The author finds a value of 1.92 sq in., the difference being no doubt due to differences in plotting and reading the diagrams.

An additional advantage of this method of analysis is that where the compressive stress is too high, compressive steel may be proportioned readily by the methods used in the design of ordinary rectangular beams reinforced for compression, proportioning for the bending moment, $T\,e'$.

The author treats of beams subject to bending and direct tension. As a corollary of this discussion, however, it may be noted that the foregoing analysis applies equally to the common case of beams under bending and direct compression, except that the area of the tensile steel is reduced, rather than increased, for the direct stress, the expression bcoming, $A_s = p_1\,b\,d - \dfrac{C}{f_s}$ in which C is the direct compression.

F. C. Snow,[8] M. Am. Soc. C. E. (by letter).—No attempt to design for compressive and tensile reinforcement is made by Mr. Gumensky, and this is often necessary in members of fixed size, subject to bending and direct stress. The following modifications of Mr. Gumensky's methods apply to reinforcement for tension only or for tension and compression if both are needed. Equation (10) can be written:

$$k_0 = \frac{1}{1 + \dfrac{f_s}{n\,f_c}} \qquad \text{.......................(26)}$$

k_0 being the value of k which represents the limit of use of tensile steel alone, and demands the use of both compressive and tensile steel, if the f_c-stress is not to exceed a certain value.

If the value of f_c from Equation (10) is substituted in Equation (20):

$$\frac{T\,e'\,n}{f_s\,b\,d^2} = \frac{k^2(1 - \frac{1}{3}k)}{2\,(1 - k)} \qquad \text{.....................(27)}$$

in which,

$$e' = \frac{M}{T} - d + \frac{d_t}{2} \qquad \text{.......................(28)}$$

[8] Prof. of Civ. Eng., Georgia School of Technology, Atlanta, Ga.

If the same value of f_c is substituted in Equation (21):

$$A_s = \frac{T}{f_s} + \left(\frac{k^2}{2(1-k)}\right)\frac{b\,d}{n} \quad \ldots\ldots\ldots\ldots\ldots\ldots(29)$$

In Table 1 various values of k are computed in terms of $\dfrac{T e' n}{f_s\, b\, d^2}$ and $\dfrac{k^2}{2(1-k)}$.

Use of Table 1 for Tensile Steel Only.—In this case k_0 is computed by Equation (26) and $\dfrac{T e' n}{f_s\, b\, d^2}$ is computed from the data of the beam. Then, k is taken from Table 1; if it is less than, or equal to, k_0 only tensile steel is needed. Area A_s is computed by Equation (29), taking the value of $\dfrac{k^2}{2(1-k)}$ from Table 1.

Applying the foregoing modifications to Example 1 of the paper, and assuming that f_c does not exceed 800 lb per sq in., and that f_s does not exceed 18 000 lb per sq in.: By Equation (26), $k_0 = 0.40$; by Equation (28), $e' = 10$ in.; and by Equation (27), $\dfrac{T e' n}{f_s\, b\, d^2} = 0.1148$. From Table 1, therefore, $k = 0.398$; and $\dfrac{k^2}{2(1-k)} = 0.1316$ by interpolation.

Since k is less than k_0 only tensile steel is needed and by Equation (29), $A_s = 1.97$ sq in.

Use of Table 1 for Compressive and Tensile Steel.—Assume that $M = 25\,000$ lb-ft, and that, otherwise, values are the same as in the foregoing case; then, by Equation (28), $e' = 14.14$ in.; and by Equation (27), $\dfrac{T e' n}{f_s\, b\, d^2} = 0.1623$. From Table 1, $k = 0.456$; and $\dfrac{k^2}{2(1-k)} = 0.1911$. Since k is greater than k_0 both compressive and tensile steel are needed.

If the reinforcement in the compressive side of a beam is, A'_s, placed a distance of d' in. from the extreme fiber, the stress carried by this steel is,

$$A'_s f_c (n-1)\left(\frac{k\,d-d'}{k\,d}\right) \qquad (30)$$

Equation (20) becomes,

$$T\,e' = \frac{1}{2} f_c\,k\,b\,d\left(d - \frac{k\,d}{3}\right) + A'_s f_c (n-1)\left(\frac{k\,d-d'}{k\,d}\right)(d-d') \qquad (31)$$

and Equation (21) becomes,

$$T - A_s f_s + \frac{1}{2} f_c\,k\,b\,d + A'_s (n-1) f_c\left(\frac{k\,d-d'}{k\,d}\right) = 0 \qquad (32)$$

Solving Equation (31) for A'_s,

$$A'_s = \frac{T\,e' - \frac{1}{2} f_c\,k\,b\,d\left(d - \frac{k\,d}{3}\right)}{(n-1) f_c \frac{(k\,d-d')}{k\,d}(d-d')} \qquad (33)$$

Solving Equation (32) for A_s,

$$A_s = \frac{T}{f_s} + \frac{\frac{k^2}{2(1-k)}\left(\frac{b\,d}{n}\right)}{f_s} + \frac{A'_s (n-1)\left(\frac{k\,d-d'}{k\,d}\right)}{f_s} \qquad (34)$$

Substituting f_s in terms of f_c from Equation (10) in Equation (34):

$$A_s = \frac{T}{f_s} + \frac{k^2}{2(1-k)}\left(\frac{b\,d}{n}\right) + A'_s (n-1)\left(\frac{k\,d-d'}{n(1-k)\,d}\right) \qquad (35)$$

If the value of A'_s from Equation (33) is substituted in Equation (34),

$$A_s = \frac{T}{f_s} + \frac{k^2}{2(1-k)}\left(\frac{b\,d}{n}\right) + \frac{T\,e'}{f_s (d-d')} - \frac{k^2\left(1-\frac{k}{3}\right)}{2(1-k)}\left(\frac{b\,d^2}{n(d-d')}\right) \qquad (36)$$

Substituting f_c in terms of f_s and k from Equation (10):

$$A_s = \frac{T}{f_s} + \frac{k^2}{2(1-k)}\left(\frac{b\,d}{n}\right) + \frac{T\,e'}{f_s (d-d')} - \frac{k^2\left(1-\frac{k}{3}\right)}{2(1-k)}\left(\frac{b\,d^2}{n(d-d')}\right) \qquad (37)$$

but $\dfrac{k^2\left(1-\frac{k}{3}\right)}{2(1-k)} = \dfrac{T\,e'\,n}{f_s\,b\,d^2}$ by Equation (27), so that Equation (37) is the

same as Equation (29). In other words, the latter can be used to compute the tensile steel whether or not compressive steel is needed.

The foregoing substitution from Equation (27) involves the assumption that f_c can be made large enough so that no compressive steel is needed—namely, that $f_c = f_s\left(\frac{k}{n(1-k)}\right)$, k in this case being greater than k_0, making f_c greater than the allowable working stress. This statement indicates directly that Equation (29) applies both to tensile and compressive reinforcement conditions, but the foregoing proof is given as a further check.

Equation (35) will be used to compute A'_s and, since f_c cannot be increased beyond its allowable value, k_0 must be used instead of k. By Equation (35), substituting the value of A_s from Equation (29):

$$\frac{T}{f_s} + \left(\frac{k^2}{2(1-k)}\right)\frac{b\,d}{n} = \frac{T}{f_s} + \left(\frac{k_0^2}{2(1-k_0)}\right)\frac{b\,d}{n} + A'_s(n-1)\left(\frac{k_0\,d - d'}{n(1-k_0)\,d}\right)$$

from which,

$$A'_s = \left[\frac{k^2}{2(1-k)} - \frac{k_0^2}{2(1-k_0)}\right]\left(\frac{(1-k_0)\,b\,d^2}{(n-1)(k_0\,d-d')}\right) \ldots\ldots (38)$$

Applying Equation (29) to the example for $k = 0.456$, Table 1 shows that $\frac{k^2}{2(1-k)} = 0.1911$; and for $k_0 = 0.400$, Table 1 shows that $\frac{k_0^2}{2(1-k_0)} = 0.1333$.

By Equation (29) $A_s = 2.45$ sq in.; and by Equation (38), $A'_s = 1.49$ sq in. In this case the compressive steel is not excessive, but suppose that $M = 21\,400$ ft-lb, $T = 3\,915$ lb, $b = 12$ in., and $d = 8$ in.; then $e' = 68.6$ in.; and $\frac{T\,e'\,n}{f_s\,b\,d^2} = 0.2913$. From Table 1, $k = 0.561$; and $\frac{k^2}{2(1-k)} = 0.3584$. With $k_0 = 0.4$, as before, $\frac{k_0^2}{2(1-k_0)} = 0.1333$, from Table 1. Then, by Equation (38), $A'_s = 6.17$ sq in. Should this steel area be considered excessive, it can be decreased by reducing f_s, keeping f_c constant. Assuming that f_s is 11 500: $\frac{T\,e'\,n}{f_s\,b\,d^2} = 0.4561$ (from the beam data). From Table 1, $k = 0.645$; and $\frac{k^2}{2(1-k)} = 0.5838$. By Equation (26), $k_0 = 0.510$; and by Table 1, $\frac{k_0^2}{2(1-k_0)} = 0.2654$. By Equation (38), $A'_s = 4.11$ sq in.; and by Equation (29), $A_s = 4.08$ sq in. This solution makes $A_s = A'_s$ and required three trials for varying values of f_s.

If f_s in terms of f_c from Equation (10), and A'_s for A_s, are substituted in Equation (35), and after solving for A'_s the resulting expression is equated to A'_s from Equation (33), a cubic equation in k_0 results, from which k_0 for $A_s = A'_s$ can be computed for any value of f_c. It is just as easy, however,

to make three or four trial computations like the one just completed for different values of f_s until $A_s = A'_s$, as it is to solve the cubic equation in terms of k_0, should it be desired to make $A_s = A'_s$.

RALPH E. BYRNE, JR.,[*] JUN. AM. SOC. C. E. (by letter).—The problem of combined tension and bending has been presented very clearly in this paper. However, when part of the section is in compression, the case of tension and bending is one part only of the more general problem of bending and direct stress, the case of compression and bending being the other part. Furthermore, by re-arranging the terms in the equations derived by the author, these equations may be obtained in forms which lend themselves more readily to solution by means of curves.

Consider the case in which part of the section is in compression, and the solution is related to the center of the reinforcement in the tension face, there being no reinforcement in the compression face. The author's notation and sign convention will be used with the following exceptions: N will be used to denote the resultant direct stress, either tension or compression, and will be considered positive when the direct stress is compression. For the case being discussed, eccentricities are measured from the center of the tension steel, and will be assumed positive when measured toward the compression face of the member; that is, in Fig. 4 of the paper, positive eccentricities are measured upward from the steel. It should be noted that the part of the section in compression is always on the positive side of the steel as defined by this sign convention.

Taking moments about the center of the tension steel,

$$N e' = \frac{1}{2} f_c \, k \left(1 - \frac{k}{3}\right) b \, d^2 \qquad (39)$$

Equating the sum of the horizontal forces to zero,

$$-N + \frac{1}{2} f_c \, k \, b \, d - A_s f_s = 0 \qquad (40)$$

Equation (40) differs from Equation (21) of the paper only in the sign of the direct stress; this difference is accounted for by the change in sign convention suggested by the writer. Equation (39) is identical with Equation (20). Since the right member of Equation (39) is always positive, it is evident that N and e' must always be of the same sign; that is, positive direct stress (compression) must always be accompanied by positive eccentricity, and negative direct stress (tension), by negative eccentricity. A third equation is obtained from the assumption of straight-line distribution of stress,

$$\frac{f_s}{n f_c} = \frac{1 - k}{k} \qquad (41)$$

Equations (39), (40), and (41), solved simultaneously, will yield the same expressions as those obtained by the author, except that all terms containing e'

[*] Structural Designer, Pacific Elec. Ry., Los Angeles, Calif.

will be of opposite sign. However, other forms of these equations more readily lend themselves to solution by means of curves.

Problems of bending and direct stress which fall into the case being considered may be divided roughly into two types: (*a*) Those in which the eccentricity is small compared to the depth of the member; and (*b*) those in which the eccentricity is large compared to the depth of the member. For the first type, curves plotted using values of the quantity, $\frac{e'}{d}$, will prove advantageous —that is, curves similar to Fig. 5. The chief objection to these particular curves, however, is that a separate set of curves is required for each value of n. This objection may be overcome as follows: Rewrite Equation (23):

$$\frac{T\,n}{f_s\,b\,d} = p\,n - \frac{k^2}{2\,(1-k)} \qquad \text{.................... (42)}$$

Using Equation (42), a set of curves similar to those in Fig. 5 could be plotted, using values of the quantity, $p\,n$, as abscissas, values of k as ordinates, and drawing curves of the quantities, $\frac{e'}{d}$ and $\frac{T\,n}{f_s\,b\,d}$. This single set of curves would then cover any problem that falls into the case being considered, and by adopting a sign convention similar to that offered in this discussion, the curves could be extended to cover the entire range of both tension and compression. For the second type, that is, problems in which the eccentricity is large compared to the depth of the member (see Fig. 6), curves plotted using values of the quantity, $\frac{d}{e'}$, will prove more advantageous. In Fig. 6, the quantities used in plotting the curves in Fig. 7 are defined; thus, $M = N\,e'$; $f_c = C\,\frac{M}{b\,d^2}$; and $R = \frac{f_s}{n\,f_c} = \frac{1-k}{k}$. It is to be noted that N and e are both positive when the direct stress is compression, and negative when the direct stress is tension. The moment, M, is always positive. The curves in Fig. 7 are for cases of large eccentricity, and were plotted from Equation (44), which was obtained as follows: Eliminating N between Equations (39) and (40) and letting $A_s = p\,b\,d$:

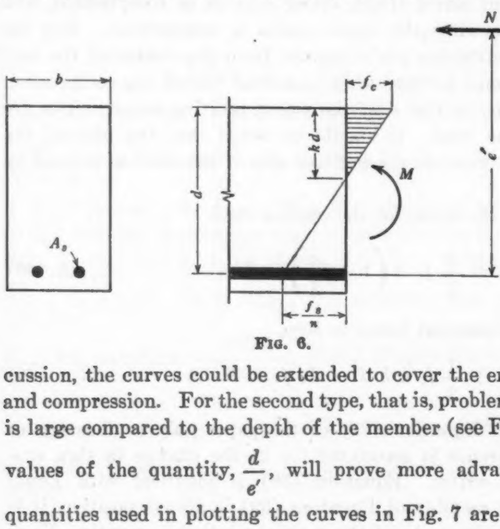

FIG. 6.

$$\frac{f_s}{f_c} = \frac{k}{2\,p}\left[\,1 - \left(1 - \frac{k}{3}\right)\frac{d}{e'}\right] \qquad \text{................ (43)}$$

Substituting the value of k from Equation (41) in Equation (43) and letting $R = \frac{f_s}{n f_c}$:

$$\frac{d}{e'} = \frac{3(R+1)}{3R+2}\,[1 - 2\,p\,n\,R\,(R+1)] \qquad (44)$$

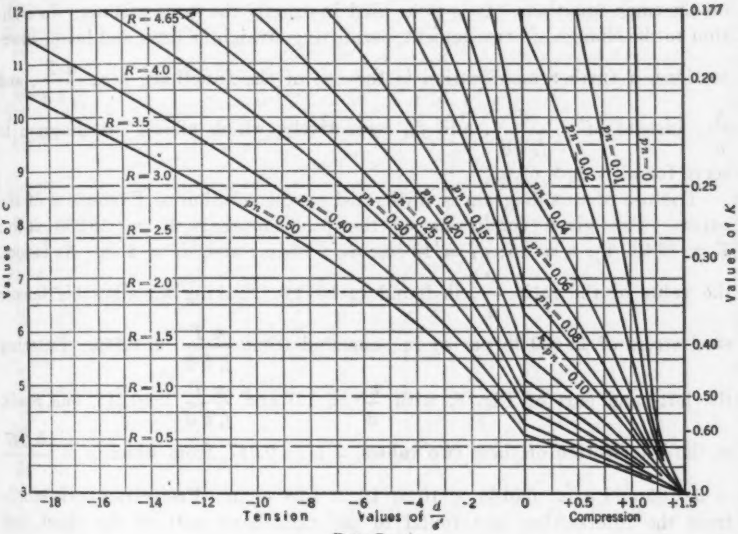

FIG. 7.

Probably of greater importance than any of the cases treated by the author is that of bending and direct stress in which both sides of the member are reinforced, and in which part of the section is in compression. In this case, again, the solution is general for both tension and compression. The case in which the direct stress is compression has already been amply treated[10], and need not be repeated here. Noting that direct tension must be accompanied by negative eccentricity, it is evident that all equations derived for the case of bending and compression can be applied directly to the case of bending and tension if the sign of every term which contains e is reversed; curves which cover the case of bending and tension are merely extensions of the curves which cover the case of bending and compression.

CARL H. HEILBRON, JR.,[11] ASSOC. M. AM. SOC. C. E. (by letter).—Useful and convenient charts are presented in this paper, for solving the usual type of problem of combined tension and bending in concrete members with reinforcement in a single layer. The writer believes that curves of the type of

[10] "Principles of Reinforced Concrete Construction", by F. E. Turneaure, Hon. M. Am. Soc. C. E., and E. B. Maurer.

[11] Asst. Engr. (Design), Metropolitan Water Dist. of Southern California, Los Angeles, Calif.

Fig. 5, rather than Fig. 3, will be of greater use, since a smaller number of diagrams will be required for the solution of all problems.

In using Fig. 5, it is rather difficult to follow some of the lines because of their curvature, and hard to determine the intersections accurately because of the sharp angles. To overcome these troubles the writer suggests the use of Fig. 8, which is fundamentally the same as Fig. 5, being based on the same equations. It is to be used in exactly the same manner. In addition to the change of arrangement, permitting straighter lines and better intersections, a further modification is the use of the functions, $n\ p$, $\frac{n\ T}{f_s\ b\ d}$, and $\frac{f_s}{n}$, instead of p, $\frac{T}{f_s\ b\ d}$, and f_s, respectively, which allows one diagram to serve for all values of n.

The use of this diagram is illustrated by the solution of Example 2 of the paper. The given conditions of the problem are: $M = 19\,230$ ft-lb.; $T = 16\,530$ lb; $n = 15$; $d_t = 12$ in.; $d = 10$ in.; and, $d_o = 2$ in. As before, the value of the ratio, $\frac{e'}{d}$, is found to be 1.0. Taking an allowable tensile steel stress of 18 000 lb per sq in., one finds that $\frac{n\ T}{f_s\ b\ d} = 0.115$. Entering the left-hand part of Fig. 8, with $\frac{e'}{d} = 1.0$ and $\frac{n\ T}{f_s\ b\ d} = 0.115$, one reads, at the intersection of these two values, $n\ p = 0.247$, from which $p = \frac{0.247}{15} = 0.0165$ and $a_s = 0.0165 \times 10 \times 12 = 1.98$ sq in. Projecting horizontally from the intersection just found to the right-hand part of the chart, one finds, at the intersection with the line, $\frac{f_s}{n} = \frac{18\ 000}{15} = 1\,200$, the value, $f_c = 800$ lb per sq in.

The value found for a_s (1.98 sq in.) is very close to 1.973 sq in., as given by exact mathematical solution of the equations involved. The value obtained by the author ($a_s = 1.92$ sq in.), although sufficiently close for ordinary design purposes, is in error by an amount indicating inaccuracy in his diagrams.

Many engineers will probably prefer to use separate diagrams for various values of n. A diagram for any given value of n can easily be prepared from Fig. 8 by writing in the values of p, $\frac{T}{f_s\ b\ d}$, and f_s, for the value of n selected, on each of the lines for $n\ p$, $\frac{n\ T}{f_s\ b\ d}$, and $\frac{f_s}{n}$, respectively. Others may prefer diagrams of the type of Fig. 3, which can be modified in the same way as Fig. 5 was re-arranged to give Fig. 8, with the same resultant advantages.

The writer wishes to call attention to another method of solving the usual type of problem involving combined bending and tension (or bending and compression) where there is reinforcement on one side of the section

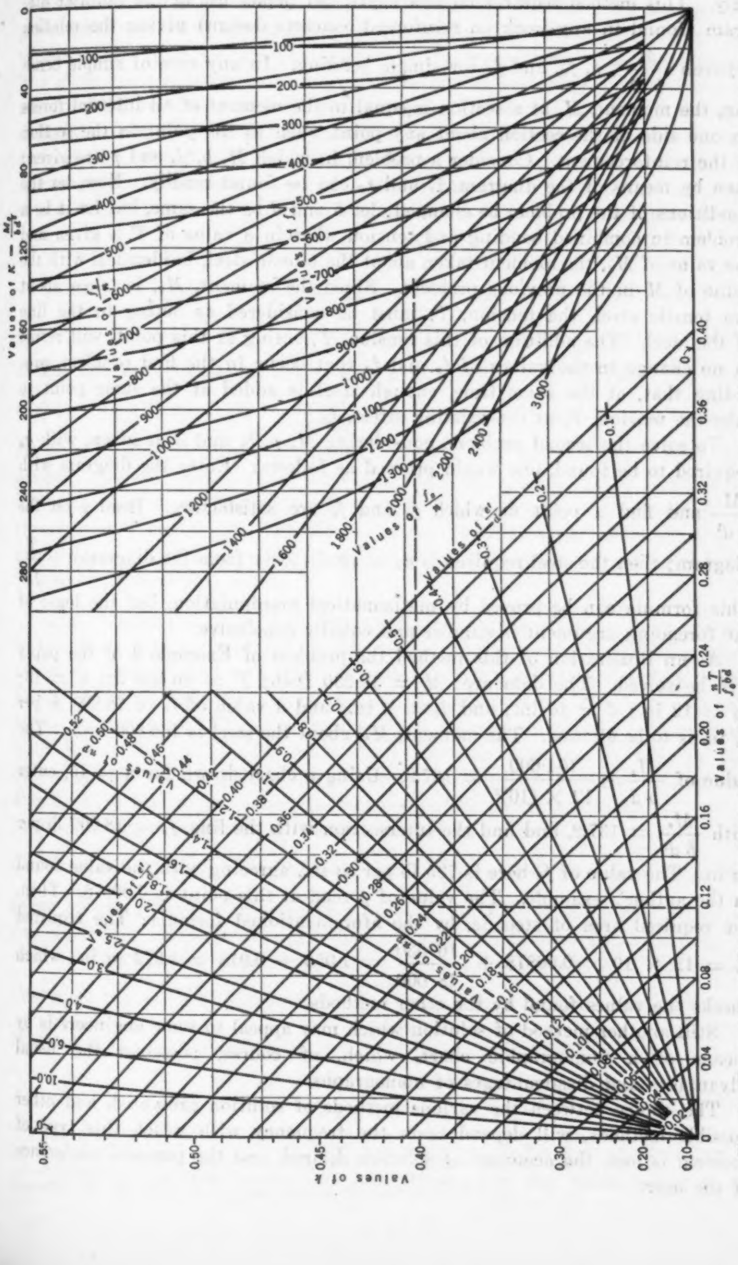

FIG. 8.—DIAGRAM FOR SOLUTION OF PROBLEMS IN REINFORCED CONCRETE, IN COMBINED BENDING AND TENSION WITH REINFORCEMENT IN A SINGLE LAYER. (MOMENT AND ECCENTRICITY ARE REFERRED TO THE CENTER OF GRAVITY OF THE TENSION STEEL.)

only. This method requires no new chart, but makes use of the familiar diagram (found in any work on reinforced concrete design) giving the relation between $\frac{M}{b\,d^2}$, p, f_c, and f_s for simple bending. In any case of simple bending, the moment, M, at a section is equal to the moment of all internal forces on one side of the section about any point, such as the point in the section at the reinforcement. Consider a problem in which M, b, d, and p are given; then by means of the diagram, f_s and f_c can be found readily. Now, let the conditions of the problem be changed; let b and d be the same, but let it be a problem in combined bending and tension wherein a value of T is given and the value of M_s, the moment taken about the tensile steel, is identical with the value of M in the previous problem. Since the moment, M_s, is taken about the tensile steel, the tension, T, must be considered as acting in the line of the steel. The addition of this tension, T, acting at this point, will result in no change in the values of f_s and f_c that occur in the first problem, providing that, at the same time, enough steel is added at the same point to take the tension, T, at the existing stress, f_s.

To solve the second problem, considering M, p, b, and d as given, with a_s required to be found, one would proceed as follows: Enter the diagram with $\frac{M}{b\,d^2}$ and find a point at which f_c and f_s are satisfactory. Read p on the diagram; then the steel required is $a_s = (b\ d) \times (p \text{ from the diagram}) + \frac{T}{f_s}$. This formula can be proved by mathematical manipulation, but the logic of the foregoing argument is simpler and equally conclusive.

As an illustration of this method the problem of Example 2 of the paper will be solved. The data are: $M = 19\,230$ ft-lb; $T = 16\,530$ lb; $n = 15$; $d_t = 12$ in.; $d = 10$ in.; and $d_c = 2$ in.; and a value of f_s of 18 000 lb per sq in. is to be allowed. The moment, M_s, about the steel is 164 600 in-lb. The value of $\frac{M_s}{b\,d}$ is $\frac{164\,600}{12 \times (10)^2} = 137.2$. Using a chart drawn for $n = 15$, enter with $\frac{M_s}{b\,d^2} = 137.2$, and find the intersection with the line, $f_s = 18\,000$ lb per sq in. The value of f_c here is 795 lb per sq in., agreeing with the value found in the author's example. The value of p read at this point is 0.00878. Then, the required area of steel is, by the aforementioned formula: The required $a_s = 12 \times 10 \times 0.00878 + \frac{16\,530}{18\,000} = 1.055 + 0.918 = 1.973$ sq in., which checks the values found by the other methods.

Still another method of solution which may appeal to some engineers is by means of a nomographic chart, which, of course, possesses the usual advantages and disadvantages of nomographs.

The choice between the various methods of solution presented, and other possible methods, will depend upon the frequency with which this type of problem is met, the accuracy of solution desired, and the personal preference of the user.

F. E. TURNEAURE,[12] HON. M. AM. SOC. C. E. (by letter).—The author has presented a very complete analysis of the problem of combined bending and tension. His diagrams are particularly useful for determining the stresses in a given beam subjected to known forces, but in designing a beam for certain specified working stresses a simpler method can be used. For this purpose the tension steel should be taken as the moment center, as done by the author in his second solution. The forces acting on the section may then be represented as a moment, M_1, and a direct tension, T, applied at the level of the steel. The beam is then designed as an ordinary rectangular beam for M_1 and the resulting steel area increased by an amount equal to $\frac{T}{f_s}$.

Taking the problem used by the author, $M_1 = 165\,300$ in-lb; and, $K = \frac{M_1}{b\,d^2} = 137.7$: For this value of K and for $f_s = 18\,000$, the usual tables or diagrams for rectangular beams give $p = 0.88\%$ and $f_c = 795$. The total steel area $= 0.0088 \times 120 + \frac{16\ 530}{18\ 000} = 1.97$ sq in. If the concrete stress is too high, the design can be adjusted by determining the value of p from the allowed concrete stress, thus increasing the steel area, or by increasing the value of d, as in any rectangular beam. Any change in the value of d, of course, will modify M_1, but this is readily re-calculated. In analyzing a given design, diagrams may be used, or the problem must be solved by "cut-and-try" methods.

H. E. WARRINGTON,[13] M. AM. SOC. C. E. (by letter).—The problem treated in this paper was encountered in the design of the tunnel from the sewage treatment plant of the Los Angeles County (Calif.) Sanitation Districts to the Pacific Ocean. Diagrams such as those in the paper would have been of great service in that case. The same problem was treated quite fully by Professor Emil Mörsch in 1908.[14] The analysis, of course, is similar to that of the author, but the resulting diagrams are not. The requisite steel is not obtained directly as in this paper, hence, further computations are necessary.

In checking the results of the aforementioned studies with the author's diagrams, it happened, unfortunately, that $\frac{T}{f_s\,b\,d}$ and $\frac{e}{d}$ were far to the left upper corner, and their intersections were too indefinite, the curves being so nearly parallel. Mörsch's diagram does not suffer in this respect, although, in order to use it, a preliminary percentage of steel must be chosen. His graph then gives the value of k from that of $\frac{M}{T\,d_t}$, which is known. With k given, all stresses are determined at once. Therefore, the general formula,

$$e = \frac{M}{T} = \frac{x^2\,(3\,d_t - 2\,x) + 6\,n\,p\,d\,(d - x)\,(2\,d - d_t)}{12\,n\,p\,d\,(d - x) - 6\,x^2} \quad \ldots\ldots(45)$$

[12] Cons. Engr.; Dean, Coll. of Mechanics and Eng., Univ. of Wisconsin, Madison, Wis.
[13] Asst. Engr., Los Angeles County San. Dists., Los Angeles, Calif.
[14] "Concrete Steel Construction", by Emil Mörsch; see, also, translation by E. P. Goodrich, M. Am. Soc. C. E., Engineering News Pub. Co., 1910.

was used, in which $x = k\, d_t$ and all other quantities are known. The cubic in x is best solved by trial approximation. Usually, two or three trials are all that are necessary. A check against numerical errors in the value of k is given by substituting the resulting foregoing data in the formula for,

$$M \text{ (in-lb)} = f_c \frac{b\, k\, d_t}{2} \left(\frac{d_t}{2} - \frac{k\, d_t}{3} \right) + f_s A_s \left(d - \frac{d_t}{2} \right) \ldots\ldots (46)$$

For preliminary results, Mörsch treats the rectangular section as a beam, without reinforcement, by the well-known formula,

$$f_c = \frac{T}{b\, d_t} \pm \frac{6\, M}{b\, d^2_t} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

thus finding the edge stresses. Then, he assumes all the tension to be taken by the steel, determining a quantity,

$$Z = \frac{b^2\, d^3_t\, f^2_c}{24\, M} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

in which f_c is the tensile unit stress. This value of Z is the total steel stress, and the area required, of course, is $\frac{Z}{f_s}$. Trials of this method showed that the steel area thus found was a little larger than that given by the more accurate formulas. This method, by the way, is equally applicable to compression and bending. Possibly a diagram such as the valuable one for bending and compression, with single reinforcement, as presented[15] by F. E. Turneaure, Hon. M. Am. Soc. C. E., and Professor E. R. Maurer, could be made.

WILLIAM A. LARSEN,[16] ESQ. (by letter).—The topic of this paper is one that has been peculiarly avoided in the past. If it has been one's experience to design members of reinforced concrete structures for direct tension and bending, one will realize how little is recorded concerning it, but one must also realize that work of this nature has been constructed for some time. The reason for omitting discussions and charts on this topic in the American texts on concrete design is not fully understood by the writer. Simple bending and compression is a common problem and is covered fully in many books. Bending and tension are so closely related to it that it should offer no difficulty, as is shown by the author. This is also verified by other works.

It was pointed out by the author that the curves of Fig. 3 are less desirable than those of Fig. 5. The writer concurs and will direct the succeeding discussion primarily to the method presented, using the tensile steel as a reference for the eccentricity of the normal force.

The use of charts for the solution of equations similar to those encountered in this case not only expedites the work but also provides a graphical picture

[15] "Principles of Reinforced Concrete Construction", by F. E. Turneaure and E. R. Maurer, Fourth Edition, p. 434.

[16] With U. S. Bureau of Reclamation, Denver, Colo.

of the variables assisting the designer to visualize which of them has the most pronounced effect. It is best, therefore, to make the charts as simple and clear as possible. It is also desirable to keep them similar to other reinforced concrete diagrams in current use. The angle of intersection of the curves on a chart should approximate 90° if accuracy is desired. Based on these restrictions, the writer suggests a few changes which would make Fig. 5 more desirable.

The author finds the value of k by use of $\frac{T}{f_s\,b\,d}$ and $\frac{e}{d}$. The intersection of the lines representing these values is not definite in the upper part of the chart. As $\frac{T}{f_s\,b\,d}$ approaches zero and $\frac{e}{d}$ approaches infinity, the angle of intersection of these curves approaches zero. The points of intersection are thus obscured, especially if interpolation is necessary. It would be better to use other curves to obtain better intersections. With this purpose in mind, re-arrange Equation (20) in the form,

$$\frac{T\,e'}{b\,d^2} = \frac{f_c}{2}\,k\left(1 - \frac{k}{3}\right) = \frac{f_c}{2}\,k\,j \quad\ldots\ldots\ldots\ldots\ldots(49)$$

This relationship is the same as has been used to plot the curves of the right-hand part of Fig. 5, if $\frac{M}{b\,d^2} = \frac{T\,e'}{b\,d^2}$. If $K = \frac{T\,e'}{b\,d^2}$ is used as the abscissa, k can be found by entering the chart at the bottom for a known K-value, trace upward to the intersection of either f_c, or f_s, and a value of k is thus defined. With the determined value of k, follow horizontally to the intersections with the desired $\frac{e'}{d}$ - line and thence down to the required p-value. This gives the same results as those obtained by the author, but without the use of the $\frac{T}{f_s\,b\,d}$ - curves. This also gives the same procedure as that used for charts on compression and bending[11]. The one operation gives, directly, the values for f_c and f_s in addition to the p-value. It is suggested, therefore, that the $\frac{T}{f_s\,b\,d}$ - curves be omitted, and $\frac{M}{b\,d^2}$ be changed to read $\frac{T\,e'}{b\,d^2}$. This will simplify the charts as well as their use.

The writer believes the curves as now shown, with values, $K = \frac{M}{b\,d^2}$, are misleading, thus emphasizing the need to change to $\frac{T\,e'}{b\,d^2}$. For instance, from Example 2, $K = \frac{M}{b\,d^2} = \frac{19\,230 \times 12}{12 \times 100} = 192.3$. Entering the chart at the lower right and tracing vertically to $f_s = 18\,000$, $f_c = 1\,000$ lb per

sq in. (approximately, which is erroneous). Thus, using $\frac{T\,e'}{b\,d^2} = 134$, Point B is located, giving the correct values for f_c and f_s.

It is interesting to note that in 1918, E. Suenson[18] published a chart similar to Fig. 9(*b*) dealing with tension and bending, giving the same results as Fig. 5, but plotted to different co-ordinates. It is simple and easily applied. By adding a set of K, f_c, and f_s-curves (Fig. 9(*a*)), the chart can be used as was suggested for Fig. 5.

Fig. 9 is unique in that it was plotted as a bending and direct stress diagram, using $-N$ for tension. It can be used for either bending and tension, or bending and compression. For that reason it may be of greater value than Fig. 5. Its use is illustrated by Example 3.

Example 3.—In Example 1 of the paper, $M = 19\,230$ ft-lb; $T = 16\,530$ lb; $n = 15$; $d_t = 12$ in.; and $d = 10$ in. The eccentricity relative to the geometric center $= \frac{M}{T} = \frac{19\,230}{16\,530} = 1.163 = 14$ in. The eccentricity relative to the tension steel is equal to $e' = e - d + \frac{d_t}{2} = 14 - 10 + 6 = 10$ in.; and, $\frac{e'}{d} = \frac{10}{10} = 1$. Furthermore, assume that $f_s = 18\,000$ lb per sq in., $\frac{T\,e'}{b\,d^2} = \frac{16\,530 \times 10}{12 \times 100} = 134$; then find the intersection of $\frac{T\,e'}{b\,d^2}$ and the f_s-curves, which gives $f_c = 795$ and $k = 0.395$ (Point B, Fig. 9(*a*)). Follow the horizontal line from Point B to the intersection of the vertical line, $\frac{e'}{d} = 1$, and p is found to be 0.016. These results are precisely the same as those found by the author in Examples 1 and 2.

One of the features of Fig. 9(*b*) is the plotting of the abscissas. The value of $\frac{e'}{d}$ ranging from 0 to ∞ necessitated a particular graph paper. A quadrant of a circle was used, the quarter circumference being assumed to represent a distance of 0 to ∞ (Fig. 9(*c*)). Points at equal distances were laid off on the tangent, $O\,B$, starting at Point O. Lines were drawn from these points to the center of the circle, the intercepts between these lines on the circumference being used as abscissa to plot the graph paper.

The necessity of using a different chart for each value of n is a serious disadvantage to diagrams of the type shown in Figs. 5 and 9(*a*). At present, there is a tendency to use n-values ranging from 6 to 15. To eliminate the need of so many charts J. A. Wineland, Jun. Am. Soc. C. E.,[19] in connection with his work at the Bureau of Reclamation, has prepared a diagram embodying n as a variable (see Fig. 10). Various co-ordinates were tried, using different combinations of variables until a diagram giving pronounced intersection of the curves was found. This diagram may be used for any value of n for tension and bending and, with a slight modification, for compression

[18] "Jaernbeton—Teori og Praksis", by E. Suenson, 1918, P. E. Bluhmes Book Co., Copenhagen, Denmark.

[19] Not published.

and bending. The diagram was plotted for members with a unit width of 12 in. Values of the ordinates are expressed in terms of,

$$\frac{e_1}{d} = \frac{k}{2}\left(\frac{2-k}{k+np}\right) + \frac{\left(1-\frac{k}{3}\right)\left(\frac{k^3}{1-k}\right)}{2\,np - \frac{k^2}{1-k}} \qquad (50)$$

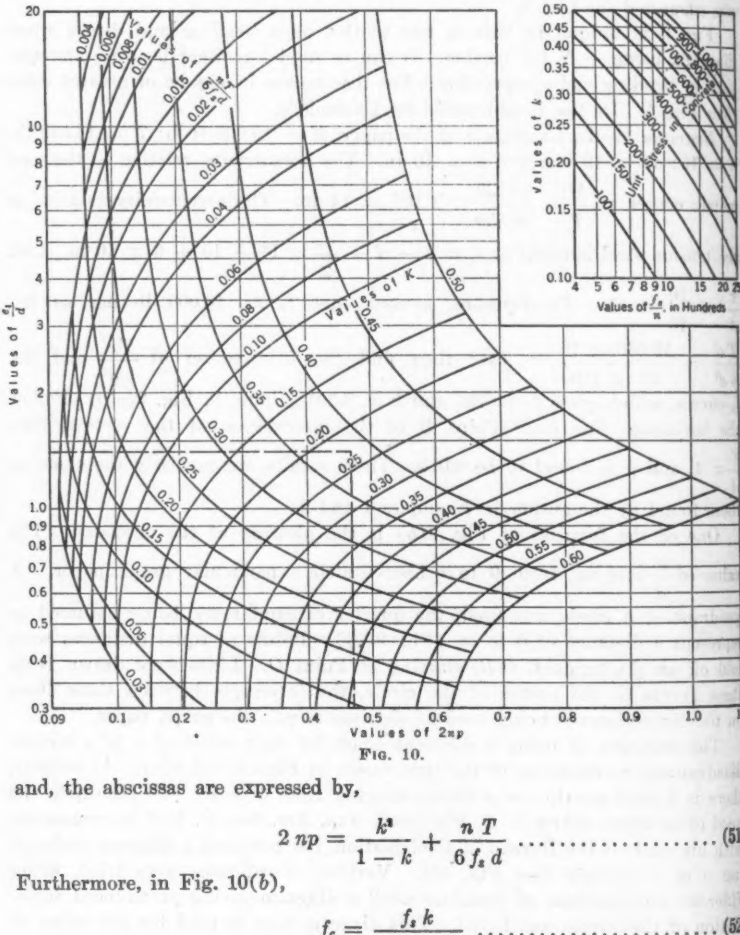

FIG. 10.

and, the abscissas are expressed by,

$$2\,np = \frac{k^2}{1-k} + \frac{n\,T}{6\,f_s\,d} \qquad (51)$$

Furthermore, in Fig. 10(*b*),

$$f_c = \frac{f_s\,k}{n\,(1-k)} \qquad (52)$$

in which, in addition to the notation of the paper, e_1 = eccentricity of the resultant force, T, with respect to the geometrical axis of the stressed areas.

The procedure in solving problems by Fig. 10 is very similar to that given by the author concerning the curves of Fig. 3:

(1) Knowing the moment, M, and the tension, T, determine the value, $e_1 = \dfrac{M}{T}$.

(2) With a trial value of d determine $\dfrac{e_1}{d}$.

(3) Using the desired value of n determine the value of $\dfrac{n\,T}{6 f_s d}$.

(4) Determine the relation of $\dfrac{f_s}{n}$.

(5) Using the values of $\dfrac{e_1}{d}$ and $\dfrac{n\,T}{6 f_s d}$, determine values for $2\,p\,n$ and k by use of Fig. 10(a). Enter the left side of the chart at the $\dfrac{e_1}{d}$ - value and trace horizontally to the right to the intersection with the $\dfrac{n\,T}{6 f_s d}$ -curve; k may be found by reading the curves practically 90° with the $\dfrac{n\,T}{6 f_s d}$ -curves. The value of $2\,pn$ is found at the top of the chart directly above the point just located.

(6) With the value of k and $\dfrac{f_s}{n}$, Fig. 10(b) is used to find f_c.

(7) The necessary steel area is found by multiplying $2\,pn$ by $\dfrac{b\,d}{2\,n}$.

It is seen that it is as easy to use Fig. 10 as Fig. 5 and only the one chart is necessary for all values. This compact diagram should appeal to designers who are concerned with various values of n.

The solution of a problem by the use of Fig. 10, with the moment as given in Eample 1, will give slightly different results from those found by the use of Fig. 3 or Fig. 5, because of the assumptions used in deriving the formulas. The author assumed the working lines to go through the geometrical axis of the gross concrete area. The curves of Fig. 10 were made feasible by assuming the working lines to go through the center of gravity or the geometrical axis of the stressed areas of the reinforced concrete member. This means that the value of the moment, M, will vary slightly, depending upon the working lines used. The eccentricity, $e_1 = \dfrac{M}{T}$, should be referred to the same working lines to which the moment is referred. Usually, however, sufficiently accurate results may be obtained by using the center line of the member as the working line, thus referring e_1 to the center line of the member.

Example 4.—The solution of the problem in Example 1, by use of Fig. 10 will give results comparable to those already obtained. For example: $M = 19\,230$ ft-lb; $T = 16\,530$ lb; $n = 15$; $d_t = 12$ in.; $d = 10$ in.; $b = 12$ in.;

and $f_s = 18\,000$. Finally, $e_1 = \frac{M}{T} = \frac{19\,230}{16\,530} = 1.163$ ft $= 14$ in.; $\frac{e_1}{d} = \frac{14}{10} = 1.4$; $\frac{n\,T}{6 f_s d} = \frac{15 \times 16\,530}{6 \times 18\,000 \times 10} = 0.23$; and, $\frac{f_s}{n} = \frac{18\,000}{15} = 1\,200$. From Fig. 10(*a*), $2\,pn = 0.47$, or $p = 0.0157$; and, $k = 0.385$. From Fig. 10(*b*), $f_c = 750$ lb per sq in.

If the moment, M, is referred to the proper working lines for use in Fig. 10, exactly the same results as those obtained in the other examples will be found.

The geometrical axis of the stressed area is given by:

$$y = \frac{k\,d\left(1 - \frac{k}{2}\right)}{k + n\,p} \qquad (53)$$

in which y = the distance to the geometrical axis of the stressed areas from the steel axis. From Example 2: $k = 0.395$; $p = 0.016$; $n = 15$; $y = 5$ in., or 0.0833 ft above the center line; and,

$$M_1 = M + T\ (0.0833) \qquad (54)$$

in which M_1 = the moment referred to the geometrical axis of the stressed areas. In other words, $M_1 = 19\,230 + 16\,530 \times 0.0833 = 20\,608$ ft-lb. Finally $e_1 = \frac{M'}{T} = \frac{20\,608}{16\,530} = 1.25$ ft, or 15 in.; $\frac{e_1}{d} = \frac{15}{10} = 1.5$; and by the same procedure as in Example 3, $p = 0.016$ and $f_c = 795$ lb per sq in.

Conclusion.—The preference of the individual designer for the use of different diagrams and charts, the problems at hand, and the general designing practice will determine which type of diagrams are to be used. It is hoped that this discussion has added constructive information to that already given by the author to clarify this topic, which has been so carefully avoided in concrete design texts.

There is one more important question that should be considered carefully although it has not thus far been mentioned: What are the bond stresses and how may they be calculated? After the designer has conducted a careful analysis and has determined the required steel area by any method similar to those presented, it is necessary that he obtain the correct bond values. The familiar, $u = \frac{V}{b\,j\,d}$, will not satisfy the necessary requirements for bending and direct stress. The direct pull, T, tends to increase the tensile force in the steel over that caused by pure bending.

The change in the total tension per unit length of bar is equal to the bond stress. If a curve is drawn representing the total tension in the steel at any point along the length of the bar, the bond may be determined by the slope of the tangent to that curve. The unit bond stress, being equal to the bond divided by the peripheral area, may then be found. This is an accurate and easily remembered method.

B. KOVEDIAEFF,[20] ESQ. (by letter).—The subject of direct tension combined with bending in reinforced concrete members has been discussed in the more modern textbooks on reinforced concrete. However, the Engineering Profession, and especially engineers interested in structural work, will more than welcome a consistent discussion covering such an important subject.

In the "Introduction", the author states that the paper is an attempt to analyze the stress distribution in reinforced concrete members under direct tension and bending, and yet his first assumption is that of a "straight-line distribution of stress." There seems to be some inconsistency between these two statements. Obviously, if the author is attempting to analyze the stress distribution in the section, he should continue to do so instead of assuming it.

Case 1, in which the entire section is under tension, has been very well treated by Messrs. Taylor, Thompson, and Smulski[8] and, therefore, no attempt need be made to carry the discussion further, since it deals with the reinforcement of both faces of the section, which is obviously not the nature of the problem undertaken by the author.

The first true attempt at an analysis is begun by the introduction of Equation (8). Except for a change of sign and slightly different notation, the same equation is presented in one of the standard handbooks in current use.[21] Furthermore, in Equation (12), the author introduces the term, d_t, and, later, d_c, primarily for the purpose of simplifying the matter to follow; but these terms led the author into difficulties which could be overcome only by means of the introduction of a great number of diagrams. As an example, each diagram is dependent upon n and upon $a = \frac{d_c}{d}$. Using four values for n (8, 10, 12, and 15), and at least five values for a (0.1, 0.15, 0.20, 0.25, and 0.30), the total number of diagrams required to solve problems falling within this scope is twenty, which can scarcely be termed simple. Any value of a within the 0.05 interval would have to be interpolated, which would further complicate the problem.

It is apparent that the value, d_c (depth of cover on the steel), as shown in Fig. 2, has no direct bearing on the solution of the problem, because no matter how large d_c becomes, the distribution of stress remains unchanged. For this reason all formulas used for the determination of steel reinforcement in a single face disregard this value of depth of cover.

It appears that the author finally realized the inconvenience of the numerous curves necessary for the solution of these problems and decided to change the lever arm of the force-producing moments, by introducing Equation (22). Taking Equation (23) and solving for p, the expression for bending and tension is expressed as:

$$p = \frac{k^2}{2\,n\,(1-k)} + \frac{T}{f_s\,b\,d} \quad \text{.....................} (55)$$

---

[20] With U. S. Engr. Office, Los Angeles, Calif.

[21] Concrete Engineer's Handbook, by Hool and Johnson, McGraw-Hill Book Co., 1918, p. 403.

An identical equation can be written for bending and compression by changing the sign of the second term to minus; thus:

$$p = \frac{k^2}{2\,n\,(1-k)} - \frac{C}{f_s\,b\,d} \qquad \text{(56)}$$

To obtain the expression for p required for the pure bending moment, the second term is omitted; thus,

$$p = \frac{k^2}{2\,n\,(1-k)} \qquad \text{(57)}$$

Equations (55), (56), and (57) give three very simple expressions for steel percentage in single-face reinforcement. Determine $K = \frac{M}{b\,d^2}$, and from a set of diagrams of pure bending moments[22] (M being the transformed moment taken about the steel), read the value for p for pure bending as expressed by Equation (57). By one simple computation a value for $\frac{T}{f_s\,b\,d}$ is determined. Adding or subtracting this term to, or from, the value of p as found by Equation (57) will give the value of p for bending moment combined with tension or for bending moment combined with compression, respectively. Therefore, for the determination of the value of p in all three cases, the only diagrams required are those for the solution of pure bending. On the other hand, in the author's discussion, four diagrams for each case are required, or twelve in all.

This brief discussion points out the futility of a set of curves such as those suggested in the paper because of the simplicity of the relation existing between the forces, moments, and the steel ratio.

A. Floris,[23] Esq. (by letter).—In this elaborate paper the author derives formulas for the design of reinforced concrete members subjected to direct tension and bending. He states that the problem has received little attention from authors of engineering texts. This statement is rather broad and not quite correct because the subject is fully covered in several books on reinforced concrete. Suffice it to mention the well-known treatises by Moersch[24], Manning[25], and others. Perhaps the author has in mind American textbooks in which the design of reinforced concrete structures under the combined action of direct tension and bending has been somewhat neglected. In addition to closed water conduits such a stress condition exists in tanks, silos, bunkers, etc.

The formulas derived by the author are based on the standard method which involves the ratio of modulus of elasticity of steel to that of concrete—

[22] "Principles of Reinforced Concrete Construction", by F. E. Turneaure, Hon. M. Am. Soc. C. E., and E. R. Maurer, Fourth Edition, John Wiley & Sons, Inc., N. Y., 1932, pp. 414–415.

[23] Dipl.-Ing., Los Angeles, Calif.

[24] "Der Eisenbetonbau, seine Theorie und Anwendung", von E. Moersch, Stuttgart, 1923, Vol. 1, Pt. 1, pp. 454–466.

[25] "Reinforced Concrete Design", by G. P. Manning, Lond., 1924, pp. 54–67.

the well-known n. It is becoming increasingly evident by tests and actual experience, however, that this method of designing reinforced concrete structures is fundamentally erroneous. The reasons are many and varied.

The strength of a member subjected to bending depends on the ultimate strength of steel and concrete and not on the value of n as the standard method appears to convey. Using this ratio in the calculations, the concrete and steel stresses of the structural member near the breaking point are considerably greater than the ultimate strength of the two materials determined separately. By applying the standard method, authorities permit far smaller stresses for concrete than steel in comparison to their ultimate strength. This leads to the absurdity that heavily reinforced members will resist external forces less than poorly reinforced members under the same conditions. This conclusion as to the standard method of designing structures is not backed by experience and tests. The introduction, in the analysis, of a constant or variable n does not improve matters, since it is not in agreement with the experimental evidence. Furthermore, the factor of safety determined by the standard method is not the same for various conditions.

All these facts indicate clearly the desirability of abandoning the present standard method of designing reinforced concrete structures. Attempts to develop methods without using the ratio, n, have been made by Stussi, M. and S. Steuermann, Saliger, Gebauer[26], and Bittner.

David B. Hall,[27] Assoc. M. Am. Soc. C. E. (by letter).—Whenever physical conceptions can be substituted for algebraic operations, understanding of any problem usually becomes clearer. Apparently, Case 1 of this paper, in which the resultant tension on a section falls between two layers of reinforcement, could have been covered completely by treating the two layers of steel as simple beam reactions and calculating the area of steel to furnish these reactions at the allowable working stress. The extreme simplicity of this case results from the fact that it is a statically determinate problem, and, therefore, no question of consistent deformations enters into it. Case 2 may also be a little easier to grasp[28] when viewed apart from its mathematical surroundings, and certain aspects can be treated in somewhat greater detail.

When it is possible to proportion a structure (in this case a concrete section) to resist the loads acting on it, instead of determining the stresses in an existing structure, then, as far as the designer is concerned, the structure ceases to be statically indeterminate. (This principle, incidentally, has many and varied applications; for instance, a two-span continuous truss with a jack placed under one support at the time of erection.) This will be the case in the design of concrete sections. It may be possible to vary the dimensions of the concrete, and it will practically always be possible to vary the area of the reinforcement.

When there is only one layer of steel, and moments are taken about the center of the steel, the moment of the concrete must be equal to the moment

[26] "Das alte n-Verfahren und die neuen n-freien Berechnungsweisen des Eisenbetonbalkens; Kritische Besprechung und Schlussfolgerungen", von Franz Gebauer, *Beton u. Eisen*, January 20, 1936, p. 29.

[27] Asst. Engr., State Dept. of Public Works, Albany, N. Y.

[28] *Engineering News-Record*, July 26, 1928, p. 127.

of all external forces (Equation (20)), and hence the concrete stress can be found either by calculation or from ordinary concrete tables. The unit stress in the steel is proportional to the distance from the neutral axis (Assumption (1) of the paper); and the total stress in the steel is the sum of the compression in the concrete and the external tension, since both these forces tend to push or pull the member apart while the steel tends to pull it together Although, in a sense, the foregoing is only a re-statement of Equations (20) and (21) in words, the fact is that once these principles are understood, the design of sections will actually be found as easy if the analysis stops at this point as if it is carried any further, as exemplified by Fig. 5. The steps, in brief, are as follows: (1) Determine a concrete section to resist the moment about the steel; (2) determine the steel for such a concrete section; and (3) determine also the steel to resist the tension (or compression) on the section, and add to (or subtract from) the steel found by Step (2).

It so happens that it is not always possible to fit the concrete section to the loads. In designing sections at intervals along a beam, many parts will be found to be understressed. On the other hand, in continuous beams with curved bottoms, there is usually an overstressed part near the middle which would receive more moment and would be stressed still more severely if made deeper. Thus, when the depth of the beam is fixed, two distinct cases may arise, depending on whether the moment about the tension steel is less or more than the resisting moment of the concrete in a "balanced section"; that is, one in which the steel and concrete stress are both the maximum allowable. The first case differs little from that in which the concrete as well as the steel can be controlled. It can be solved by means of the author's charts, or directly from the principles underlying Equations (20) and (21).

In connection with the latter method an expedient used by the writer may be found to be helpful: The function least sensitive to the variation of K (defined as $K = \dfrac{M}{b\,d^2} = \dfrac{1}{2}\,f_c\,k\,j$) is j, the fraction of the depth between the steel and the center of compression of the concrete. Since the steel area for moment may be calculated from the relation, $A_s = \dfrac{M}{f_s\,j\,d}$, the writer uses a table of values of $(f_s\,j)$ for the full range from zero moment to the moment for balanced steel. Since $(f_s\,j)$ varies only between 16 000 and 14 000 lb per sq in. (when f_s = 16 000 lb per sq in.) in this entire range, a table with twenty entries is as accurate as a table of steel percentage value containing eight or ten times as many entries, and the preliminary determination of K can be very rough.

The second case (in which the strength of the concrete is the limiting factor and must be aided by shifting the neutral axis, adding compression steel, or more often both) is usually beyond the scope of the author's charts, and needs to be considered in some detail if the paper is to be reasonably complete. Unless there are restrictions on the amount of steel to be placed in either face of the beam, the most desirable solution will be the one which makes the total steel area in the two faces a minimum. Contrary to a wide-

spread belief, this condition is usually not fulfilled by assuming maximum steel stress. Two causes can be mentioned which may make this fact easier to digest: (1) In cases of bending and compression, it can be seen that the use of a high steel stress, thereby crowding the neutral axis (and hence the area of concrete in compression) over to one side, will be inefficient whenever there is considerable direct compression and not much moment on a section; and (2) when a beam is not very deep and the compression steel is close to the neutral axis, this steel cannot be very effective. Its effectiveness, as well as that of the concrete, furthermore, is increased by shifting the neutral axis farther toward the tension side.

In terms of fundamental relations, only one additional operation is necessary in designing for compression steel, after a given position for the neutral axis has been assumed or established. Assumption (1) of the paper together with Hooke's law, establishes the stress in both layers of steel; compressive steel and additional tensile steel are added to provide a couple to care for the difference between the concrete moment and the external moment. With a good comprehensive table, made up for specified values of f_c and n, giving values of k, K, f_s, and p (with k varying by hundredths from the value corresponding to a balanced section up to 0.60 or 0.70), it is not especially difficult to make a few trials and obtain suitable steel areas. Even without such a table the foregoing constants are not very difficult to compute. Instead of by trial, the desired value of k can be found quite expeditiously with the aid of Fig. 11[9], which is self-explanatory.

It will be noted that the three quantities required for its use are all abstract numbers, so that the chart is independent of any particular units of force or distance. For a strict interpretation of Fig. 11 it is necessary to assume that the compression steel displaces no concrete, but the diagram will undoubtedly be found sufficiently accurate by designers who prefer to deduct the concrete (by using $n - 1$ instead of n for the compression steel). The construction of the chart involves considerable algebra, but not much mystery. An equation for the total area of steel can be written in terms of $k, \frac{d_c}{d}, \frac{d}{e'}$, and $\frac{f_c}{K}$, and can be differentiated with respect to k. The resulting derivative contains k and $\frac{d_c}{d}$ in a relatively complicated form, but can be arranged to contain $\frac{d}{e'}$ and $\frac{f_c}{K}$ as simple linear quantities. This is what makes the use of a nomogram possible. Examination of Fig. 11 will verify the statements made earlier concerning the causes for shifting the neutral axis. It will be observed: (1) That the compressive area is greater when there is thrust on a section than when there is tension; and (2) it is greater when the compression steel is deeply buried than when it is near the face.

[9] "Calcul des armatures principales des pieces en béton armé a section rectangulaire sollictée en flexion composée", by Henri Dumontier, *La Tecnique des Travaux*, Vol. IV, No. 2, February, 1928, p. 135.

This chart will not always give usable results. It may sometimes call for steel stress higher than the allowable and, being purely algebraic, it can (and sometimes does) lead to the calculation of a negative area of steel, or less than would nominally be used, in one face or the other.

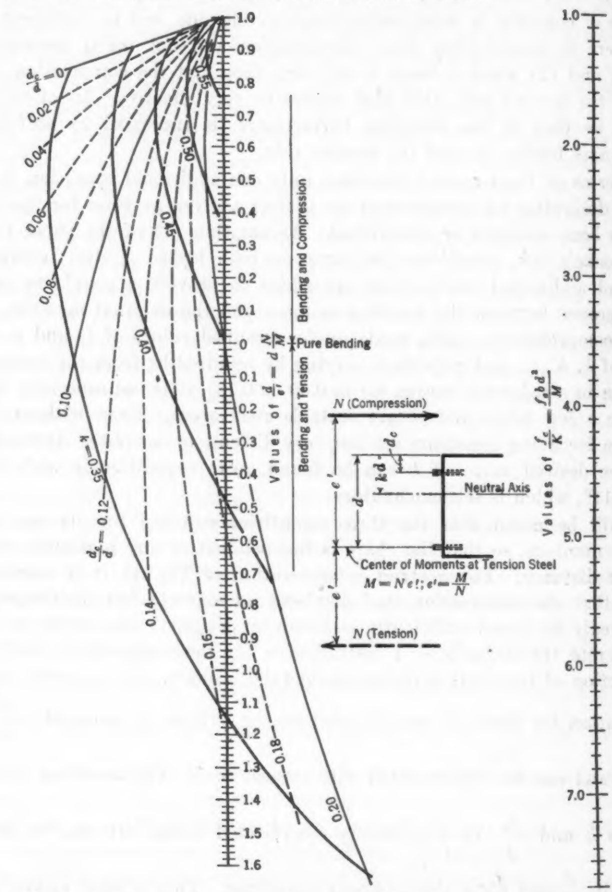

FIG. 11.—POSITION OF NEUTRAL AXIS FOR MINIMUM STEEL AREA. (GIVEN $\frac{f_s}{K}, \frac{d}{e'}, \frac{d_c}{d}$, THE CURVE GIVES k.)

In developing his special type of chart for direct tension and bending, the author has utilized principles which by themselves are as easy to apply as the chart (see Figs. 3 and 5), and which, furthermore, apply equally well to either tension or compression and bending, and may be applied to one important part of the subject of bending and direct stress to which the chart cannot be applied.

ODD ALBERT,[30] ASSOC. M. AM. SOC. C. E. (by letter).—The statements made in this paper are correct, but the author has not treated the complete problem. There are three general cases in which part of the section is in compression; namely: (*a*) Tension steel only; (*b*) tension steel and compression steel; and (*c*) tension steel and compression steel alike.

The author treats only Case (*a*) in which steel is placed in the tension side. This produces a design in which steel acts in tension and concrete in compression, and results in some rather complicated diagrams, which involve eleven operations for each solution. He also states that, should the intersection of the curves fall outside the limits of the chart, a re-design may be necessary.

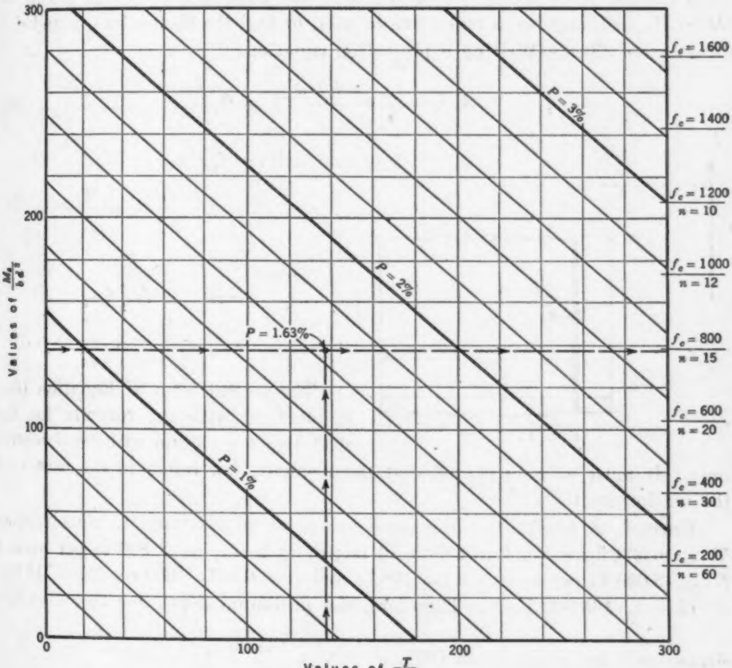

FIG. 12.—COLUMN IN BENDING AND TENSION

The problem can be simplified considerably, and a chart, such as Fig. 12, can be produced with only straight lines, that will take care of all conditions.

Effective Depth.—Referring to Fig. 2 and taking moments about the center of the steel (see Fig. 13):

$$T\left(e - d + \frac{d_t}{2}\right) = \frac{f_c\,b\,d\,k}{2}\left(d - \frac{k\,d}{3}\right) \qquad (58)$$

[30] Faculty Lecturer, Advanced Design of Structures, New York Univ.; Engr., Brick Mfrs. Assoc. of New York, New York, N. Y.

the moment, M_s, with reference to the tension steel is:

$$M_s = T\left(e - d + \frac{d_t}{2}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (59)$$

or, $M_s = 0.5\ b\ d^2\ k\ j\ f_c$. Solving for d:

$$d = \sqrt{\frac{M_s}{K\,b}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (60)$$

Equation (60) is identical with the beam formula for tension steel only. The difference is that the moment, M_s, is taken with reference to the tension steel instead of to the center of the section. Therefore, after the change of M to M_s, ordinary beam tables can be used to find the dimensions, b and d.

Tension Steel.—Writing a projection equation:

$$A_s f_s - T - \frac{b\,k\,d}{2} f_c = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (61)$$

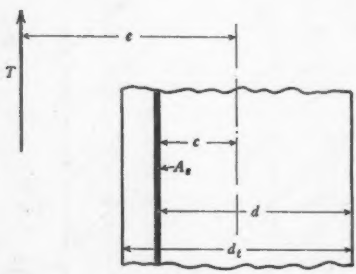

FIG. 13

and, solving for A_s,

$$A_s = \frac{b\,k\,d\,f_c}{2\,f_s} + \frac{T}{f_s} \quad \ldots\ldots (62)$$

Since $\dfrac{b\,k\,d\,f_c}{2\,f_s} = \dfrac{M_s}{f_s\,j\,d}$:

$$A_s = \frac{M_s}{f_s\,j\,d} + \frac{T}{f_s} \quad \ldots\ldots (63)$$

The second term of Equation (63) is identical with the formula for the steel area for a beam with tension steel only. It must be remembered that the moment, M_s, refers to the center of the tension steel.

Example A-1.—Assume the same values as in Example 1, namely, that $T = 16\,530$ lb; $e = 14$ in.; $d = 10$ in.; $d_c = 2$ in.; $f_c = 800$ lb per sq in.; $f_s = 18\,000$ lb per sq in.; $K = 138.7$; and $j = 0.867$: Hence, $M_s = 16\,530 \times 14{-}4 = 165\,300$ in-lb. Therefore, the minimum depth for the allowable stresses will be, by Equation (60): $d = \sqrt{\dfrac{165\,300}{138.7 \times 12}} = 9.93$ in.

The selection of 10 in. will correspond to a somewhat lower concrete stress. The author gives $f_c = 795$. The tension steel will be: $A_s = \dfrac{165\,300}{18\,000 \times 0.867 \times 10} + \dfrac{16\,530}{18\,000} = 1.97$, which is correct, although a little higher than the value obtained by the author.

Plotting the Chart.—Equation (63) indicates that the most economical section is obtained by using the maximum allowable steel stress. Therefore, it is scarcely necessary that variable steel stresses be introduced on a

chart. It is better to begin with the allowable steel stress, and to let the concrete stress vary. From Equation (59):

$$\frac{M_s}{b\,d^2} = \frac{f_c\,k}{2}\left(1 - \frac{k}{3}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(64)$$

Introducing the quantity, $n\,f_c = 12\,000$ (that is, $n = 10$ for $f_c = 1\,200$; $n = 12$ for $f_c = 1\,000$, etc.), Equation (64) yields $k = 0.4$. Hence,

$$\frac{M_s}{b\,d^2} = 0.1733\,f_c \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(65)$$

Also, for $k = 0.4$, $f_s = 18\,000$, and $A_s = p\,b\,d$, Equation (63) yields:

$$18\,000\,p = 0.20\,f_c + \frac{T}{b\,d} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(66)$$

and if f_c is eliminated from Equations (65) and (66):

$$15\,600\,p = \frac{M_s}{b\,d^2} + 0.8667\,\frac{N}{b\,d} \ldots\ldots\ldots\ldots\ldots\ldots(67)$$

Equation (67) gives the relation between p, M_s, and N. It will be noted that this formula represents a straight line, and, therefore, two points only are necessary to determine this line. For example, for $p = 1\%$:

$$156 = \frac{M_s}{b\,d^2} + \frac{26}{30}\,\frac{N}{b\,d} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(68)$$

For $M_s = 0$, $\frac{N}{b\,d} = 180$ in Equation (68); and, for $N = 0$, $\frac{M_s}{b\,d^2} = 156$. These two points connected, establish the line representing $p = 1\%$, etc.

Equation (65) demonstrates that the concrete stress varies in direct relation to the $\frac{M_s}{b\,d^2}$ - values, and, therefore, that they can be plotted on the right side of Fig. 12. These values represent Equation (60) graphically.

Example A-2.—Referring again to the data in Example 1: As before, $M_s = 165\,300$ in-lb, and $\frac{M_s}{b\,d^2} = \frac{165\,300}{12 \times 100} = 137.7$. Similarly, $\frac{N}{b\,d} = \frac{16\,500}{12 \times 10} = 137.7$. The intersections of these two lines (see the broken dotted lines in Fig. 12) give $p = 1.63\%$ and $f_c = 795$, which checks with previous results.

D. B. Gumensky,[21] Assoc. M. Am. Soc. C. E. (by letter).—Many additional data and a further development of the subject were brought to light by those who discussed this paper. With the advancements made recently in the analyses of continuous frames and with the generally increasing scale of construction, particularly of hydraulic structures, the problem of designing reinforced concrete members subjected to combined stress of bending and direct tension is becoming more and more important.

[21] With Metropolitan Water Dist. of Southern California, Los Angeles, Calif.

By taking the moments about the tension steel, the problem can be divided into two distinct steps: (1) Determining the section to resist this moment; and (2) determining the additional steel in the tension face required by the direct tension; in case of direct compression, the additional amount is negative. This fact was demonstrated very ably in different ways by Messrs. Fischer and Wilbur.

Professor Snow takes the matter of design for compressive and tensile reinforcement and presents a complete solution of the problem. In connection with this question the writer would like to call attention to the fact that the seemingly simple solution of his original Case 1 in Fig. 1 may become more complicated when the direct pull is within the section, but still close enough to the tension steel to produce compression in concrete outside the farther steel layer. This situation recently presented itself to the writer in the interpretation of the experimental measurement of a double reinforced member subjected to a combined stress of direct tension and bending. Fig. 14 illustrates this condition which overlaps Case 1.

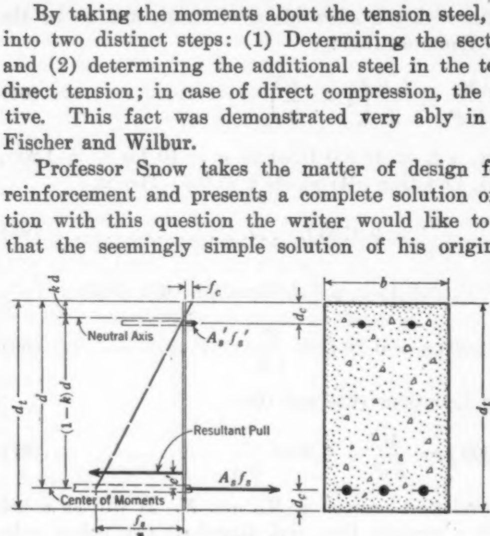

FIG. 14

Mr. Byrne treats the general problem of a direct stress and bending with very gratifying results. Mr. Heilbron, by clever modifications of the original charts and formulas, produces a new chart (Fig. 8) that has the advantage of definite intersections and increased general usefulness, as it can be used for any value of n. In his brief discussion Dean Turneaure contributes toward a clearer understanding of the problem. The "cut-and-try" method of solution mentioned by him seems to be favored by many designers.

The solution and the references presented by Mr. Warrington are of interest and were entirely unknown to the writer. Mr. Larsen should be congratulated on his elaborate and excellent discussion. His Fig. 9, and the charts presented by Mr. Wineland as shown in Fig. 10, should be of great interest to those interested in this broad problem.

The writer wishes to acknowledge his gratitude to Mr. Kovediaeff for his discussion and for his assistance in the preparation of the paper. He also appreciates the discussion by Mr. Floris and sincerely hopes that the comments thus offered will provide a stimulus for further investigations and a better understanding of reinforced concrete problems.

Thinking in terms of the physical action of structures and structural members rather than in mathematical terms, is what the designer strives to do. Mr. Hall recapitulates the problem of combined stresses in its true physical meaning. His discussion illuminates the aspects of the problem not covered by other writers, particularly the solution for a minimum total area of steel in a member reinforced in both faces.

The chart constructed by Mr. Albert possesses the advantage of extreme simplicity in construction and in use. This method and chart give a quick, simple means of designing a new member for a given condition of stresses. In analyzing an existing structural member, one would need to resort to "trial and error", or should have a series of such charts constructed for several unit stresses in steel covering a range, say, from 1 000 lb per sq in. to 25 000 lb per sq in.

Acknowledgments.—In closing, the writer wishes to express his appreciation of the interest displayed by those who commented on his paper. He also wishes to state that the material contained in the discussion represents a valuable contribution to engineering literature, and, in this light, his original presentation now seems justified. The paper had been prepared in connection with the design of hydraulic structures in the Colorado River Aqueduct and was submitted to the University of Southern California in partial fulfillment of requirements for the degree of Master of Science.

TALL BUILDING FRAMES STUDIED BY MEANS OF MECHANICAL MODELS

By Francis P. Witmer[1], M. Am. Soc. C. E., and Harry H. Bonner,[2] Esq.

With Discussion by Messrs. L. C. Maugh, L. J. Mensch, Gilbert Morrison, Fang-Yin Tsai, George E. Large and Samuel T. Carpenter, A. W. Fischer, and Francis P. Witmer and Harry H. Bonner.

Synopsis

A study of tall building bents under the action of transverse forces, by the use of a mechanical model, is contained in this paper. Information is lacking as to the actual effects produced upon vertical reactions and direct stresses in columns from such transverse forces when the bent is varied by changing the relative width of bays, or the relative size of girders or columns in different parts of the frame. Such information can be obtained mathematically only by the application of laborious theoretical methods; but by the aid of a mechanical model results may be found quickly and with reliable accuracy so far as they concern the trend of reactions for assumed variations in design. The only theoretical consideration utilized is the well-known Maxwell reciprocal theorem.

The conclusions drawn from the study are believed to be of interest to engineers who are concerned with the designing of tall buildings and may also have practical value in guiding the design of such structures along lines which are more accurately in accord with true behavior than most of the admittedly approximate methods in common use, and without, at the same time, entailing any unnecessary sacrifice in economy of material.

Note.—Published in January, 1936, *Proceedings*.

[1] Director of Civ. Eng., Univ. of Pennsylvania, Philadelphia, Pa.
[2] Instr. in Mech. Drawing, Frankford High School, Philadelphia, Pa.

Outline of the Study

The study herein described was confined to the determination of the vertical reactions from transverse forces acting upon bents of four and of six columns having small connections of a pure bending type, with no diagonal sway-braces or knee-braces.

Until quite recently the analysis of such a frame under wind action has generally followed one of two theories: (1) The portal theory; and (2) the cantilever theory. Both are based on fundamental assumptions that are not theoretically correct, but either of them results in satisfactory design for structures of ordinary proportions.

By the portal theory as herein understood the wind shear is assumed to be so distributed over the different columns of the bent that the direct compression in any interior column is equal to the direct tension, so that the resultant direct stresses in interior columns are all equal to zero. The direct wind stress is thus confined to the two exterior columns, being compression in the leeward, and tension in the windward, column.

By the cantilever theory as herein understood the wind shear is assumed to be so distributed that the unit direct stress from wind in any column will be in proportion to the distance of that column from the neutral axis of the bent, columns on the leeward side of this axis being in compression and columns on the windward side in tension. This distribution is analogous to the distribution of fiber stresses in a vertical cantilever beam fixed at the bottom.

Various modifications of these two methods have been devised and used with greater or less success. For analysis on a theoretically correct basis, two principal methods have been available: (1) The slope-deflection method; and (2) the method of moment distribution. In this case, again, modifications have been employed, usually in the nature of approximations for the purpose of abbreviating what otherwise would be a lengthy and laborious operation.

In 1930, Henry V. Spurr, M. Am. Soc. C. E., advanced a method of equal deflections[3], recommended specifically for very tall, narrow towers, in which a more correct theoretical basis is desired than is provided with either the portal or the cantilever method, but where the limitations of the slope deflection and the moment distribution methods, both theoretical and practical, render them undesirable, in the judgment of the designing engineer.

This method is based primarily upon the assumption that vertical reactions and direct column stresses from wind are in accordance with the cantilever theory, but with the further condition that sizes of girders and columns must be adjusted so as to render such an assumption justifiable. It is clear that, in general, this relation of stresses and reactions from wind loads will not be developed automatically and that, therefore, some adjustment of sizes will be required in order to produce the relation assumed.

As the time necessary to perform a complete analysis of a tall tower by any theoretically exact method precludes its application to a considerable number of frames of varying proportions, in order to determine convincingly

[3] "Wind Bracing", by Henry V. Spurr, N. Y., McGraw-Hill Book Co., 1930.

the actual trend of reactions and stresses, the plan was conceived of determining vertical reactions by means of a mechanical model of simple and economical construction and, at the same time, capable of ready transformation from one set of proportions to another, so that a maximum number of cases might be considered in a minimum time. The scale ratio of model to prototype was 1 to 60 for 12-in. bents and 1 to 120 for 6-in. bents.

Description and Use of Model

The columns and girders of this model were composed of strips of steel, $\frac{3}{4}$ in. wide and of varying gauge thickness, to produce the desired relative values of moment of inertia. At each intersection the column and the girder were notched half-way across, and the notches mutually fitted together. A gusset-plate connection was simulated by using a wooden block, $\frac{1}{2}$ in. square and 2 in. long, which was notched in two right-angled directions for a depth of $\frac{3}{4}$ in., and forced down upon the joint, one notch receiving the column and and the other the girder so as to hold them firmly out to the edge of the block. The bending was thus confined to the clear length of column or girder between the blocks at two adjacent joints.

In operation, the bases of all columns except one were securely clamped to a table, the model being laid flat and being held clear of the table by two wires suspended from a gallows frame located at a point about three-fourths the distance from the base to the top. A special device was used to prevent rotation at the base of the column that was not clamped down. A micrometer screw was used to move this column longitudinally through a known distance (usually 0.005 in.) and the transverse movement induced at any desired floor was observed by a micrometer microscope. By the familiar Maxwell principle the ratio of the transverse movement to the vertical movement was equal to the vertical reaction produced at the column under observation by a transverse force of unity applied at the floor in question.

Fig. 1 illustrates the construction and use of the model. Obviously, by building up members of one or more properly selected thicknesses of material, any desired relation between values of moment of inertia can be reasonably well obtained.

For each case considered, vertical reactions were found for each column from a load of unity applied at each of several different floors. By varying the relation between moments of inertia, it was possible to find: (*A*) The actual vertical reactions produced with any assumed form of bent and any desired size of members; (*B*) the relative values of moment of inertia in members necessary to produce the cantilever relation of reactions; and (*C*) the relative values of the same function necessary to produce agreement with the portal theory.

The results, while not intended to be exact quantitatively, do show, unmistakably, the qualitative trend of vertical reactions for assumed variations in size of members and proportions of bays and, it is believed, give quantitative results closely enough to justify conclusions as to the relative values of vertical reactions for the various cases.

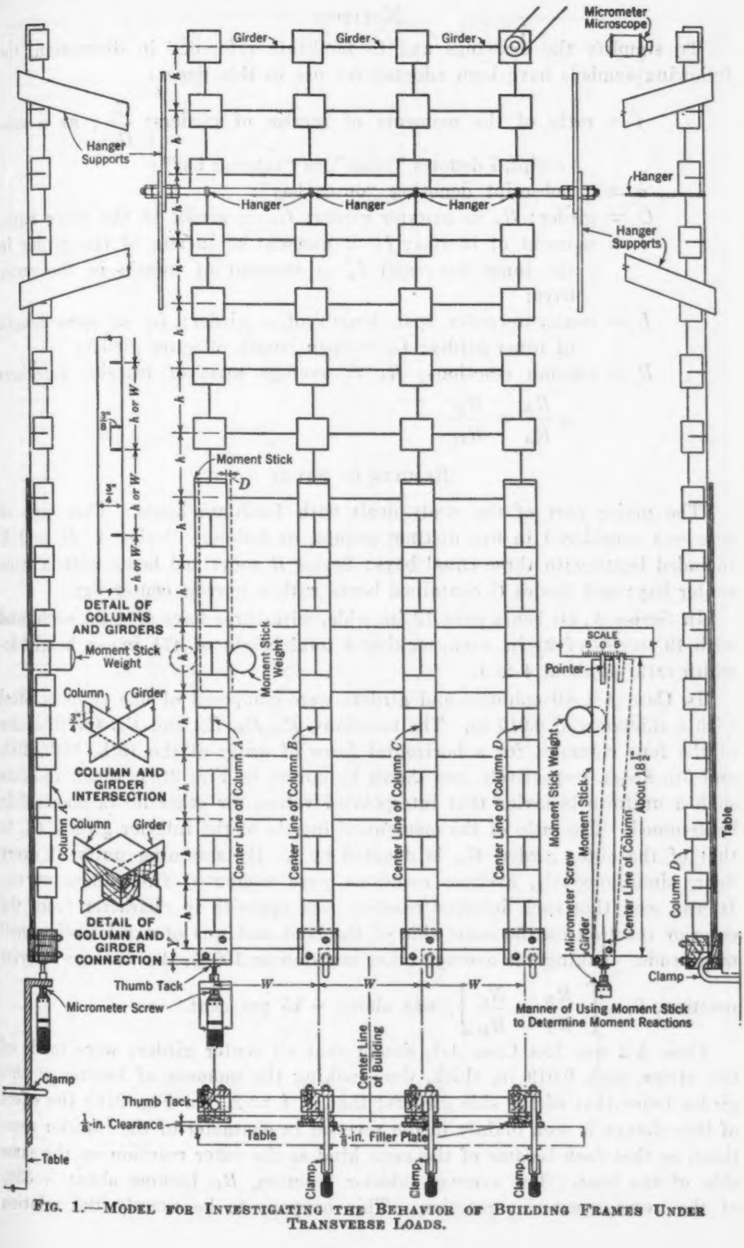

FIG. 1.—MODEL FOR INVESTIGATING THE BEHAVIOR OF BUILDING FRAMES UNDER TRANSVERSE LOADS.

Notation

To simplify the drawings and to facilitate reference in discussion, the following symbols have been adopted for use in this paper:

i = ratio of the moments of inertia of girders: $\frac{G_i}{G_o}$; as a subscript, i denotes "inner", or "interior bay";
o = a subscript denoting "outer bay";
G = girder; G_i = interior girder; G_o = girder in the outer bays;
I = moment of inertia; I_i = moment of inertia of the girder in the inner bay; and I_o = moment of inertia in the outer bays;
L = center-to-center span length of a girder; L_i = span length of inner girder; L_o = span length of outer girder;
R = column reactions; R_i = average ratio of interior reactions $= \frac{R_B}{R_A} = \frac{R_C}{R_D}$.

Results of Study

The major part of the study dealt with 4-column bents. This type of case was considered in five distinct groups, as follows: Series A, D, and E included bents with three equal bays; Series B contained bents with a wide center bay; and Series C contained bents with a narrow center bay.

In Series A, all bents were 12 in. wide, with three bays of 4 in. each, and with 19 stories of $2\frac{1}{2}$ in. each, making a total height of $47\frac{1}{2}$ in.—a height-to-width ratio of about 4 to 1.

In Case A-1 all columns and girders were composed of one strip of steel with a thickness of 0.019 in. The reactions, R_A, R_B, R_C, and R_D, for this case at the four columns, for a horizontal force of unity at the 19th, 15th, 10th and 5th floors, respectively, are shown by curves in Fig. 2(a), which indicate such a uniform behavior that interpolated values for other floors may safely be assumed. The ratio of the moment of inertia of the interior girder, G_i, to that of the outer girder, G_o, is denoted by i. By assuming unity at every floor, simultaneously, average reactions were computed from these curves. It was seen that each interior reaction was opposite in character from the exterior reaction on the same side of the bent and was of a relatively small magnitude. Taking the average outer reaction as 100%, the average interior reaction, $R_i = \left[\frac{R_B}{R_A} = \frac{R_C}{R_D}\right]$, was about -15 per cent.

Case A-2 was like Case A-1, except that all center girders were made of two strips, each 0.019 in. thick, thus making the moment of inertia of this girder twice that of the side girders; that is, $i = 2$. In Fig. 2(b) the effect of this change is seen plainly in the reversal in character of the interior reactions, so that each became of the same kind as the outer reaction on the same side of the bent. The average interior reaction, R_i, became about $+33\%$ of the average exterior reaction. This happens to be exactly the relation

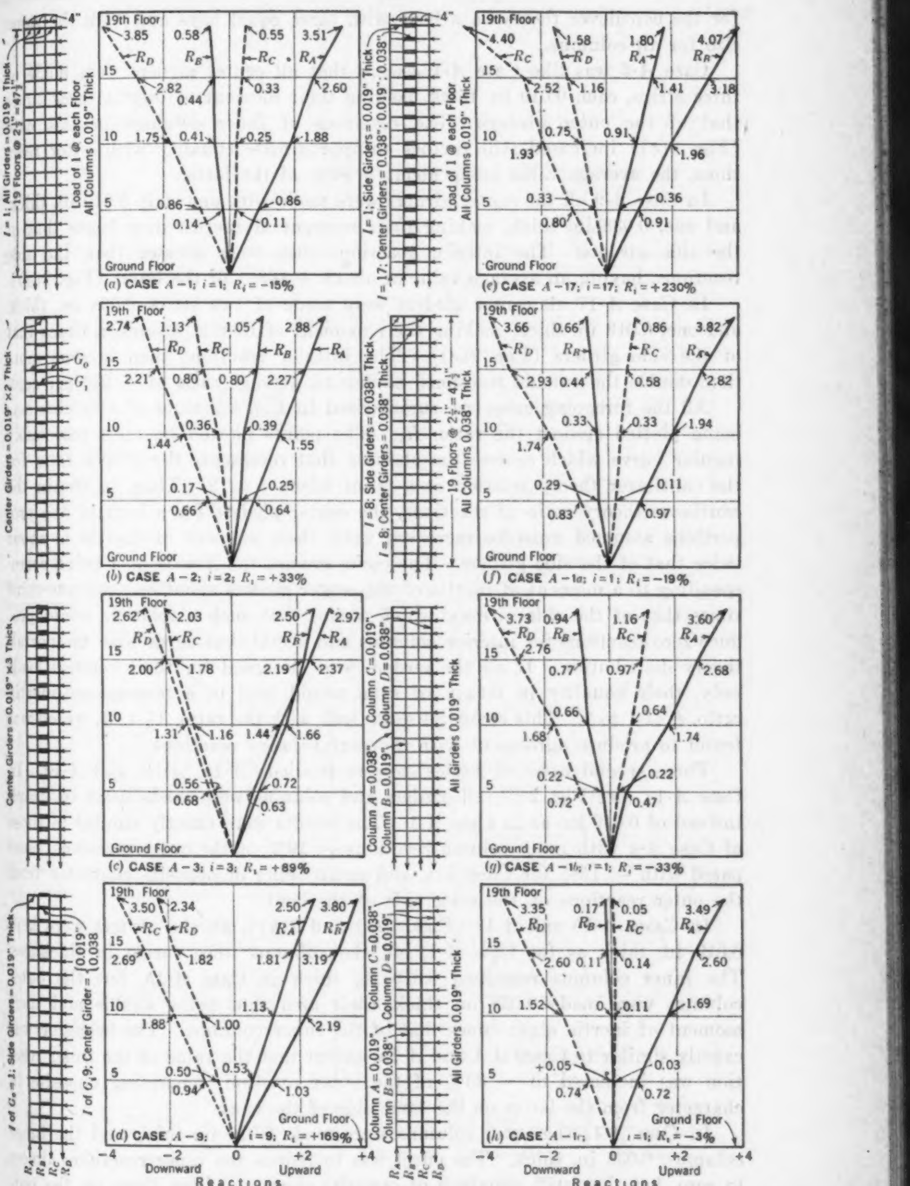

FIG. 2.—REACTION DIAGRAMS, SERIES A.

for the cantilever theory in a bent with three equal bays and with the same size for all columns.

Case *A*-3 was like Case *A*-1, except that all center girders were made of three strips, each 0.019 in. thick, making their moment of inertia three times that of the outer girders. The reactions of inner columns in this case (Fig. 2(*c*)) increased still further to approximate equality with outer reactions, the average value being about + 89% of the latter.

In Case *A*-9 all the center girders were made with one strip 0.019 in. thick, and one, 0.038 in. thick, making their moment of inertia nine times that of the side girders. The interior reactions then were greater than the side reactions, having an average value of about + 169% of the latter (Fig. 2(*d*)).

In Case *A*-17 all center girders were made of two strips 0.038 in. thick, and one, 0.019 in. thick, making their moment of inertia seventeen times that of the side girders (Fig. 2(*e*)). The interior reactions then became more than double the outside reactions, having an average ratio of + 230 per cent.

All the foregoing cases are summarized in Fig. 3, values of i as abscissas being plotted against the ratio, R_i. The points plotted lie on a reasonably regular curve which crosses the abscissa that represents the proper ratio for the cantilever theory relation at a point where $i = 2$. Thus, to obtain the cantilever-theory ratio of reactions, the center girders for a bent of the proportions assumed must be increased until their moment of inertia is about twice that of the side girders. The curve crosses the X-axis at a point corresponding to a moment of inertia of the center girders about one and one-third times that of the side girders, which means that such a relation would produce zero reactions for interior columns and would thus agree with the portal-theory distribution. If all the girders were designed for their vertical loads only, their equality in length of span would lead to a moment of inertia ratio, i, of 1 to 1. This compares quite well with the ratio, $1\frac{1}{3}$ to 1, which was found to produce agreement with the portal-theory reactions.

Three special cases of Series *A* were studied: *A*-1*a*, *A*-1*b*, and *A*-1*c*. In Case *A*-1*a* (see Fig. 2(*f*), all girders and columns were made 0.038 in. think instead of 0.019 in. as in Case *A*-1. The results were exactly similar to those of Case *A*-1 with inner column reactions — 19% of the outer reactions, compared with — 15% for Case *A*-1, and again being of opposite character from the outer reactions on the same side of the bent.

In Cases *A*-1*b* and *A*-1*c* (Figs. (2*g*) and 2(*h*)), all the girders were kept 0.019 in. thick as for Case *A*-1, but the columns were varied in thickness. The inner columns remained 0.019 in. thick in Case *A*-1*b*, but the outer columns were made 0.038 in. thick, their area thus being double and their moment of inertia eight times that of the inner columns. The behavior was exactly similar to Cases *A*-1 and *A*-1*a*, except that the value of the inner reaction was increased to — 33% of the outer reaction, remaining opposite in character from the latter on the same side of the bent.

In Case *A*-1*c* the outer columns were made 0.019 in. thick and the inner columns, 0.038 in. thick. The effect was to reduce the inner reactions almost to zero, but they still remained of opposite character from those on the outside of the bent. This relatively great increase in the size of inner columns

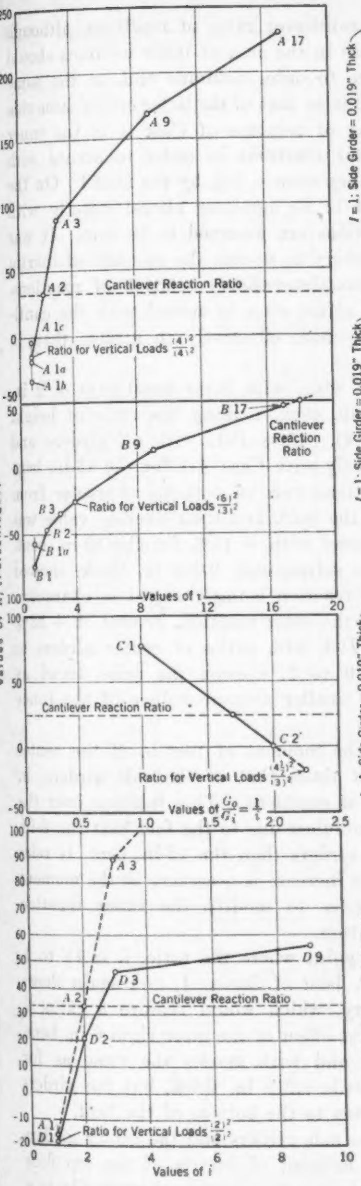

FIG. 3.—SUMMARY, VALUES OF i PLOTTED AGAINST R_t.

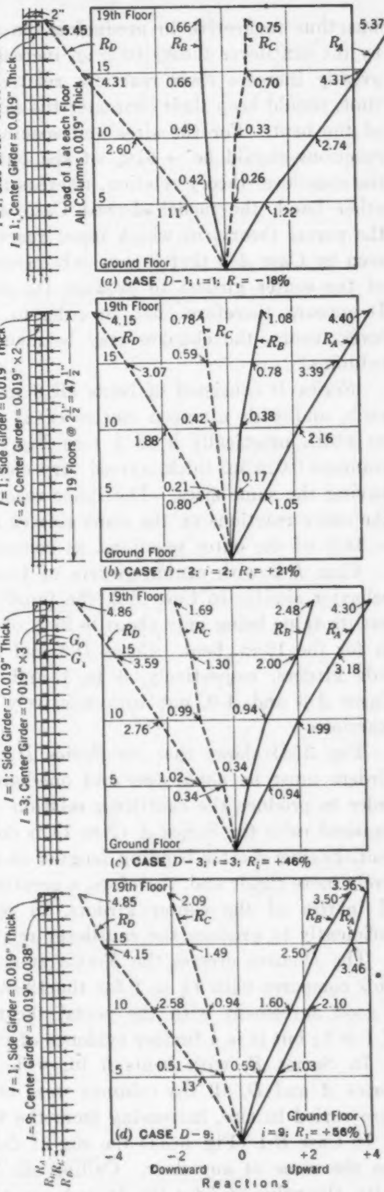

FIG. 4.—REACTION DIAGRAMS, SERIES D.

was thus ineffective in producing the cantilever ratio of reactions, although by the cantilever theory such an increase in the area of inner columns should greatly increase their reactions relative to outer columns and, at the same time, should keep their character the same as that of the latter on the same side of the bent. For the sizes and spacing of columns of Case A-1c the inner reactions should be + 67% of the outer reactions in order to accord with the cantilever-theory relation, whereas they were − 3% by the model. On the other hand, the model showed Case A-1c as agreeing almost exactly with the portal theory, in which inner reactions are assumed to be zero. It was seen by Case A-2 that it was only necessary to double the moment of inertia of the center girders to produce the cantilever-theory relation of reactions. It appears, therefore, that, in order to adjust sizes to accord with the cantilever theory, the changes may be made more effectively in girders than in columns.

Series D consisted of bents all 6 in. wide, with three equal bays of 2 in. each, and with nineteen stories of $2\frac{1}{2}$ in. each, making the ratio of height to width practically 8 to 1 (see Fig. 4). Case D-1, with all girders and columns 0.019 in. thick, agreed very closely with Case A-1 for the 12-in. bent having the same sizes. The inner reactions were of opposite character from the outer reactions on the same side of the bent, and their average value was − 18% of the outer reactions, as compared with − 15% for the 12-in. bent.

Case D-2 with center girders of two strips, each 0.019 in. thick, showed behavior similar to Case A-2, the inner reaction being changed in character, but its value being only about + 21% of the outer reaction, instead of + 33% as for the 12-in. bent. Cases D-3 and D-9, with ratios of center girders to side girders, respectively, 3 to 1 and 9 to 1, showed the same trend as Cases A-3 and A-9, but with relatively smaller average values of the inner reactions.

Fig. 3(d) shows that for Series D the moment of inertia of the center girders must be about two and one-half times that of the side girders, in order to produce the cantilever relation of reactions. This increase over the required ratio for Series A (2 to 1) is doubtless due to the fact that the 6-in. bent, having shorter bending lengths of girders than the 12-in. bent, is relatively more rigid; and, therefore, a greater increase is necessary in the moment of inertia of the center girders, in order to modify the inner reaction sufficiently to produce the cantilever relation.

The D-curve crosses the X-axis at a point where the ratio, i, is $1\frac{1}{2}$ to 1. This compares with $1\frac{1}{3}$ to 1 for the 12-in. bent of Series A, and again shows a good agreement with the portal theory, which would require a ratio, i, of 1 to 1; but it is a further evidence of the effect of the more rigid 6-in. bent.

In Series E, with bents 6 in. wide and with stories the same as for Series A and D, all the columns were made 0.019 in. thick, but the girders were varied in size, increasing from the top to the bottom of the bent.

In Case E-1 (Fig. 5(a)) the size of the side girders and the center girders was the same at any floor. Calling the moment of inertia of the top floor unity, the value of I for the floors below the top floor increased gradually to a relative value of 8.0 at the bottom. The resulting inner column reactions

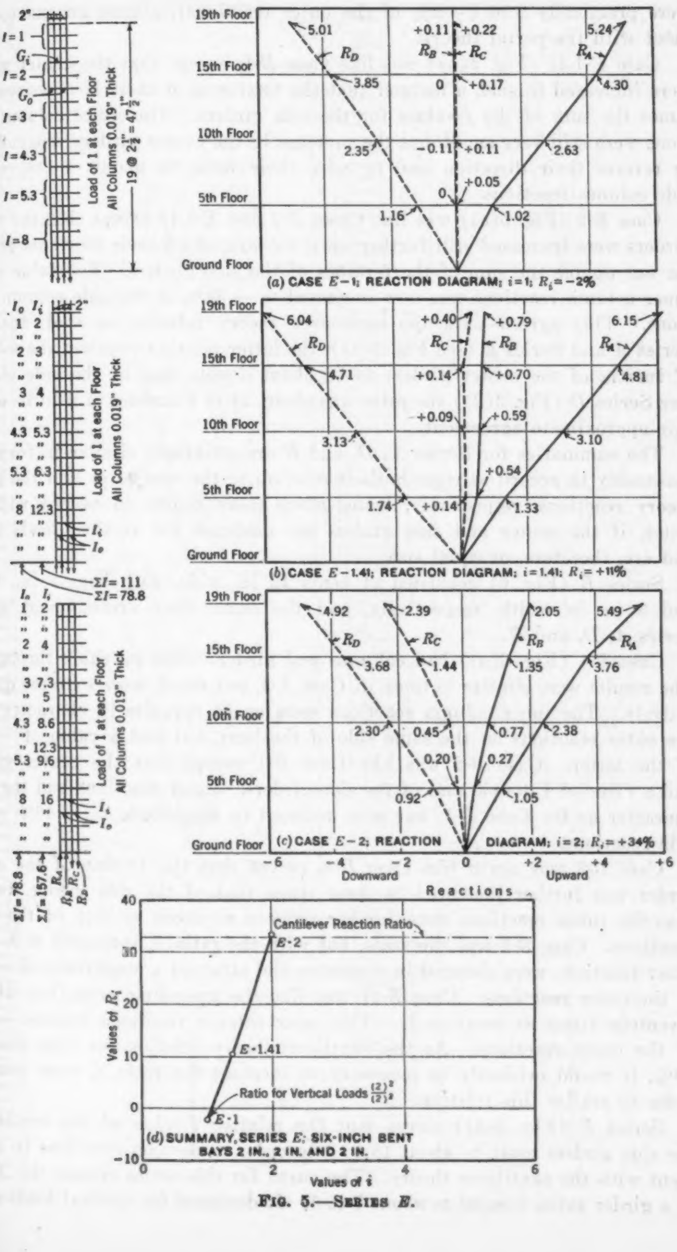

FIG. 5.—SERIES E.

were practically zero (-2% of the outer reactions), almost an exact agreement with the portal theory.

Case E-1.41 (Fig. 5(b)) was like Case E-1, except that the center girders were increased in such a manner that the total sum of their I-values was 1.41 times the sum of the I-values for the side girders. The inner column reactions were still very small, but the increase in the center girders was sufficient to reverse their direction and to raise their value to about $+11\%$ of the side column reactions.

Case E-2 (Fig. 5(c)) was like Cases E-1 and E-1.41 except that the center girders were increased still further until the sum of all their moments of inertia was double the sum of the I-values of the side girders. The value of the inner column reactions was now increased to $+34\%$ of the side column reactions. This agreed with the cantilever theory relation so that, for both Series A and Series E (see Fig. 5(d)), the latter relation required the moment of inertia of the center girders to be about double that of the side girders. For Series D (Fig. 3(d)) the ratio was about $2\frac{1}{2}$ to 1 instead of 2 to 1—a very fair approximate agreement.

The summaries for Series A, D, and E are strikingly similar in form and reasonably in accord as regards their relation to the cantilever and the portal theory reactions, respectively, being much more nearly in accord with the latter, if the center and side girders are designed for vertical loads alone, and are, therefore, of equal size.

Series B (Fig. 6) consisted of bents 12 in. wide, with bays 3 in., 6 in., and 3 in. in width, respectively, and the same story arrangement as for Series A, D, and E.

Case B-1 (Fig. 6(a)) had columns and girders 0.019 in. thick throughout. The results were similar to those of Case A-1, but much more extreme quantitatively. The inner column reactions were again opposite in character from the outer reactions on the same side of the bent, but had a value of -76% of the latter. Case B-2 was like Case B-1 except that the center girders had a value of I double that of the side girders. Inner reactions had the same character as for Case B-1, but were reduced in magnitude to -46% of the side reactions.

Case B-3 was again like Case B-1, except that the I-value of the center girder was further increased to three times that of the side girder. In this case the inner reactions were further reduced to about -33% of the outer reactions. Case B-9 was the same, but with the ratio, i, increased to 9. The inner reactions were changed in character and attained a magnitude of $+13\%$ of the outer reactions. Case B-17 was like the preceding cases, but with I_i seventeen times as great as I_o. The inner column reactions became $+46\%$ of the outer reactions. As the cantilever-theory relation for this case was 50%, it would evidently be necessary to increase the ratio, i, even more, in order to realize this relation.

Series B (Fig. 3(b)) shows that the relative I-value of the center and the side girders must be about 18 to 1 in order to develop reactions in agreement with the cantilever theory. The curve for this series crosses the X-axis at a girder ratio, i, equal to about 7 to 1. If designed for vertical loads alone,

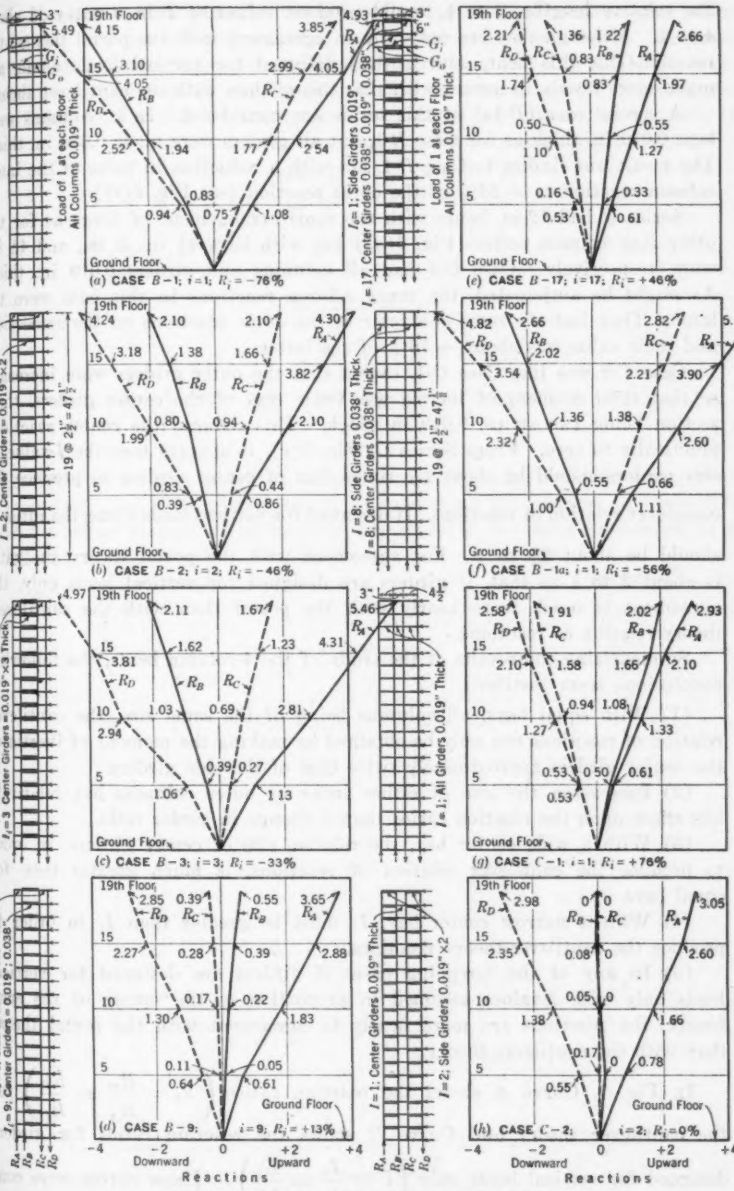

FIG. 6.—REACTION DIAGRAMS; SERIES *B* AND *C*.

the relative lengths, 2 to 1, would produce values of I in a ratio of about 4 to 1. Although they are not quite in agreement with the portal theory, the reactions for this bent, with girders designed for vertical loads alone, are much more nearly in accord with that theory than with the cantilever theory.

A special case (B-1a) of this series was considered. In it, columns were kept 0.019 in. thick as for Case B-1, but all girders were made 0.038 in. thick. The result was similar to Case B-1, but with a reduction in value of the inner column reaction to $-$ 56% of the outer reaction (see Fig. 6(f)).

Series C had 12-in. bents with the same arrangement of floors as for the other four column series (Fig. 6(g)) but with bays $4\frac{1}{2}$ in., 3 in., and $4\frac{1}{2}$ in. wide, respectively. Case C-1 had all columns and girders 0.019 in. thick. As might be anticipated, the inner column reactions in this case were too large. They had the same character as the outer reactions on the same side, and their value was about + 76% of the latter.

Case C-2 was like Case C-1, except that the outer girders were increased so that their moment of inertia was twice that of the center girders, their section being two strips, 0.019 in. thick. This reduced the center reactions practically to zero. From Series C, Fig. 3(c), it appears that the I-value of side girders should be about 1.7 times that of center girders to produce the cantilever relation of reactions. If designed for vertical loads alone, the ratio, $\frac{1}{i}$, should be about $2\frac{1}{4}$ to 1. For agreement with the portal theory the ratio is about 2 to 1 so that, if girders are designed for vertical loads only, the agreement is much more nearly with the portal than with the cantilever-theory relation of reactions.

Summarizing the results of the study of the 4-column bents, the following conclusions seem justified:

(1) With equal bays, all columns being of the same size, the cantilever relation of reactions can only be obtained by making the moment of inertia of the center girders approximately twice that of the side girders.

(2) Increasing the size of either inner or outer columns has relatively less effect upon the reaction ratios than a change in girder ratio.

(3) With a wide center bay, the relative size of center girders, in order to produce the cantilever relation of reactions, is much greater than for equal bays.

(4) With a narrow center bay, I_i must be greater than I_o in order to produce the cantilever-theory reactions.

(5) In any of the foregoing cases if girders are designed for vertical loads only with I-values assumed in proportion to the square of the span length, the reactions are more nearly in agreement with the portal theory than with the cantilever theory.

In Fig. 7, Curve A shows the reaction ratios $\left(R_i = \frac{R_B}{R_A} = \frac{R_C}{R_D}\right)$ for the cantilever theory and Curve B shows the reaction ratios for girders designed for vertical loads only $\left(i = \frac{I_i}{I_o} = \frac{L^2_i}{L^2_o}\right)$. These curves were constructed from Series A, B, and C, as plotted in Fig. 3.

Abscissas are the ratios of inner to outer bay and ordinates are the ratios of inner to outer column reaction, R_i. Apparently, these curves can never intersect. Curve A is necessarily always positive and Curve B is always negative for the cases considered. Hence, for these cases, if girders are designed for vertical loads only, inner reactions will always be opposite in

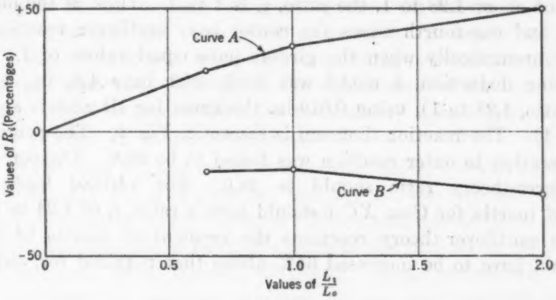

FIG. 7.

character from outer reactions on the same side, and cantilever theory reactions can never be developed except by increasing the moment of inertia, I_i, of the center girders. The increase required for the cases considered, is as follows:

Series	Percentage increase
A	100
B	350
C	33
D	150
E	100

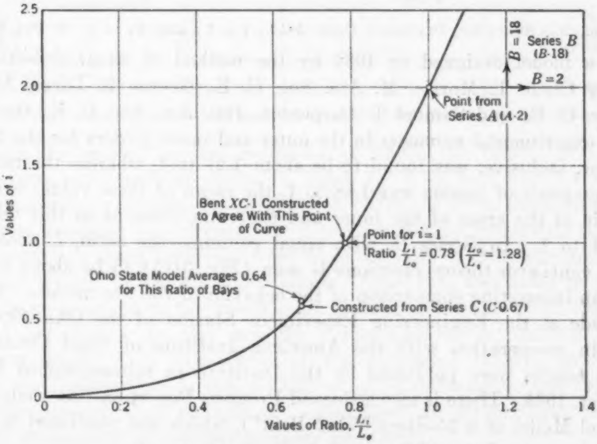

FIG. 8.—CURVE FOR CANTILEVER RATIOS.

It is seen from this tabulation that Series C is naturally most nearly in accord with the cantilever theory.

Fig. 8 shows the ratio, i, necessary to produce cantilever-theory reactions for a varying ratio of bays. It is seen that with a ratio, $\frac{L_o}{L_i}$, of outer bay to inner bay of about 1.28 to 1, the ratio, i, is 1 to 1. Thus, if the outer bay is about one and one-fourth times the center bay, cantilever reactions will be developed automatically when the girders have equal values of I. To verify the foregoing deduction, a model was made with bays $4\frac{5}{16}$ in., $3\frac{3}{8}$ in., and $4\frac{5}{16}$ in. (ratio, 1.28 to 1), using 0.019-in. thickness for all girders and columns (Case XC-1). The reaction diagram is shown in Fig. 9. The percentage, R_i, of inner reaction to outer reaction was found to be 28.8. The percentage for the cantilever-theory ratio should be 28.0. For vertical loads only the moments of inertia for Case XC-1 should have a ratio, i, of 1.64 to 1. Hence, to produce cantilever-theory reactions the moment of inertia of the center girder would have to be increased 64% above that required for vertical loads only.

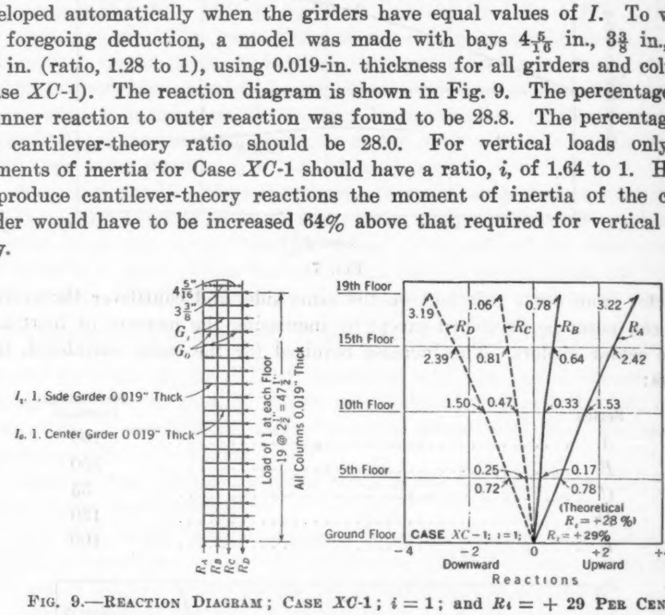

FIG. 9.—REACTION DIAGRAM; CASE XC-1; $i = 1$; and $R_i = +29$ PER CENT.

For a model designed in 1934 by the method of equal deflections and tested by Clyde T. Morris, M. Am. Soc. C. E., George E. Large, Assoc. M. Am. Soc. C. E., and Samuel T. Carpenter, Jun. Am. Soc. C. E., the average ratio of experimental moments in the outer and inner girders for the 3d to the 13th floor, inclusive, was found to be about 1.21 to 1, whereas the ratio, i, of actual moments of inertia was 1.88 to 1, the mean of these values being 1.55. The ratio of the areas of the inner and the outer columns in this test model was 1.14 to 1. In Series C, with equal columns, the ratio, i, necessary to produce cantilever-theory reactions is seen (Fig. 3(c)) to be about 1.68 to 1. This is an interesting comparison of the behavior of the two models. The tests were made at the Engineering Experiment Station of the Ohio State University in co-operation with the American Institute of Steel Construction, and the results were published by the Institute in mimeographed form, in November, 1934. There is also a Second Progress Report on this study ("Tests of a Steel Model of a 55-Story Wind Bent"), which was published in mimeographed form, in June, 1935.

Study of Six-Column Bent

In addition to the foregoing study of 4-column bents, a rather limited study (Series *F*) was also made of 6-column bents.

In 1933, Professor Morris made a study of a 6-column bent in order to elucidate the method of equal deflections. He used a bent with bays of unequal widths, the center bay being wider than the others and these latter being equal. The columns were of different sizes. A height of about nine times the width of bent was used, 80 stories being assumed, and the girders in the different bays were adjusted in the application of the method of equal deflections in order to accord with the preliminary assumption of the cantilever-theory relation of column reactions.

In the model used for the study of 6-column bents, a width of $8\frac{1}{4}$ in., with bays of $1\frac{9}{16}$ in., $1\frac{9}{16}$ in., 2 in., $1\frac{9}{16}$ in., and $1\frac{9}{16}$ in., was assumed, and a height of $71\frac{11}{16}$ in. in 31 stories of $2\frac{5}{16}$ in. each. These proportions simulated those of the aforementioned 6-column bent, except as to the number of stories. Thicknesses of columns, from outside to center, were, respectively, 0.019 in., 0.026 in., and 0.030 in., agreeing as closely as was practical with the columns in the method of equal deflections.

In Case *F*-1 a single strip, 0.019 in. thick, was used for all girders; in Case *F*-2 the thickness of the center girders was increased to two strips of 0.019 in,; and in Case *F*-3 the thickness of the center girders was increased to three strips, 0.019 in. each, and the adjacent girders to two strips, 0.019 in. thick, leaving the outside girders of one strip, 0.019 in. thick. These sizes were reasonably in accord with the sizes in the method of equal deflections.

TABLE 1.—Reaction Ratios for Six-Column Bent (Percentages)

Series *F*, Case:	Side column	Second column	Inner column
F-1	100	+32	−15
F-2	100	+50	+16
F-3	100	+91	+38
Cantilever-theory relation..............	100	+85	+41

Taking the outside column reactions at 100%, the results of the study for the three cases were as shown in Table 1. It is seen that for Case *F*-1 the inner column reactions are reversed in character from those of the other columns on the same side of the bent. For Case *F*-2, by increasing the girders in the center bay these inner reactions were changed in character and reached a value of + 16% of the outside columns. Case *F*-3, was made to simulate, as closely as practicable, the relation of girders and columns in the method of equal deflections. In this case the percentages for all column reactions agree surprisingly well with those of the cantilever theory, which was a fundamental assumption in the method of equal deflections, and thus verify the correctness of that method of adjustment of girder sizes to accord with the assumption of cantilever-theory reactions.

If girders were designed for vertical loads only, with moments of inertia in proportion to the square of the span length, the proportions of I-values for the side girder, second girder, and center girder, respectively, would be as 1:1:1.7. These values lie between the ratios for Cases F-1 and F-2.

By considering Table 1, the probable relation of column reactions for this relation of moments of inertia in the girders would be about as 100% : 40% : 0%. This seems to indicate that, if girders are designed for vertical loads only, the inner column reactions for this 6-column bent will accord very closely with those of the portal theory and will be quite out of agreement with the cantilever theory.

The following general conclusions appear to be warranted by the foregoing study:

(1) The natural tendency of both 4-column and 6-column bents in which girders are designed for vertical loads only is to develop vertical reactions much more nearly in agreement with the portal theory than with the cantilever theory.

(2) In order to make an assumption of the cantilever-theory distribution of vertical reactions justifiable, it will generally be necessary to increase the moments of inertia of certain girders by an appreciable percentage. For 4-column bents with a wide center bay this increase will be in the center girders and may be prohibitive from a standpoint of economy. For bents with equal bays, the center girder will require a moment of inertia approximately double that which would be required for girders designed for vertical loads only. For bents with a narrow center bay, the side girders must be greater than the center girders, but such bents naturally accord more nearly with the cantilever-theory relation than bents of the foregoing types.

(3) If the assumption of cantilever-theory reactions is desired for any reason, a carefully constructed model should furnish, *a priori*, information as to the probable percentage of increase in the I-value of any set of girders in order to develop the assumed relation of reactions.

(4) If a minimum adjustment of girder sizes for wind stress is desired, such a model should furnish a reasonably close relation between the reactions which will actually be developed, and these might be used as the basis of a rational design. This might necessitate assuming that direct stresses in the columns in any story, were in the same proportion as vertical column reactions, but this should not be very far from the truth.

Each column in the foregoing study was always assumed to have the same size from top to bottom. It is not believed that a normal variation in such size, increasing toward the bottom, would greatly vary the general relations discovered and, of course, the sizes of columns in different stories could readily be varied at will in a model of the kind herein described. It is to be remembered that the purpose of the study was to learn trends rather than true quantitative values of reactions for varying proportions of bents. It is thought, however, that, with great care in determining the thicknesses of material to agree with the sizes of an assumed design, and with care in assembling the

model, particularly as regards the tightness of fit of joint blocks, reliable quantitative values may be obtained.

Where the model is made with considerable bending length of girders and is, therefore, relatively flexible, the results are most satisfactory. It is found that for such a case the micrometer screw actuates the columns through the entire distance indicated by the screw, and only the horizontal movement at a floor need be observed with the microscope. If the bent is narrow, with short girders, its greater rigidity may cause a backward movement of the screw where it is clamped so that the actual motion of the column is less than the nominal movement of the screw. In such a case, two microscopes may be used and both the horizontal movement at a floor and the vertical movement of the column observed simultaneously. Their ratio will give the true reaction. It is strongly recommended that models with excessively rigid members be avoided, as liberal a width of bay as practicable being adopted, so that the aforementioned loss will not occur. This will produce results having a maximum degree of reliability.

DISCUSSION

L. C. Maugh,[4] Assoc. M. Am. Soc. C. E. (by letter).—The use of small models in the study of complicated structural frames is undoubtedly a valuable adjunct to the various algebraic methods that are in current use. The results that are recorded must be considered as applying more to the conditions that exist in the usual hypothetical frame than in the actual tall building. From this viewpoint, the writer has made a comparison of the results that were obtained by the authors with those obtained by an approximate method that will be explained briefly in order that the comparison may be more complete.

In most regular building frames in which wind stresses are of any importance, the columns will be more rigid than the girders and will not vary greatly in stiffness from exterior to interior. For this condition, each bent can be considered as composed of a series of vertical Vierendeel trusses in which the columns are the chord members; the exterior columns act with only one truss whereas the interior columns are a part of two trusses. For Vierendeel trusses in which the chord members are approximately of equal rigidity, the writer has shown that the panel is the primary unit of the structure and can be used to provide a convenient method of solution by successive approximations.[5] The importance of the panel as a structural unit was also shown by Professor R. V. Southwell in his studies of stresses in rigid airships.[6]

To illustrate the foregoing, let Fig. 10(*a*) represent a typical building frame of three bays. Panel *abed* will then be a part of the vertical truss, *T*-1, and Panel *bcfe* will be part of Truss *T*-2. In Fig. 10(*b*) Panel *abed* is considered as a rigid frame that is acted upon by a shearing force, V_o, and is restrained by the forces, $\frac{V_o h}{L_o}$, at Joints *d* and *e*. The horizontal displacement of Joints *a* and *b* with respect to Joints *d* and *e* will be equal to,

$$\Delta = \frac{V_o h^3}{24 E}\left(\frac{1 + n_o}{K}\right) \qquad (1)$$

in which n_o equals the ratio of the rigidity of the columns to that of the girder, $\left(n_o = \frac{K_c}{K_o}\right)$, and should be greater than unity to provide the truss action shown; Panel *bcfe* is similarly shown in Fig. 10(*c*) and in the same manner,

$$\Delta = \frac{V_i h^3}{24 E}\left(\frac{1 + n_i}{K}\right) \qquad (2)$$

[4] Asst. Prof. of Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

[5] "Analysis of Vierendeel Trusses by Successive Approximations", by L. C. Maugh, Publications of the International Assoc. of Bridge and Structural Eng., Vol. 3; also, "A Rapid and Concise Method of Analyzing Rigid Viaduct Bents", *Engineering News-Record*, March 14, 1935.

[6] "On the Calculation of Stresses in the Hulls of Rigid Airships", by R. V. Southwell, R and M No. 1057, Aeronautical Research Comm. of Great Britain.

in which V_i equals the shear taken by the panel and n_i equals the ratio of the rigidity of the columns to that of the girders $\left(n_i = \frac{K_c}{K_i}\right)$.

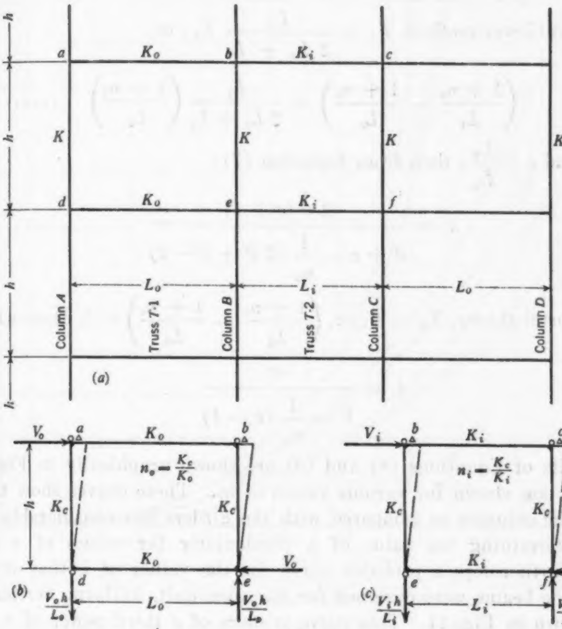

FIG. 10.

Since the value of Δ must be the same for each panel in the story, $V_i\,(1 + n_i) = V_o\,(1 + n_o)$; or,

$$V_i = V_o \left(\frac{1 + n_o}{1 + n_i}\right) \dots\dots\dots\dots\dots\dots\dots (3)$$

and if V is the total shear in the story then, $2\,V_o + V_i = V$, from which,

$$V_o = \frac{1 + n_i}{3 + n_o + 2\,n_i}\,V \dots\dots\dots\dots\dots\dots (4a)$$

and,

$$V_i = \frac{1 + n_o}{3 + n_o + 2\,n_i}\,V \dots\dots\dots\dots\dots\dots (4b)$$

By referring to Fig. 10(*b*) and Fig. 10(*c*) it can be seen that the increment of stress in Column *A* will be,

$$T_A = \frac{V_o\,h}{L_o} = \frac{V\,h}{L_o}\left(\frac{1 + n_i}{3 + n_o + 2\,n_i}\right) \dots\dots\dots\dots\dots (5)$$

and in Column B,

$$T_B = \frac{V_i h}{L_i} - \frac{V_o h}{L_o} = \frac{V h}{3 + n_o + 2 n_i}\left(\frac{1 + n_o}{L_i} - \frac{1 + n_i}{L_o}\right) \ldots\ldots (6)$$

In the cantilever method, $T_B = \dfrac{L_i}{2 L_o + L_i} T_A$; or,

$$\left(\frac{1 + n_o}{L_i} - \frac{1 + n_i}{L_o}\right) = \frac{L_i}{2 L_o + L_i}\left(\frac{1 + n_i}{L_o}\right) \ldots\ldots\ldots\ldots (7)$$

If $i = \dfrac{I_i}{I_o}$ and $c = \dfrac{L_i}{L_o}$, then from Equation (7):

$$i = \frac{2 c^2 (c + 1)}{2 + c - \dfrac{1}{n_o}(2 c^2 + c - 2)} \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

In the portal theory, $T_B = 0$; or, $\left(\dfrac{1 + n_o}{L_i} - \dfrac{1 + n_i}{L_o}\right) = 0$, from which,

$$i = \frac{c^2}{1 - \dfrac{1}{n_o}(c - 1)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

The results of Equations (8) and (9) are shown graphically in Fig. 11 in which curves are shown for various values of n_o. These curves show that the rigidity of the columns as compared with the girders has considerable importance in determining the value of i, particularly for values of c greater than 0.8. Furthermore a probable curve for the values of i, that would be obtained if the beams were designed for the same unit, uniform, vertical load, has been shown in Fig. 11. This curve is more of a third power of c than a second power.

From a study of the relative positions of the curves in Fig. 11 it would seem that the following general statements can be made, most of which corroborate the conclusions of Messrs. Witmer and Bonner:

(1) For values of c less than 0.6, the portal theory will probably be most correct for girders that are designed for vertical loads only, but that small changes in the rigidity of the girders or columns will tend to produce considerable percentage changes in the results.

(2) For values of c between 0.6 and 1.2, the portal theory will be most correct for all rigidity ratios of girders and columns unless the center girders are arbitrarily increased in size.

(3) For values of c greater than 1.2, the cantilever theory will be most correct if the columns are much more rigid than the outer girders; otherwise, neither theory will give great accuracy.

(4) For values of n_o less than 1.5, the rate of change of i with respect to c is too rapid to make a numerical comparison of much use. The reason for this difference in accuracy can be most easily seen by referring to Fig. 12 in which the variation of i with respect to n_o is given for a particular value of c.

From this curve it can be seen that any conclusions that might be made from the portion of the curve for values of n_o less than 1.5 would be very uncertain in view of the practical difficulty of calculating the true value of n_o.

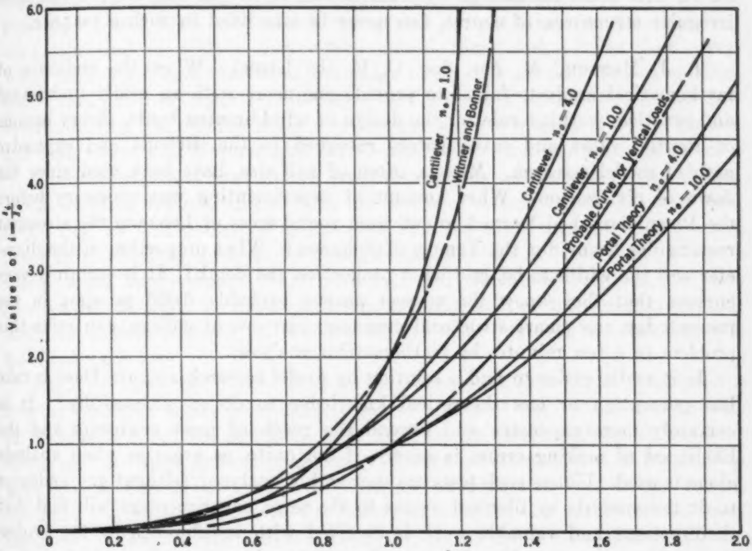

FIG. 11.—RELATION OF SPAN AND MOMENT OF INERTIA OF GIRDERS FOR CANTILEVER AND PARTIAL METHODS OF ANALYSIS.

In conclusion, the writer wishes to make the usual observation that the effect of the direct stress in the columns may modify the final results both for the hypothetical frame and for the model. In this respect a model that is proportioned according to the dimensions of the actual structure will have

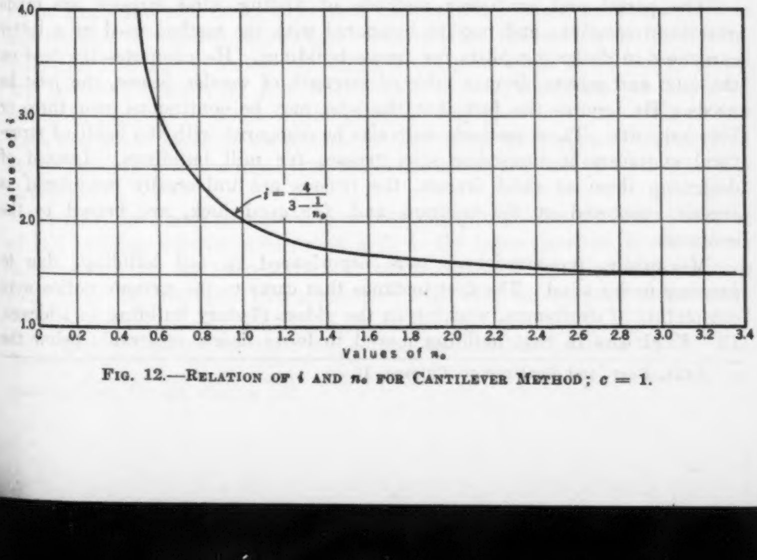

FIG. 12.—RELATION OF i AND n_o FOR CANTILEVER METHOD; $c = 1$.

considerable advantage, but there may be greater disadvantages. There is no general law that any type of structure will inherently follow, except the law of minimum energy, but perhaps certain regular types of structures can be forced into some definite group without undue loss of economy. Special or irregular structures, of course, can never be simplified in such a manner.

L. J. MENSCH,[7] M. AM. SOC. C. E. (by letter).—When the endeavor of mathematical analysts failed to provide engineers with an easily understood and practical working rule for the design of wind-bracing bents, theory became of limited value and investigators returned to the difficult and expensive path of model research. Models, often of full size, have been used since the dawn of civilization. What amount of experimenting was necessary before the Phœnicians had learned to cut from round trees of Lebanon the strongest rectangular beams for the Temple of Solomon? What proportion of the diameter was the width to be, and what proportion the depth? It is certainly very curious that they knew the correct answer probably 3 000 yr ago; in the present day any smart structural engineer, just out of college, can solve this problem in a few minutes by mathematical analysis.

Is it really easier to find a solution by model research alone? Does it take less perception or less theoretical knowledge to do so successfully? It is certainly more expensive and beyond the reach of most engineers and the likelihood of making errors is nearly, if not quite, as great as when analysis alone is used. Unless such tests are thoroughly analyzed, without any endeavor to fit the analysis by illogical means to the tests, experimenters will find that their patient and valuable work is received with indifference by the profession. The reverse holds also true, however; when a mathematical analyst investigates a new problem his endeavors are only of little value to the profession unless he substantiates his findings by careful tests.

The writer proposes to show that the models described in this paper were not as perfect as they should have been, a fact evidently known to the authors, as they wisely stated that their results should be accepted more to indicate trends of the reactions for the relative proportions of columns and girders.

The portal and cantilever methods of finding wind stresses are crude guesses at solutions and may be compared with the method used by a better carpenter in designing joists for frame buildings. He computes the load on the joist and selects, from a table of strength of wooden beams, the joist he needs. He ignores the fact that the joist may be continuous over three or four supports. These methods may also be compared with the habit of structural engineers in designing steel trusses for mill buildings. Instead of designing them as rigid frames, the trusses are universally considered as simply supported at the columns and, for good luck, are braced to the columns.

Meanwhile, inconveniences were experienced in tall buildings due to swaying under wind. The first instance that came to the writer's notice were complaints of draftsmen, working in the oldest 17-story building in Chicago, Ill. Engineers in that building moved to lower floors, preferably below the

[7] Civ. Engr. and Constructor, Chicago, Ill.

tenth. Investigations were made, and the amplitude of the vibrations were found to be of the order of $\frac{1}{16}$ in.; the building was strengthened by knee-braces at some of the columns and vibrations were greatly reduced. In another 16-story building draftsmen could not work on the tenth floor of the building when a high wind was blowing and the partitions in that building were vibrating so visibly that clerks moved their desks many feet away. When high hotel and apartment buildings came into general use, complaints were heard from occupants that they could not sleep on account of window weights hitting the window boxes and because water was spilling out of glasses and wash bowls, and pictures and chandeliers were swinging in a high wind.

It became apparent that a more accurate analysis was needed for the design of tall building frames, and it is to the credit of Albert Smith, M. Am. Soc. C. E., that he first published[8] a practical rule for the design of such frames, based on a laborious analysis by Castigliano's theorem of least work; his rule was a great improvement over the portal and cantilever methods, but was received indifferently by those engineers who did most of the designing of tall building frames, possibly on account of the labor involved in checking the basic calculations.

W. M. Wilson and G. A. Maney, Members, Am. Soc. C. E.[9], analyzed a 20-story building frame by assuming the rotations of the joints as unknowns in the elastic equations and gave their analysis the novel and rather unfortunate name of "slope-deflection theory." Their method and that of Mr. Smith were just as correct as Clapeyron's method of analyzing continuous beams, but were not used as much as the latter, because, in the nature of the case, these methods are too laborious for practical use. Furthermore, Messrs. Wilson and Maney deduced from their research a rule for simplifying the analysis, which is more correct for varying sections and spans than Mr. Smith's simple rule, but still too complicated for most practising engineers. The result of these two most important endeavors was that most engineers used the method of least work, namely, the crude and easily understood portal and cantilever methods.

Although it was long known that longitudinal deformation of the columns under wind, and also under dead load and live load, might produce considerable changes of stress in the girders of tall frames, and was found by Messrs. Wilson and Maney to amount to only a small percentage in a 20-story building, Henry V. Spurr, M. Am. Soc. C. E., in 1930, introduced an improved cantilever method[8] in which the longitudinal deformation of the columns was made the corner stone of his method of computing wind moments, neglecting at the same time other important factors, such as the law of least cost of a structure.

In 1931, the writer undertook to write a paper[10] on deflection and vibrations of tall building frames under wind and, at the same time, to give a simple working rule for the computation of wind stresses which the busy engineer could use. He first faced this problem in 1910 when he designed column sup-

[8] *Journal*, Western Soc. of Engrs., April, 1915.

[10] "Deflections and Vibrations in High Buildings", by L. J. Mensch, *Proceedings*, Am. Concrete Inst., Vol. 28, 1932, p. 387.

ports for high elevated tanks of reinforced concrete without diagonal braces. The frames were, in fact, two column bents of several stories. When computing the deflection and rotations of the joints he noticed that the members far away from a joint had little influence on stresses produced there, and that

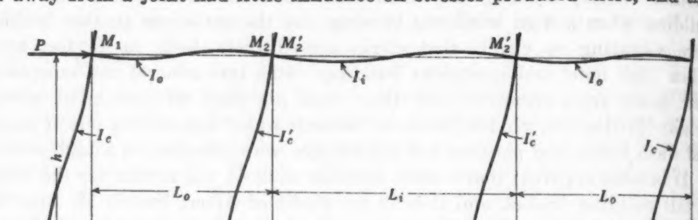

FIG. 13.— $\left(n_o = \frac{I_o}{L_o} + \frac{I_c}{h}\right)$; AND $n_i = \frac{I_o}{L_o} + \frac{I'_c}{h}\Big)$

fairly accurate results could be obtained for bents with any number of spans and stories by the following assumptions:

(1) The point of contraflexure of all columns, except in the lowest story, is in the center of the story height;

(2) Where the values of stiffness of the girders, $\frac{I}{L}$, adjoining an inside column are alike, the wind moments in the girders at each side of the column at the joint are alike;

(3) Where the values of stiffness of the girders adjoining inside columns are not alike, the moments in the girders induced by the deflection of the columns are proportionate to the stiffness of the girders.

For the case shown in Fig. 13, which embraces all cases with four columns treated in the present paper, the writer deduced the formulas in the paper[*] mentioned:

$$X_1 = \frac{P}{4}\left(n_i + \frac{6}{1+N}\right) \div \left(\frac{n_o + n_i}{2} + \frac{6 + 3\,N}{1 + N}\right) \quad \text{(10)}$$

$$X_2 = \frac{P}{2} - X_1 \quad \text{(11)}$$

$$M_1 = X_1\, h \quad \text{(12)}$$

$$M_2 = \frac{X_2\, h}{1 + N} \quad \text{(13)}$$

$$M'_2 = \frac{X_2\, h\, N}{1 + N} \quad \text{(14)}$$

$$R_A = \frac{M_1 + M_2}{L_o} \quad \text{(15)}$$

and,

$$R_A + R_B = \frac{2\,M'_2}{L_t} \quad\text{.......................(16)}$$

in which, in addition to the notation of the main paper and the symbols illustrated in Fig. 13, P = the entire wind load above the middle of any story considered; n = ratio of stiffness between girders and columns; and,

$$N = \frac{L_o\,I_t}{L_t\,I_o} \quad\text{.......................(17)}$$

When all columns are alike and when the values of stiffness of the girders are all alike, Equation (10) reduces to,

$$X_1 = \frac{P}{4}\,\frac{n_o + 3}{n_o + 4.5} \quad\text{.......................(18)}$$

and,

$$M_2 = M'_2 = \frac{X_1\,h}{2} \quad\text{.......................(19)}$$

In the lower part of very tall buildings the stiffness of the columns is often ten times as great as that of the girders, and no great error is made by assuming n_o and n_t as zero in Equations (10) and (18), and Equation (10) becomes,

$$X_1 = \frac{P}{4}\,\frac{2}{2 + N} \quad\text{.......................(20)}$$

which means that the shear and reactions in the columns are mainly dependent on the relative stiffness of the girders.

When it is desired to find the relative stiffness of the girders, which would satisfy Mr. Spurr's idea of proportionate column stress reactions, one can proceed in this case as follows: Substitute Equation (20) in Equation (11),

$$X_2 = \frac{P\,(2 + 2\,N)}{4\,(2 + N)} \quad\text{.......................(21)}$$

substituting Equation (20) in Equation (12), and Equation (21) in Equation (13),

$$M_1 = M_2 = \frac{2\,P\,h}{(2 + N)\,4} \quad\text{.......................(22)}$$

which means that the point of inflection of the girders, where very heavy columns are used, is in the center of the girders. Consequently, Equations (14), (15), and (16) become:

$$M'_2 = \frac{X_2\,h\,N}{1 + N} = \frac{2\,N}{(2 + N)}\,\frac{P\ h}{4} \quad\text{...............(23)}$$

$$R_A = \frac{M_1 + M_2}{L_o} = \frac{4}{(2 + N)}\,\frac{P\ h}{4\ L_o} \quad\text{...............(24)}$$

and,

$$R_A + R_B = \frac{2\,M'_2}{L'_t} = \frac{4\,N}{(2 + N)}\,\frac{P\ h}{4\ L_t} \quad\text{...............(25)}$$

When $L_o = L_i$, $R_A + R_B = N\,R_A$; and,

$$R_B = (N - 1)\,R_A \qquad (26)$$

Mr. Spurr's assumptions of a straight-line deformation of a transverse section of a frame may be expressed mathematically in this case of equal spans by $\frac{R_A}{A_o} \div \frac{R_B}{A_i} = 3$; but, from Equation (26), $\frac{R_A}{R_B} = \frac{1}{N-1}$; and, therefore,

$$N = 1 + \frac{A_i}{3\,A_o} \qquad (27)$$

in which A_o = the cross-section area of the outside column; and A_i = the cross-section area of the inside column. In other words, regardless of the requirements of dead and live load and wind-bending stresses, the section of the central girder must be increased which in most cases invites a waste of materials, especially in the lower part of the frames. The authors' models did not show this relation, as their columns were not much stiffer than the girders.

For young engineers who have done much research in the analysis of wind-bracing bents and who may be still doubtful as to the validity of Equation (10) on account of the writer's Assumptions (2) and (3), the following formula is presented, but is not needed in actual practice:

$$X_1 = \frac{P}{4}\left\{\frac{2 + \frac{n_i}{3} + \frac{2\,n_i\,N}{3}}{2 + \frac{n_o}{6}\left(1 + \frac{I_c}{I'_c}\right) + N\left[1 + \frac{n_o}{3}\left(1 + \frac{I_c}{I'_c}\right)\right]}\right\} \qquad (28)$$

The results of Equation (10) vary only a small percentage from those of Equation (28), whereas Equation (18) will give results that may vary 5% in the lower part of a tall building and as much as 20% at the very top.

Clear spans are the governing factors[10] in the design of building frames and the use of theoretical spans causes the computed stresses to be often 10% to 30% greater than they appear from tests to destruction. When mathematical analysts, using an "exact" theory, start with an assumption which misleads them from 10 to 30% is it to be wondered that practical engineers do not pay much attention to their work? Equations (10), (18), (20), (21), and (28) do not, as a rule, give results that differ greatly whether clear or center-to-center spans are used. The moments in the columns and girders, however, vary greatly because of the shorter lengths of the clear spans, and the deflections and vibrations are also much smaller.

The writer wishes to repeat that he has every reason to believe that his formulas give results as reliable as the continuous beam formulas, provided, of course, that the joints are properly designed. In fact, he measured the deflection and rotation of joints on two model frames of 6-story and 13-story buildings, made of brass rods, soldered at the joints, and found a very good agreement with his analysis; and when his formulas give results that differ

with the tests of the authors, he does not hesitate to state that their models did not have proper joints.

It will be interesting to check Cases A-1, A-2, A-1a, and A-1c of the paper by Equations (10) to (28). For Cases A-1 and A-1a, all columns are alike, all girders are alike, $h = 2\frac{1}{2}$ in., and $L_o = 4$ in. for center-to-center spans and, according to the authors, the clear spans are to be taken as $\frac{1}{2}$ in. less. The ratio, n, is $\frac{2.5}{4} = 0.625$ when theoretical spans are used, and n is $\frac{2}{3.5} = 0.571$ when clear spans are used. In both cases, $N = 1$. From Equation (28), $X_1 = \frac{P}{4} \frac{2 + n}{2 + \frac{n}{3} + 1 + \frac{2n}{3}} = 0.181\ P$ and $0.18\ P$, respectively. Equations (10) and (18) give identical values ($0.177\ P$ and $0.176\ P$, respectively).

Adopting the value of $0.18\,P$ for X_1, $X_2 = \frac{P}{2} - 0.18\,P = 0.32\,P$. From Equation (12), $M_1 = 0.18\,P\,h$ for center-to-center spans and $0.18\,\frac{3.5Ph}{4}$ for clear spans. Furthermore, from Equations (13) and (14), $M_2 = M'_2 = \frac{0.32\,P\,h}{2}$ and $\frac{0.32\,P\,h}{2}\frac{3.5}{4}$, respectively. Equation (15) yields: $R_A = \frac{P\,h \times (0.18 + 0.16)}{3.5} \times \frac{3.5}{4} = 0.85\,P\,h = 0.2125\ P$, and Equation (16), $R_A + R_B = \frac{0.32\ P\ h}{3.5} \times \frac{3.5}{4} = 0.08\ P\,h = 0.08\ P \times 2.5 = 0.200\ P$; or, $R_B = 0.200\ P - 0.2125\ P = -\ 0.0125\ P = -0.0588\ R_A$, against $-0.15\ R_A$ and $-0.19\ R_A$ from Models A-1, and A-1a.

Case A-2 was like Case A-1 except that all center girders were twice as stiff as the outside girders; Hence, $N = 2$, whereas $n_o = 0.571$, as before. From Equations (10) to (16), respectively: $X_1 = \frac{P}{4} \times \frac{0.571 + 2}{0.571 + 4} = 0.1406\ P$; $X_2 = 0.3594\ P$; $M_1 = X_1 h \times \frac{3.5}{4} = 0.1406\ P\ h \times \frac{3.5}{4}$; $M_2 = \frac{X_2 h}{1 + N} \times \frac{3.5}{4} = 0.1198\ P\ h \times \frac{3.5}{4}$; $M'_2 = \frac{X_2 h N}{1 + N} \times \frac{3.5}{4} = 0.2396\ P\ h\ \frac{3.5}{4}$; $R_A = \frac{0.1406 + 0.1198}{3.5} \times P\ h \times \frac{3.5}{4} = 0.163\ P$; $R_A + R_B = \frac{2 \times 0.2396}{3.5} \times P\,h \times \frac{3.5}{4} = 0.299\ P$; and $R_B = 0.299\ P - 0.163\ P = 0.136\ P = 0.835\ R_A$. The model for this case showed that $R_B = 0.33\ R_A$, which is a proof in the writer's mind that the connections in this case were not very effective.

In Case A-1c all girders and outside columns were as in Case A-1 except that the inside columns were twice as thick and their stiffness eight times as great; hence, $n_o = 0.571$; $n_i = \frac{0.571}{8} = 0.0714$; and $N = 1$.

From Equations (10) to (16), respectively: $X_1 = \frac{P}{4} \times \frac{0.571 + 3}{0.321 + 4.5} = 0.1855\ P$; $X_2 = 0.3144\ P$; $M_1 = 0.1855\ P\,h \times \frac{3.5}{4}$; $M_2 = M'_2 = 0.1572\ P\,h \times \frac{3.5}{4}$; $R_A = \frac{0.1855 + 0.1572}{3.5} \times P\ h \times \frac{3.5}{4} = 0.0857\ P\ h$; $R_A + R_B = \frac{2 \times 0.1572}{3.5} \times P\,h \times \frac{3.5}{4} = 0.0786\ P\,h$; and $R_B = 0.0786\ P\,h - 0.0857\ P\,h = -\ 0.0071\ P\ h = -\ 0.0828\ R_A$, which is very close to the result found by the writer for Cases *A*-1 and *A*-1*a*, and, this time, more in agreement with the model test reported in the paper.

From the foregoing examples one may conclude that the authors were correct in their statement that the tests on the models showed the trend of reactions, but their values differed considerably with that obtained by analysis. No answer was given for the reactions for a horizontal load applied at the first-floor level which often varies considerably from the upper floors.

It would have been of great interest if, on one welded model, tests had been made on the period and amplitudes of vibrations and if the amplitudes had been compared with those of a solid bar of the same material having the same period of vibration.

Gilbert Morrison,[11] M. Am. Soc. C. E. (by letter).—Information of much interest to designing engineers, on the subject of lateral forces, on tall building bents, has been presented in this paper. The results of the behavior of the many different combinations of bent structures, under tests shown by the authors, should be of material assistance in predetermining how similar structures are likely to act under lateral forces.

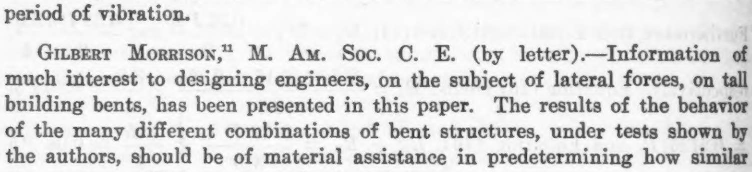

Fig. 14.—Case *M*.

An investigation of the effect of lateral forces on tall buildings was made by the writer in 1933. Although this investigation did not cover as wide a range of bent structures as that reported by the authors, a comparison of the results is of interest. The first bent tested (see Fig. 14) was a four-column

[11] In Chg. of Structural Design, Cooper Union Inst. of Technology, New York, N. Y.

frame with equal, 14-ft bays and eight stories, each 12 ft high, giving a slenderness ratio of 2.3 to 1. The model was made of celluloid, to a scale of 1 in. = 4.0 ft. The apparatus used in the test was a Beggs deformeter. In this bent all girders were of the same size, having a moment of inertia of 1 728. The inner and outer columns of any floor were the same; but were increased in size downward for each two stories. The value of I for columns in the first and second stories was 2 920; for the third and fourth-story columns, $I = 2.835$; for the fifth and sixth-story columns, $I = 1\,728$; and for the seventh and eighth-story columns, $I = 1\,028$. All members of the model were proportioned to the cube root of their moment of inertia and the aforementioned scale. A lateral force of unity was acting at each floor above the first.

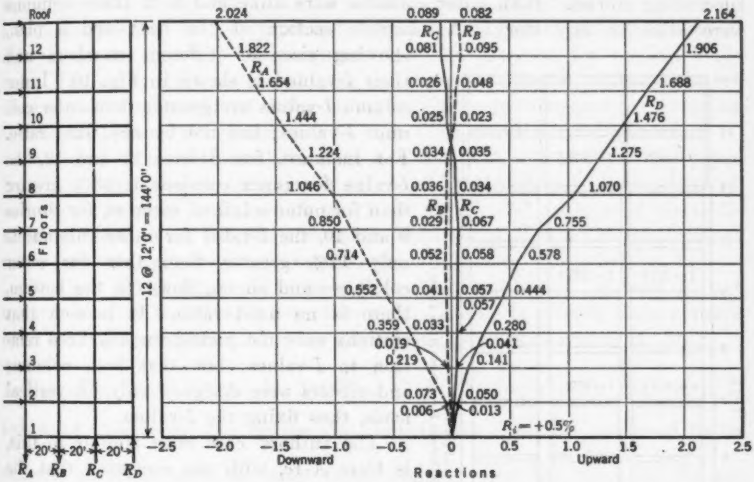

FIG. 15.—CASE N.

In Fig. 14, negative reactions, acting downward, are plotted to the left and positive reactions, acting upward, are plotted to the right. The summation of the abscissas from the top down to any floor, for any column, indicates the value of the vertical reaction for that column, for the unit loads applied at those floors. Hence, the summation of all the abscissas, from top to bottom, gives the value of the vertical reaction for that column, with lateral forces acting at all floors simultaneously, proper care being given to positive and negative signs. This shows that the vertical reaction for Column $A = -8.667$, for Column $B = +0.296$, for Column $C = -0.709$, and for Column $D = +9.087$, indicating an almost exact balance.

In this case, as in that of the paper, it is seen that the interior reaction is opposite in character from the exterior reaction on the same side of the bent, and also of relatively small magnitude, the average interior reaction being approximately − 5% of the exterior reaction. This is less than the − 15% shown for the authors' Case A-1. It should be noted that the only difference

between the bents treated by the authors and the writer, is that in the former all the columns were kept the same size throughout the full height of the structure, whereas, in the latter, the column sizes were changed every two floors.

The results of the second bent tested by the writer (see Fig. 15) was also a four-column frame with equal, 20-ft bays and 12 stories each 12 ft high, giving a slenderness ratio of 2.4 to 1. This model was also made of celluloid, to a scale of 1 in. = 4 ft and tested with the Begg's deformeter. In this case all floor girders were of the same section, being 18-in. I-beams at 55 lb, with $I = 889.9$. However, the roof girders were 16-in. I-beams at 45 lb., with $I = 583.3$. Like Case *M* column sections were changed at each two succeeding stories. Both outer columns were alike and both inner columns were alike in any story. A complete section of the bent and a plan, showing sizes of different members and their *I*-values, is shown in Fig. 16. Inner column *I*-values are greater than outer column *I*-values; but not by any fixed ratio. For instance, for Stories 11 and 12, the *I*-value for inner columns is 33% greater than for outer columns, whereas, for Stories 9 and 10, the *I*-value for inner columns is only 12% greater than that for outer columns—and so on, down to the bottom, there is no fixed ratio. It is seen that sections were not picked for any fixed relation to *I*-values; but that both columns and girders were designed only for vertical loads, thus fixing the *I*-values.

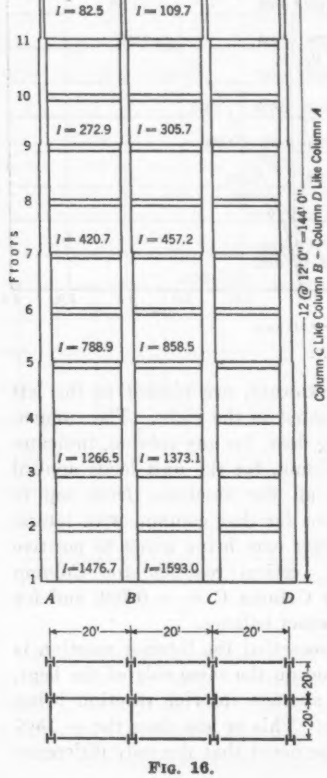

FIG. 16.

The authors' case most similar to this, is Case *A*-1*c*, with the exception that the latter carries the same size of columns for the entire height of the bent and keeps the relation of the *I*-values of the inner columns eight times the *I*-value of the outer columns; the writer's case shows actual sizes in an existing typical building bent. However, a study of Fig. 15, will show that the character of the reactions was the same on each side of the bent, contrary to that shown for Case *A*-1*c*. This test shows an almost exact agreement with the distribution indicated by the portal theory. It should be noted that the reaction for both inner columns changes direction in the ninth story.

The upward and downward reactions in Column *B* balance each other within

0.002, whereas the same items in Column C balance each other within 0.141. It should also be noted that the average interior reaction is + 0.5% of the exterior reaction. The total vertical reactions for Column $A = -11.981$, for Column B, -0.002, for Column C, $+0.141$, and for Column D, $+11.827$, again showing an almost exact balance.

In view of these tests and the tests described in the paper, the writer is in agreement with the authors' statement that, if a structure is designed for vertical loads only, with I-values of girders assumed in proportion to the square of the span length, the reactions are in very close agreement with distribution determined by the portal theory. However, it is believed that a bent designed for vertical loads only, is not a typical frame from which to verify the application of any theory as to the distribution of lateral forces because a bent designed for both vertical and lateral loading, would undergo considerable change in structural requirements over one designed for vertical loads only. The writer does not feel that he would care to support, without reservations, the authors' statement that a normal variation in column sizes, increasing toward the bottom, would not greatly vary the general relations shown.

It should be noted that Cases A-1, A-2, A-3, A-9, and A-17, of the paper (in which I-values of center bays are increased by 2, 3, 9, and 17, respectively) indicate an increase in R_i, which was to be anticipated, because of the additional stiffness given; but the additional increases in R_i are not proportional to the increases in moments of inertia, which is clearly shown in Fig. 3.

In Case E-1.41 it would appear that the reactions, A, B, and C, act upward, whereas Reaction D acts downward. If this is correct, there appears to be about 20% variation between upward and downward reactions.

FANG-YIN TSAI,[12] ASSOC. M. AM. SOC. C. E. (by letter).—In Figs. 3, 5, 7, and 8, of this paper, the curves are plotted with i, or $\frac{L_i}{L_o}$, assumed to be variable as if it were the only factor that governs the value of R_i for the various bents. W. M. Wilson and G. A. Maney, Members, Am. Soc. C. E., have shown[13] that the distribution of moments in columns and girders of a symmetrical 4-column bent depends upon the ratios of the K-values of its members, in addition to the layout and loading. The writer has found that, for bents of the type of the authors' Series A, B, C, and D, the value of R_i depends upon the story number and the following factors:

$$\alpha = \frac{I'_o}{I'_i} \qquad (29)$$

$$\beta = \frac{I'_o}{I_o} \times \frac{L_o}{h} \qquad (30)$$

$$r = \frac{L_i}{L_o} \qquad (31)$$

[12] Prof. of Structural Eng., Dept. of Civ. Eng., National Tsing Hua Univ., Peiping, China.

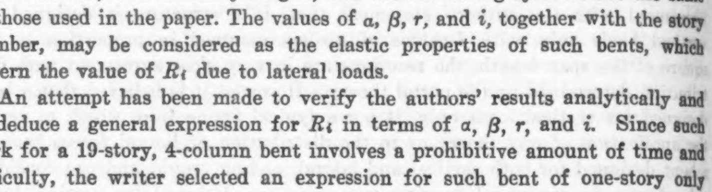
and,

$$i = \frac{I_i}{I_o} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(32)$$

in which I'_o and I'_i are, respectively, the moment of inertia of the outer and inner column; h is the story height; and the remaining symbols are the same as those used in the paper. The values of α, β, r, and i, together with the story number, may be considered as the elastic properties of such bents, which govern the value of R_i due to lateral loads.

An attempt has been made to verify the authors' results analytically and to deduce a general expression for R_i in terms of α, β, r, and i. Since such work for a 19-story, 4-column bent involves a prohibitive amount of time and difficulty, the writer selected an expression for such bent of one-story only (Fig. 17(a)). (He is indebted to several students in his class in Advanced



(a) 1-STORY 4-COLUMN SYMMETRICAL BENT (b) CANTILEVER RELATION OF REACTIONS

FIG. 17

Structural Theory for developing the formula by the slope-deflection method.) The result is as follows:

$$R_i = \frac{2\,i\,(2\,\beta - \alpha + 2)}{r^2(4\,\beta + \alpha + 1) + 3\,\alpha\,r\,i} - 1 \ldots\ldots\ldots\ldots(33)$$

The elastic properties and the authors' values of R_i for the 19-story bents of Series A, B, C, and D, together with the computed values of R_i for one-story bents of the same elastic properties, are given in Table 2, in which it is seen that, with the exception of Case A-1c, all the computed values of R_i are consistently smaller (algebraically) than the corresponding values obtained by the authors. Both sets of the values of R_i are plotted against the values of

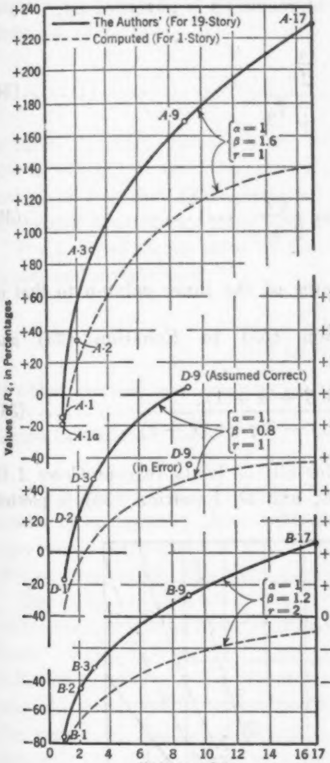

FIG. 18.—RELATION BETWEEN R_i AND i

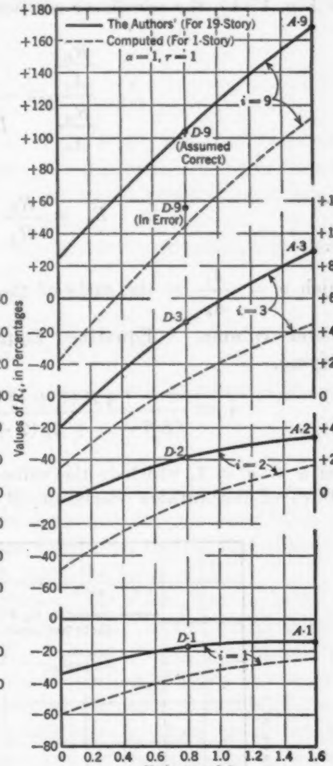

FIG. 19.—RELATION BETWEEN R_i AND β

i for Series A, B, and D in Fig. 18, which is similar to the authors' Fig. 3. It shows, not only the consistency in the trends of the curves and the correctness of the authors' results in general, but also that, with α, β, and r kept constant, the values of R_i increase algebraically as the story number increases for any value of i, and that the larger the value of i, the greater will be the increase in the value of R_i.

Fig. 19 shows the relation between R_i and β, with α, r, and i kept constant, comparing the authors' values for the 19-story bent with those computed for the one-story bent. It is seen that, for this case, the values of R_i increase algebraically as the story number increases for any value of β, and that the larger the value of i, the greater the increase in the value of R_i.

The authors' Fig. 8 shows the relation between i and r for the cantilever relation of R_i, neglecting again the other elastic properties of the bents. From Fig. 17(b), the cantilever relation of reactions is governed by;

$$\frac{\dfrac{R_B}{A_i}}{\dfrac{R_A}{A_o}} = \frac{\dfrac{L_i}{2}}{L_o + \dfrac{L_i}{2}} \quad \text{..................... (34)}$$

or,

$$R_i = \frac{R_B}{R_A} = \frac{q\,r}{2 + r} \quad \text{..................... (35)}$$

in which $q = \dfrac{A_i}{A_o}$ = the ratio of the area of the inner column to that of the outer column. Equating Equation (35) to Equation (33) and simplifying,

$$i = \frac{q\,r^2\,(1 + r)\,(4\,\beta + \alpha + 1)}{(2\,\beta - \alpha + 2)\,(2 + r) - 3\,q\,\alpha\,r\,(1 + r)} \quad \text{........... (36)}$$

Letting $\alpha = q = 1$, which is the value for all the bents (except Cases A-1b and A-1c) of the authors' Series A, B, C, and D, Equation (36) is plotted

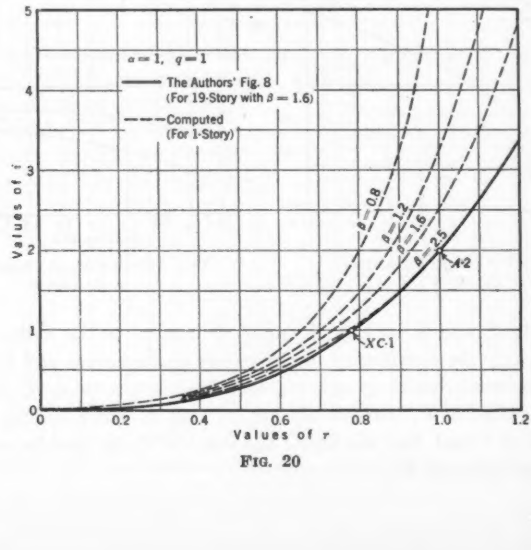

FIG. 20

with $\beta = 0.8$; 1.2; 1.6; and 2.5 in Fig. 20, in which it is seen that the curve with $\beta = 2.5$ coincides practically with the authors' Fig. 8. Fig. 20 also shows that, for a cantilever-theory value of R_t in one-story bents, with $\alpha = q = 1$, i decreases as β increases for any value of r, and that with β kept constant, i increases rapidly as r increases. Assuming the authors' Fig. 8 to be valid for 19-story bents with $\beta = 1.6$, the increase in the story number will have the same effect on i as the increase in β, and the girder length of Case XC–1 should be adjusted to make $\beta = 1.6$. Thus, by Equation (30),

$$\beta = 1.6 = \frac{I'_o}{I_o} \times \frac{L_o}{h} = \frac{I_o}{2.5} \quad \text{.................(37)}$$

in which $I'_o = I_o$. Hence, $L_o = 1.6 \times 2.5 = 4$ in.; and $L_t = i\, L_o = 0.78 \times 4 = 3.12$ in. If the foregoing values were used for L_o and L_t in Case XC–1 instead of $4\frac{5}{16}$ and $3\frac{3}{8}$ in., the value of R_t would probably be much closer to the cantilever-theory ratio than that obtained by the authors.

For a portal-theory value of R_t in one-story bents, equating Equation (33) to zero and simplifying:

$$i = \frac{r^2\,(4\,\beta + \alpha + 1)}{4\,(\beta + 1) - \alpha\,(2 + 3\,r)} \quad \text{.................(38)}$$

In order to avoid any negative value in i, which will be meaningless, α must always be less than $\dfrac{4\,(\beta + 1)}{2 + 3\,r}$.

The purpose of the foregoing discussion is mainly to verify the authors' results by comparing them with those computed for one-story bents of the same elastic properties and also to indicate the trend in the effect of the various factors, particularly the story number, upon the value of R_t.

The authors state that "the purpose of the study was to learn trends rather than true quantitative values of reactions for varying proportions of bents." Inasmuch as the value of R_t depends upon the numerous factors indicated herein, and the layout and the proportion of bents in any practical case will differ widely from those studied in the paper, it is doubtful whether the trends of any actual bent will conform to those presented by the authors. The writer thinks that the real value of the paper lies in introducing a simple and practical method of study, which, when applied carefully to an actual bent, may eventually lead to its proper proportion and design.

The authors use the title, "Reaction Diagram" for their Figs. 2, 4, etc., but the writer thinks that the diagrams will be better understood if the title is changed to read, "Reaction Influence Diagram." In the authors' Fig. 8 there are indicated Cases B–18 and C–0.67, both of which are apparently not described in the paper.

From the trends of the curves in Figs. 18 and 19, the writer concludes that the authors' value of R_t for Case D–9 is inaccurate, possibly due to the

great inflexibility of the center girders of the bent. This is also indicated by the great asymmetry of the authors' Fig. 4(*d*). Hence, the curve is plotted according to an assumed correct value of R_i for Case *D*–9.

GEORGE E. LARGE,[14] ASSOC. M. AM. SOC. C. E., AND SAMUEL T. CARPENTER,[15] JUN. AM. SOC. C. E. (by letter).—Much painstaking work is represented in the long series of tests on wind-bent models described in this paper. Although the writers cannot agree that all the conclusions of the study have general application to modern wind-bent design, they believe that this paper may be the means of defining the fields of at least two well-known methods of design with which they have experimented since 1933.

The Spurr adaptation[16] of the Cross moment distribution method has been used, as in Fig. 21, to verify the authors' experimental results. The regularity of the model framing will throw the contraflexure points at mid-story of the columns, as assumed in checking, except in a few of the lower stories where, because of the fixed column bases, the points of contraflexure will be

above the half-story level, and, in some cases, absent entirely. Nevertheless, the ratio of girder shears across a floor will be substantially the same throughout all stories, as will be the ratio of column reactions, R_i, which is the crux of the argument.

To compensate for the vertical displacement of girder ends due to floor-joint rotation, Mr. Spurr uses a reduced length for girder bending equal to

[16] "Wind Bracing of Steel Buildings." Second Progress Rept. of Sub-Committee No. 31, Committee on Steel of the Structural Division, Discussion by H. V. Spurr, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., August, 1932, p. 1133, and Fig. 26.

$\sqrt{\frac{F^2}{F+D}}$ in which F is the distance face to face of columns, and D is the depth of column section. For a 4-in. model span it is $\sqrt{\frac{(3.5)^2}{3.5+0.5}} = 3.28$ in.[17] In computing the stiffness, $\frac{I}{L}$, of the members, the center-to-center lengths of columns and the foregoing "Spurr lengths" of girders were utilized, since their use has theoretical foundation and, ordinarily, gave results nearer to experimental values both on the authors' models and on those studied by the writers.

Columns (2) and (3), Table 3, show a comparison of the principal experimental and calculated results. The upper group of three cases check very closely, indicating the correctness of the calculation method as well. Serious discrepancies occur in the next group of four cases. Some extreme cases of panel-to-panel girder proportioning exist in this group, and it seems very likely that the connection blocks were inadequate for holding the very stiff girders then used, causing experimental error. It is the writers' experience that one cannot make a theoretically rigid connection, as assumed in the calculation methods, except by developing tremendous frictional forces or by making an integral connection. Perhaps the authors, thinking of practical wind connections, did not desire complete rigidity. Nevertheless, the connections are variables which obscure the picture of girder performance.

The principal comments which the writers wish to make are as follows:

(*a*) In constructing models of tall building bents, the stiffness of the column system relative to the girder system must be reproduced faithfully, since their ratio has tremendous effect upon the distribution of girder shears and column reactions across a bent.

(*b*) The model columns in the authors' tests were so flexible relative to the model girders that most of the models did not represent practical wind bents. The experimental data, therefore, were not sound bases for drawing general conclusions in regard to the distribution of column reactions.

(*c*) A distinction should be made between wind bents upon the basis of slenderness. Design methods and assumptions which are good enough for 20-story bents can be actually dangerous when applied to a 60-story bent of the same base width.

(*d*) For a fair comparison[18] of the several methods of assigning girder shears and column "chord pulls", with economy in view, one must contemplate designs having the same calculated total lateral deflection, including that due to lengthening and shortening of columns.

[17] "Tests and Design of Steel Wind Bents for Tall Buildings," by George E. Large, Assoc. M. Am. Soc. C. E., Samuel T. Carpenter, Jun. Am. Soc. C. E. and Clyde T. Morris, M. Am. Soc. C. E., *Bulletin No. 93*, Appendix, Eng. Experiment Station, Ohio State Univ., Columbus, Ohio.

[18] "Wind Stresses and the Tall Building," by Samuel T. Carpenter, Jun. Am. Soc. C. E., presented at the meeting of the Philadelphia Section of the Society, April 15, 1936. (Not published.)

(*e*) Girder systems selected for strength only, without regard for stiffness, permit too much flexibility in a modern slender tower.

Fig. 21 is submitted in support of Item (*a*). The moment-distribution solution shown in Fig. 21(*a*) verifies the portal performance of Model *C*-2, as given in Table 3. When the columns were made eleven times as stiff, as in Fig. 21(*b*), the model dimensions conformed with the lower story of the

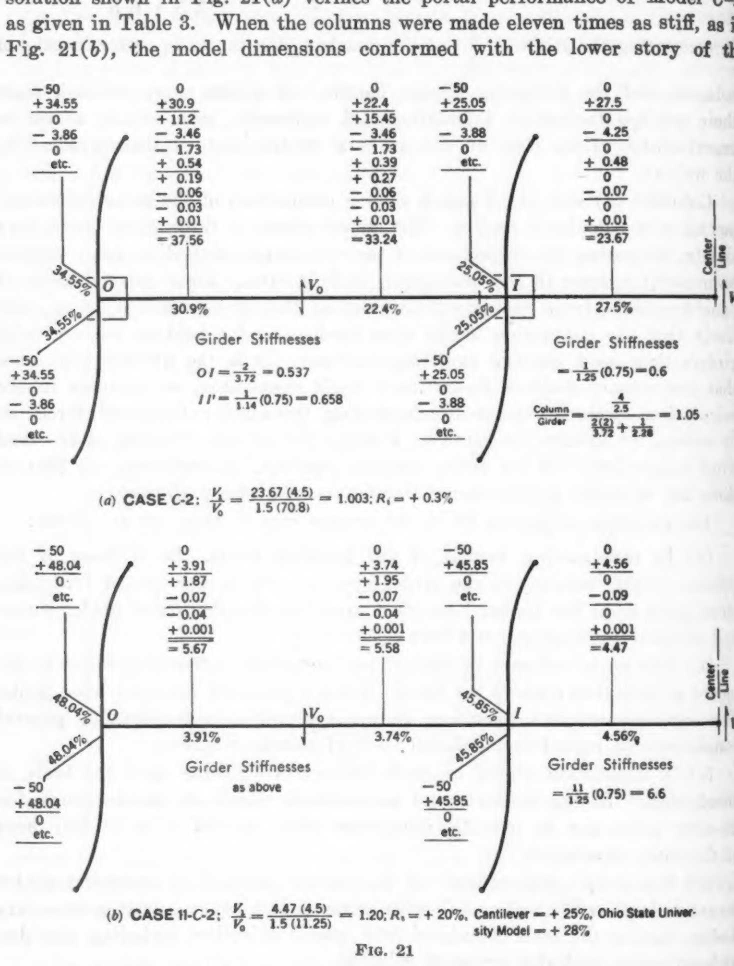

FIG. 21

writers' model, and the solution approximated the cantilever performance of that model.

Fig. 22 shows some actual wind-bent designs. Note how widely the $\frac{\text{column}}{\text{girder}}$-stiffness ratio may vary. This ratio is found by dividing the sum

of the $\frac{I}{L}$ - values of the four columns by the sum of the $\frac{I}{L}$ - values of the three girders, the lower stories being of most interest in wind design. Most of the stiffness ratios of the authors' model bents shown in Table 3 fall outside the design range of Fig. 22.

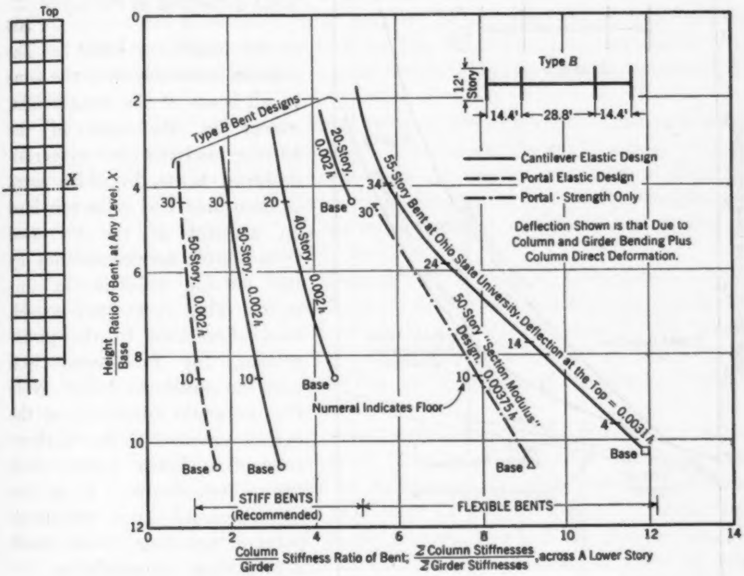

FIG. 22.

From Table 3, the authors' Case B–9 had approximately a portal performance. However, upon increasing the stiffness of the columns in Model B–9 five times, it conformed closely with the lower story of the 50-story cantilever design, in which the $\frac{\text{column}}{\text{girder}}$ - stiffness ratio is 3.16, and had a cantilever performance. It is designated as Case 5–B–9 in Table 3. (The increased size of the inside columns of the practical designs prevents perfect checks.)

Similarly, by increasing the columns of (portal) Case B–9 eight times, the cantilever performance of the 20-story cantilever design can be verified approximately. Obviously, column stiffnesses have considerable to do with performance.

Fig. 23 is a summary of the design of several bents of varying $\frac{\text{height}}{\text{base}}$ - ratios. The spans taken were chosen because they are generally con-

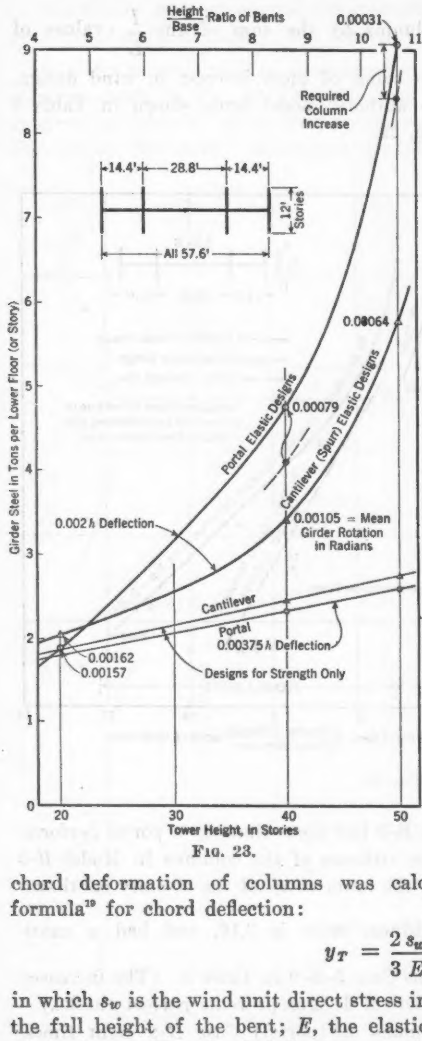

Fig. 23.

sidered favorable to the portal method. Both cantilever and portal designs were made for each height. All the bents represented by the two upper curves were designed to have a total deflection at the top of $\frac{1}{500}$ of the height, or 0.002 h. The column selections were the same in all bents of the same height, except in the case of the 40-story and the 50-story portal designed bents, in which extra column area had to be provided on account of the increased "wind-pull", carried entirely by the outside columns in this case. This extra was considered chargeable to the girder system, for fair comparison with the cantilever design. Note the economic advantage of the cantilever method for shallow-connection bents higher than twenty-five stories. It is also most desirable from the standpoint of avoiding column chord deformation accumulation.

These girders were designed as follows: With columns set, the portion of the entire 0.002 h deflection which was due to chord deformation of columns was calculated quickly by the following formula[19] for chord deflection:

$$y_T = \frac{2\, s_w\, h^2}{3\, E\, B} \quad \text{.........................(39)}$$

in which s_w is the wind unit direct stress in the outside basement column; h is the full height of the bent; E, the elastic modulus; and B, the base width of the bent. The chord deflection was deducted from 0.002 h to find how much deflection was to be contributed by the bending of girders and columns, and girders were selected on the basis of required moment of inertia by the formula:

$$I_G = \frac{V\, b^2}{3\, E\, \theta} \quad \text{.........................(40)}$$

[19] For derivation of Equations (39) and (40) see *Bulletin No. 93*, Eng. Experiment Station, Ohio State Univ., Columbus, Ohio.

in which V is the assigned girder shear; b is the half-length of the girder; and θ equals the remaining deflection assignable to girders, divided by h, equals the joint rotation angle.

The point to be emphasized is that the chord deflection of the portal design was greater than that of the corresponding cantilever design, which meant that the girders designed by the portal method had to have smaller angular deformations, θ, at their ends if the bents were to have the same total deflection, and had to be stiffer and (usually) heavier than the girders designed by the cantilever method, as shown in Fig. 23. The small numerals near each curve point show in each case the required girder rotation angle, θ, in radians.

The two straight lines near the bottom of the graph show girders selected on the basis of section modulus solely to meet allowable stress, without regard for stiffness as defined by moment of inertia. As seen in Figs. 22 and 23 such a 50-story portal girder design has about one-half the weight, but almost twice the deflection, of the corresponding cantilever elastic design. What priced wind-bracing will you have?

In its 1933 report[20], the Wind-Bracing Sub-Committee, Committee on Steel of the Structural Division of the Society, recognized that limiting the design deflection to 0.002 h has produced satisfactory results[21] in very slender towers, and suggested that fully twice that value may be allowable in less extreme bents. This is rather evident from Fig. 23 if one compares bents of heights to base ratios of 10 and 4, respectively.

It has been found by a moment-distribution check that the 50-story portal design for strength only has reversed interior column reactions due to the disregard of elastic requirements in designing. On this account the chord deflection of this bent had to be calculated by a more general formula than Equation (39), and was found to be 0.00185 h, which is greater than in the portal elastic design where it was 0.00163 h. In order to have the bent under consideration deflect only 0.002 h for fair comparison with the elastic designs, the girder contribution would have to be reduced to about 0.00009 h, since the columns will contribute about 0.00006 h. This would require ridiculously large girders, twenty times as stiff, and at least five times as heavy, as those represented in Fig. 23, exceeding even the portal elastic design in weight.

Allowable values for deflection should be established as in the case of stress in order to insure against the application of 20-story methods to 50-story towers. Deflection data from the authors' models would be enlightening.

A. W. Fischer,[22] Esq. (by letter).—A considerable mass of experimental data as to the values of the vertical reactions of the columns at the first story of three-bay structures with equal vertical heights, is presented in this paper,

[20] "Wind Bracing in Steel Buildings," Third Progress Rept. of Sub-Committee No. 31, Committee on Steel of the Structural Division on Wind-Bracing for Steel Buildings, *Proceedings*, Am. Soc. C. E., December, 1933, p. 1614.

[21] The Ohio State University experimental bent was designed to have 50% greater deflection in order to facilitate the detection of joint rotations (θ). (See Fig. 22.)

[22] Care, Pennsylvania Sugar Co., Philadelphia, Pa.

and the authors' results seem to agree very well with those obtained by mathematical analysis. Additional experiments should be made, however, to determine the ratio of the vertical reactions at other stories (especially at the top story) before a general conclusion can be made. The authors' state that for equal bays (all columns being of the same size), the cantilever relation can be obtained by making the moment of inertia of the center girder approximately twice that of the side girders, or that if the moment of inertia of the center girders was about one and one-third times that of the side girders, zero reaction would result for interior columns and would thus agree with the portal-theory distribution.

The writer applied the slope deflection method to a two-story structure with sizes of girders and columns as given for the authors' Case *A*-1 and with a horizontal unit load of 1 lb applied at the top of the second story. In this manner it was found that $R_A = +\ 0.2976$ lb and $R_B = -\ 0.05065$ lb, which makes R_t for the first story equal to $-\ 17\%$, and this value agrees fairly well with the results reported in the paper. If more stories had been used the results would be changed somewhat, but still the value of R_A would have an opposite sign from R_B. For the second story, $R_t = -\ 21$ per cent.

The writer also applied the slope deflection method to a two-story structure with the sizes of girders and columns as given for Case *A*-17 and with a horizontal unit load of 1 lb applied at the top of the second story. For the first story, $R_A = +\ 0.14985$ lb, and $R_B = +\ 0.43935$ lb, which makes R_t for the first story equal to $+\ 293$ per cent. This result does not agree so well with that of the paper. If more stories had been used, no doubt the results would change somewhat, but still the values of R_A and R_B would be of the same sign, as the authors' experiments show. For the second story, $R_t = +\ 243$ per cent.

With the so-called exact methods of analysis the sizes of the girders and columns must be known before the analysis can be started, especially in the case of the slope deflection method and the Cross method, and, therefore, the methods are rather tedious for the design of a new structure.

In his analysis of a three-span structure (equal spans) by relative deflections, Professor H. Yu[23] assumes that the ratio of the columns to the girders is 1.5, the story height being equal to 1.0 and the span length to $\frac{4}{3}$. For a new design, three bays wide and with equal story heights, Professor Yu's method is very flexible because, with the span and story height given, the ratio of the moment of inertia of the columns to that of the girders (the moment of inertia is the same for the columns in each story, but for different stories it will be different) can be selected so as to fit approximately the relation assumed by Professor Yu in deriving his general equations. This assumed relation cannot be adhered to exactly, but if the sizes of the girders at each floor are increased gradually from the top of the structure to the bottom, the final results will agree very closely with any of the results obtained by the so-called exact methods.

[23] "Wind Stresses in Tall Buildings in Stresses in Statically Indeterminate Structures", by H. Yu, National Wuhan Univ., Wuchang, Hupeh, China, Second Edition, 1935, pp. 70 to 84.

Case A-1 of the paper agrees very closely with the conditions assumed by Professor Yu. If the moment of inertia of the girders were 1.25 times that of the columns, the size of members, the story heights, and the span lengths will agree with these assumed conditions.

Applying the general equations introduced by Professor Yu to the fifth story of a 19-story structure of three equal bays with a unit horizontal load at each floor, the value of R_A for the fifth story is equal to $-$ 29.1579 lb and R_B is equal to + 2.945 lb, which makes R_t for the fifth story equal to $-$10.10% and this result agrees very closely with the experimental data as given for Case A-1. In all stories the analytical sign values of R_A and R_B are of opposite sign, which agrees with the experimental data as given for Case A-1 of the paper.

Francis P. Witmer,[24] M. Am. Soc. C. E., and Harry H. Bonner,[25] Esq. (by letter).—The writers are gratified at the satisfactory verification of their results on the part of several who have discussed this paper. It must be borne in mind that their intent was not to produce exact quantitative values, but only to determine trends of reaction ratios resulting from assumed variations in the design of the bents. Agreement with the writers' results is particularly noticeable in the two upper curves of Fig. 11, in the discussion by Professor Maugh, and also in the celluloid model tests of Mr. Morrison. Professor Tsai obtains very interesting relations for single-story bents, which are also confirmatory of the writers' results, and Mr. Fischer shows a similar agreement with theory.

The failure of total upward and downward reactions to be equal in some cases, as mentioned by Mr. Morrison, is not surprising, since actual readings were recorded in all cases without any attempt, arbitrarily, to correct them in order to produce the agreement demanded by statics. It is believed that, in most cases, the discrepancies will not be great. The model has since been improved by the use of positive metal clamps, tightened by screws, instead of the wooden joint blocks, and with these the equality of upward and downward reactions is much more nearly obtained in all tests. It is interesting to note, however, that, with these metal connections, repetition of tests previously made with wooden blocks produces reaction ratios in very close agreement with those first found, thus indicating a surprising degree of efficiency on the part of the wooden blocks.

The discussion by Professor Large and Mr. Carpenter is very interesting and to a considerable extent confirmatory. It is felt, however, that they have expected rather too great a degree of exactness in some cases where they find what they term "serious discrepancies." The extension of their study to cases with relatively heavy columns is not necessarily contradictory of the writers' results. In subsequent tests, the writers have found that, when all columns are increased in size, but are still kept equal to each other, the reaction ratio will be increased algebraically. Some results in this connection are indicated in Table 4. The last ratio, + 23%, for Case C-2 with heavier columns, compares well with + 20% for Case 11-C-2 in Table 3.

[24] Director of Civ. Eng., Univ. of Pennsylvania, Philadelphia, Pa.
[25] Instr. in Mech. Drawing, Frankford High School, Philadelphia, Pa.

Professor Large and Mr. Carpenter state that, in computing the stiffness of the members, reduced lengths of girders ("Spurr lengths") were used instead of center-to-center lengths, as they ordinarily "gave results nearer to experimental values." In their original report[17] they state that the use of "center-to-center lengths of members in computing stiffness corresponds more nearly to the actual performance so far as girder shears are concerned." These two statements appear to be contradictory. The improved metal connections used by the writers in their later tests approximate closely the center-to-center length relation, whereas the original wooden blocks caused a reduced length of all members. The close agreement in results obtained with the two types of connections made it appear that the reaction ratios were not greatly affected by the shortened lengths. If further model study could demonstrate that this is true, the use of center-to-center lengths would greatly simplify the determination of reactions. Of course, reduced lengths are necessary in computing moments in girders.

TABLE 4.—Comparison of Reaction Ratios

Case	Reaction Ratios, $\frac{R_t}{R_o}$

Relative moments of inertia	1	8
$A-1$	−15%	0%
$C-1$	+76%	+92%
$C-2$	0%	+23%

The writers would not expect their conclusions to apply to relations not reasonably within the range comprehended in their tests. Considerable increase in the size of columns might naturally call for some modification. They believe, however, that the qualitative trends which they endeavored to determine have been well substantiated by the various discussions.

The reference by Professor Large and Mr. Carpenter to the impropriety of applying "20-story methods to 50-story towers", of course, is unquestioned, as is also the proper consideration of deflection in the case of tall towers. The writers' models, in some cases, had a height-to-width ratio as great as 8.7 to 1, and were thus properly in the tower class. The number of stories is not so significant as the height-to-width ratio. No attempt was made to determine whether considerations of deflection should demand one method of computation rather than another in order to maintain a maximum degree of economy. The purpose was to ascertain the facts as to how frames of certain assumed proportions will naturally behave and what kind of modification is necessary to compel them to behave in a certain predetermined manner. The question of economy consistent with strength and stiffness is a compelling one, of course, but the relations among these three essential factors were not considered as a part of this study.

With regard to Conclusion (1) of the paper, the writers have subsequently shown that, for any bent of the type under consideration, for which both girders and columns are of the proportions required for vertical floor loads

(assuming girders to be non-continuous and neglecting effect of column distortion from direct wind stress), the following relations are generally true, regardless of the number of columns, the number and height of stories, the length of girders, and the values of horizontal forces at the different floors:

(1) Girder moments are equal at both ends of any girder;
(2) Girder moments are proportional to their length;
(3) Girder shears are equal in all girders of any floor; and
(4) Direct stresses and vertical reactions for all interior columns are equal to zero.

These conditions were practically fulfilled for two assumed cases, applying Equations (10) to (17), inclusive, in the discussion by Mr. Mensch.

Thus, assuming $L_0 = 1$; $L_t = 2$; and $h = 1$, Equations (12) to (16), inclusive, become:

$$M_1 = \frac{4\,P}{29} \qquad (41a)$$

$$M_2 = \frac{3.5\,P}{29} \qquad (41b)$$

$$M'_2 = \frac{7\,P}{29} \qquad (41c)$$

$$R_A = \frac{7.5\,P}{29} \qquad (41d)$$

and,

$$R_B = -\frac{0.5\,P}{29} \qquad (41e)$$

Furthermore, assuming $L_0 = 3$; $L_t = 1$; and $h = 1$, the corresponding equations are:

$$M_1 = \frac{19\,P}{94} \qquad (42a)$$

$$M_2 = \frac{21\,P}{94} \qquad (42b)$$

$$M'_2 = \frac{7\,P}{94} \qquad (42c)$$

$$R_A = \frac{13.3\,P}{94} \qquad (42d)$$

and,

$$R_B = \frac{0.7\,P}{94} \qquad (42e)$$

Relation (4) was also practically fulfilled by the second model test reported by Mr. Morrison, and by Case *A*-1*c* of the paper, although in proportioning the frame for this latter case the writers did not have in mind the fact that the

areas of the columns were proportional to those required for vertical floor loads. In these two cases the moments of inertia of columns were not in proportion to their areas, but the resultant reaction ratio in each case was approximately zero, thus practically agreeing with the portal theory.

The probability of such relations as those in Equations (41) and (42) was indicated by experimental results and recorded in the Fifth Progress Report of Sub-Committee No. 31 of the Structural Division, on Wind-Bracing in Steel Buildings[26], the proof being given in a discussion of the report.[27]

These relations are in exact agreement with the fundamental portal theory. It is thus interesting to discover that this theory has the backing of mathematical proof in the case of wind action on bents proportioned for vertical floor loads in the manner described in the aforementioned report.[26] The economic aspects of this conclusion would seem to be of considerable importance.

It is further of interest to note that if girders are assumed to act continuously, the interior column loads will be relatively increased and the other loads decreased, but an allowance for weight of outer walls will increase outer column loads and thus tend to offset the continuous girder effect. Under these conditions the relation between column loads across the bent will tend to approximate that for vertical floor loads alone with non-continuous girders.

MODERN CONCEPTIONS OF THE MECHANICS OF FLUID TURBULENCE

By Hunter Rouse,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs Chesley J. Posey, S. Franz Yasines, Benjamin Miller, Ralph W. Powell, Joe W. Johnson, Warren E. Wilson, Theodor von Kármán, and Hunter Rouse.

Synopsis

Throughout the past century, numerous efforts have been made to understand the problem of resistance in turbulent flow, but only in recent years has a satisfactory analytical basis been laid for such research. The purpose of this paper is to summarize and interpret the modern scientific methods of approach that have made such progress possible, using the subject of flow in circular pipes as the simplest and most pertinent means of illustration.

After a brief discussion of pipe resistance in terms of general dimensionless parameters, the physical nature of turbulence is described qualitatively; the inner mechanism of flow is then followed from the laminar stage through the critical zone and well up into the region of high Reynolds numbers for both smooth and rough pipes. The Prandtl-von Kármán theory of the mixing length, the significance of the laminar boundary layer with relation to surface roughness, the latest experiments on artificial roughness, and von Kármán's universal relationship between the velocity distribution and resistance to flow, are finally treated in terms of the foregoing discussion of the mechanics of fluid motion. The notation used in the paper is summarized in the Appendix.

Dimensional Analysis of Pipe Resistance

For many decades the complexities of turbulent motion in fluids remained so baffling to engineers and scientists alike, despite great progress in other

Note.—Published in January, 1936, *Proceedings*.
[1] Asst. Prof. of Fluid Mechanics, SCS, California Inst. of Technology, Pasadena, Calif.

fields of mechanics, that until recent years little had been accomplished toward placing the study of turbulent phenomena upon an analytical basis. As a result, hydraulicians have been forced to rely to a great extent upon empirical relationships for the expression of energy loss due to turbulence; and as empiricism is at best a rather haphazard means to an end, such relationships in themselves are seldom likely to suggest the correct nature of underlying physical principles. Thus it is that the subject of hydraulics now finds itself somewhat hobbled in its thought by those very methods which contributed greatly to its prestige in past generations.

Hence, it is only logical that the first successful approach to the analysis of turbulence should have come from scientists endeavoring to further the development of a new engineering field. Aeronautics recently found itself confronted with a vast assortment of problems in fluid motion, not the least of which dealt with turbulent formations; and as the new profession was unhampered by tradition, it turned eagerly to the scientific world for much-needed assistance. Astonished as many engineers may have been who had learned to mistrust the ideal notions of classical hydrodynamics, a new and intensely practicable science of fluid mechanics has been developed to meet these needs.

Since turbulence is completely general in its nature, its study through the methods of fluid mechanics is fully as applicable to problems of hydraulics as to problems of airplane design. Those scientists who helped place aeronautics on a sound physical basis have also turned with unabated zeal to the field of pipe flow, and it is only to the advantage of hydraulic engineers that they give serious heed to recent progress in various parts of the world. As the purpose of this paper is to summarize and interpret the most important of these advances in their application to pipe resistance, no attempt has been made at a proper historical treatment; however, abundant references are given in the several texts and papers listed in the footnotes, of which probably the most lucid and complete account is that presented by L. Schiller[2], in 1932.

The first great forward strides were made by Osborne Reynolds in the early Eighties of the Nineteenth Century through his investigations of laminar and turbulent resistance. Although these contributions to the science were forgotten for many years, his discovery of the dimensionless parameter which now bears his name has given the world perhaps its most valuable means of flow analysis. The Reynolds number is one of three dimensionless parameters applicable to the general movement of fluids in which the factor of compressibility—or elasticity—may be ignored[3]. The quality of these numbers is such that any two geometrically similar systems of flow are also dynamically similar if the corresponding dimensionless numbers, named for Froude, Reynolds, and Weber, are numerically equal in each case. Dynamic similarity, in turn, is that condition which prevails if all corresponding forces acting in the two systems are in the same ratio to each other as the inertial qualities of the existing state of motion. That is, according to

[3] "The Analytical Approach to Experimental Hydraulics—On the Use of Dimensional Numbers", by H. Rouse, *Civil Engineering*, November, 1934.

the Newtonian principle of momentum, the action of any force upon a given mass of matter will produce upon that mass a certain rate of change of momentum:

$$F = \frac{d(m\,v)}{dt} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which F denotes the active force and $\frac{d(m\,v)}{dt}$, the equal and opposite inertial reaction of the mass. In the motion of any fluid, in which the change of density is negligible, only three basic and independent forces—namely, those due to gravity, viscosity, and surface tension—may act to produce such a rate of change of momentum; of these, only the action of viscosity may influence the character of flow entirely enclosed by pipe walls, so that the other two play no further part in this paper. In order for flow through any two geometrically similar pipes of uniform diameter to be dynamically similar, all corresponding viscous forces in the two systems must then bear the same relation to each other as do the inertial characteristics of flow in the two pipes; according to the Newtonian equation, these inertial characteristics must be dimensionally equivalent to the right-hand side of the equation—that is, instead of rate of change of momentum, this inertial term characteristic of uniform flow is the rate of passage of momentum, or the momentum of a unit volume of fluid multiplied by the volume passing a representative cross-section per unit of time. Expressing this inertial quality by the symbol, I, it becomes, in general dimensions of density, velocity, length, and time:

$$I = \rho\,V\,\frac{L^3}{t} = L^2\,\rho\,V^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Similarly, any viscous force, since the intensity of viscous shear equals $\mu\,\frac{dv}{dy}$, must have the following dimensional character:

$$F_v = L^2\,\mu\,\frac{V}{L} = L\,\mu\,V \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

The essential equality of force and inertial ratios,

$$\frac{F_{v1}}{F_{v2}} = \frac{I_1}{I_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

then becomes, through substitution of Equations (2) and (3):

$$\frac{L_1\,\mu_1\,V_1}{L_2\,\mu_2\,V_2} = \frac{L^2_1\,\rho_1\,V^2_1}{L^2_2\,\rho_2\,V^2_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

and,

$$\frac{L_1\,V_1\,\rho_1}{\mu_1} = \frac{L_2\,V_2\,\rho_2}{\mu_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Thus, in order for dynamic similarity to obtain between the two geometrically similar systems of flow, it is essential that the dimensionless quantity, $\frac{L\,V\,\rho}{\mu}$,

be identical numerically in both systems. This quantity, the Reynolds number, is usually given the symbol, R:

$$\mathsf{R} = \frac{L\, V\, \rho}{\mu} \qquad (7)$$

The length parameter, L, may have any value, characteristic of the flow, which the investigator may care to select, so long as he is consistent in its use throughout the investigation. Obviously, the characteristic length which he selects will determine the final numerical magnitude of the Reynolds number for a given set of conditions; otherwise, the number will be fixed, regardless of whether metric, English, or any other units are used. For purposes of uniformity it is customary, in pipe studies, to use the diameter of the pipe as the length factor.

The Reynolds number is thus seen to represent in simplified form the ratio between the inertial and the viscous properties of flow. If the rate of passage of momentum is increased (by increasing the velocity, density, or pipe diameter), the Reynolds number will grow in magnitude; if the viscosity is increased, the Reynolds number will diminish. As will be shown directly, the larger the value of R, the larger will be the tendency toward instability of flow; conversely, the smaller the value of the Reynolds number, the larger will be the stabilizing effect of viscosity. The magnitude of this number is then a direct indication of the flow characteristics, once a basic value has been established for purposes of comparison. Furthermore, if R has the same numerical value for movement in any two geometrically similar pipes, one may be certain that general conditions of flow in both pipes are identical, regardless of wide variation in diameter, velocity, density, and viscosity between the two systems. It is customary to write the Reynolds number in the form, $\mathsf{R} = \dfrac{V\,D}{\nu}$; one must remember, however, that the kinematic viscosity, $\nu_k = \dfrac{\mu}{\rho}$, is the ratio of two independent fluid properties, each of which must be regarded as distinct from the other.

The motion of a fluid passing through a pipe is resisted by a certain tangential stress between the fluid and the pipe walls. Denoting this wall stress per unit area by the customary symbol, τ_0, it is reasonable to presume that the magnitude of the resistance will be a function of pipe diameter, density, viscosity, and average velocity; wall roughness will be omitted for the time being, on the assumption that the pipe is very smooth; that is,

$$\tau_0 = \phi\,(D, \rho, \mu, V) \qquad (8)$$

or, assuming for the present that the function is exponential:

$$\tau_0 = C\; D^{x}\; \rho^{y}\; \mu^{z}\; V^{n} \qquad (9)$$

Through the principle of dimensional analysis, the form of this function

may be found by expressing the terms of Equation (9) in general *M-L-T* units (M = mass, L = length, and T = time):

$$\frac{M}{L\,T^2} = (L)^x \left(\frac{M}{L^3}\right)^y \left(\frac{M}{L\,T}\right)^z \left(\frac{L}{T}\right)^n$$

The three unknown exponents, x, y, and z, are found in terms of the fourth unknown exponent, n, by the solution of three simultaneous equations, thus:

For M,

$$1 = y + z$$

for L,

$$-1 = x - 3y - z + n$$

and for T,

$$-2 = -z - n$$

Hence: $x = n - 2$; $y = n - 1$; and $z = 2 - n$. By substituting these values for x, y, and z in Equation (9),

$$\tau_0 = C \times D^{n-2} \times \rho^{n-1} \times \mu^{2-n} \times V^n \quad (10)$$

which may also be written in the form,

$$\tau_0 = \frac{C'}{\left(\frac{V\,D\,\rho}{\mu}\right)^{2-n}} \rho \frac{V^2}{2} \quad (11)$$

In Equation (11) the first fraction is seen to be a numerical constant, C', divided by the Reynolds number to the power, $(2 - n)$. This fraction is equal to the customary resistance coefficient, f, divided by the factor, 4; that is,

$$\frac{f}{4} = \frac{C'}{\mathbf{R}^{2-n}} \quad (12)$$

and, consequently, Equation (11) becomes:

$$\tau_0 = \frac{f}{4} \rho \frac{V^2}{2} \quad (13)$$

Inasmuch as the resistance exerted upon any portion of the moving fluid must be counterbalanced by a drop in pressure intensity from one section to the next, the pressure gradient for steady flow in a horizontal pipe of uniform diameter may be written in terms of the total shearing force along the surface of the pipe between the two normal sections:

$$(p_1 - p_2) \frac{\pi D^2}{4} = \tau_0 \pi D L \quad (14)$$

and,

$$-\frac{d\,p}{d\,L} = \frac{4\,\tau_0}{D} \quad (15)$$

from which the familiar equation for lost head in pipes may be derived, through substitution of Equation (13):

$$-\frac{d\,p}{d\,L} = \frac{f}{D} \rho \frac{V^2}{2} \quad (16)$$

and,

$$-\frac{\Delta p}{\gamma} = -\Delta h = \frac{f\,L}{D}\,\frac{V^2}{2\,g} \qquad \text{(17)}$$

If the pipe slopes, a further change in pressure intensity from one section to the next is essential to balance the longitudinal component of the fluid weight between the two normal sections. It will be clear from Fig. 1,

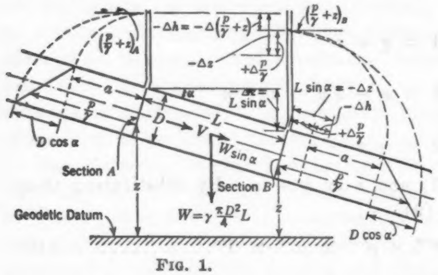

FIG. 1.

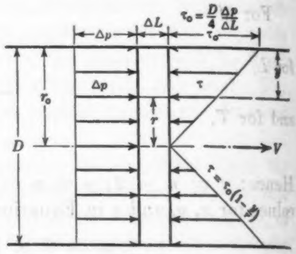

FIG. 2.

however, that this occasions no change in the foregoing relationship between wall shear and that portion of the pressure drop with which it is in equilibrium; hence the assumption of a horizontal pipe merely eliminates two equal and opposite force components from the equation. That is, it makes no difference how steeply the pipe slopes, or whether the flow is the result of pumping or of direct feed from a reservoir; the state of flow at a given section is completely defined once the Reynolds number is known, and is independent of the magnitude of the static pressure load upon the system.

General use of Equation (17) is to be avoided, therefore, unless one is completely familiar with its significance. Involving as it does the specific weight of the fluid (note the open manometer columns in Fig. 1, in a system presumed to be entirely confined by pipe walls), this again brings into the picture the force of gravity, which has just been shown to have no influence upon the flow itself. Unfortunately, the slope of the hydraulic gradient is a function not only of the Reynolds number, but of the Froude number as well—and only if both numbers are the same, respectively, will the grade lines of two different systems be geometrically similar. Since the Froude number refers to flow with a free surface, and actually has no relationship whatever with the inner mechanism of confined flow, no further mention of specific weight will be made in this paper, and Equations (13) and (16) will be considered the basic expressions for pipe resistance.

In developing Equation (15) the assumption is made that the pressure intensity varies statically across any normal section of the pipe. That this must be true will be seen from the fact that neither shear nor acceleration can occur as a continuous process in a direction normal to the pipe axis, for the general movement of the fluid must be in the longitudinal direction. Hence, the only variation in pressure intensity along a pipe diameter must be that necessary to compensate for the change in elevation from one point to the next; that is, the pressure distribution must be static. Thus, the differ-

ence in pressure per unit length for any cylinder of fluid within the pipe (see Fig. 2) must vary directly with the square of the radius, r, of the cylinder. Since this difference in pressure must be exactly counterbalanced by the shear along the outer surface of the fluid cylinder, Equation (14) may be written in terms of any radius, r:

$$(p_1 - p_2)\, \pi\, r^2 = 2\, \pi\, r\, L\, \tau \qquad (18)$$

Equation (15) will then become:

$$-\frac{d\,p}{d\,L} = \frac{4\,\tau_0}{D} = \frac{2\,\tau}{r} \qquad (19)$$

Expressing the pipe diameter, D, as twice the radius, r_0,

$$\tau = \tau_0 \frac{r}{r_0} = \tau_0 \left(1 - \frac{y}{r_0}\right) \qquad (20)$$

In other words, the intensity of shear between adjacent layers of fluid co-axial with the pipe wall will vary directly with the distance from the axis of the pipe, as plotted in Fig. 2. It is upon this very general relationship, which holds for laminar and turbulent flow in either smooth or rough pipes, that further analysis of pipe resistance is based.

If the flow is laminar (that is, if the shearing stress is purely viscous, according to the relationship, $\tau = \mu \frac{dv}{dy}$), means are now at hand for determining the velocity distribution in terms of the wall shear. Introducing the relationship,

$$\tau = \mu \frac{dv}{dy} = -\mu \frac{dv}{dr} \qquad (21)$$

in Equation (20),

$$dv = -\frac{\tau_0}{\mu\, r_0}\, r\, dr \qquad (22)$$

and integrating,

$$v = -\frac{1}{2} \frac{\tau_0}{\mu\, r_0} r^2 + C \qquad (23)$$

The value of the constant of integration may be found through use of the fact that when $r = r_0$, $v = 0$; that is, the velocity at the pipe wall is zero. Under these conditions,

$$C = \frac{1}{2} \frac{\tau_0\, r_0}{\mu} \qquad (24)$$

and the equation for velocity distribution then becomes:

$$v = \frac{1}{2} \frac{\tau_0}{\mu} \left(\frac{r_0^2 - r^2}{r_0}\right) \qquad (25)$$

Inspection will show that the distribution curve is parabolic, attaining its maximum value at the center, where,

$$v_{max} = \frac{1}{2} \frac{\tau_0 r_0}{\mu} \qquad (26)$$

Since the volume of a paraboloid of revolution is one-half that of a circumscribing cylinder, the mean velocity must be one-half the maximum:

$$V = \frac{1}{2}\, v_{max} = \frac{1}{4}\frac{\tau_0\, r_0}{\mu} \qquad \text{(27)}$$

and,

$$\tau_0 = \frac{8\,\mu\, V}{D} \qquad \text{(28)}$$

Through substitution in Equation (15),

$$-\frac{d\,p}{d\,L} = \frac{32\,\mu\, V}{D^2} \qquad \text{(29)}$$

Similarly, substitution of Equation (28) in Equation (13) yields the fundamental dimensionless relationship for laminar flow,

$$f = \frac{64}{\mathsf{R}} \qquad \text{(30)}$$

in which case the exponent, n, must have a value of unity. The problem of laminar flow is thus fully solvable mathematically.

Abundant experimental data exist to vindicate these expressions. For instance, a logarithmic plot of τ_0 against V, for a given pipe and a given fluid, results in a single straight line with a slope of unity for the entire laminar range. Once turbulent flow has begun, however, the slope of the line changes (see Fig. 3) from unity to a value varying from $n = 1.75$ for

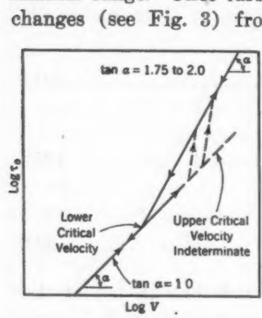

FIG. 3.

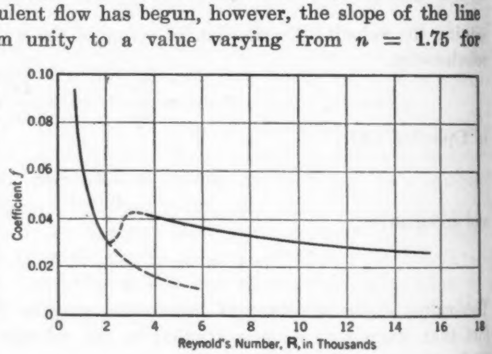

FIG. 4.

extremely smooth pipes to a maximum of $n = 2$ for pipes that are very rough. Aside from this elementary although highly instructive knowledge of the significance of the exponent, n, such a plot is of little aid in drawing general conclusions about the relationships between various systems of flow. The curve is not applicable to more than the one pipe and the one fluid for which it was determined; nor is it of use in other dimensional systems without bothersome revision of scale.

Those engineers who have followed the publications of laboratories in which the metric system is used will readily admit the superiority of dimensionless co-ordinates, if only from a utilitarian point of view. Moreover,

the use of dimensionless parameters often enables the investigator to discover very general principles which otherwise would be obscured in the maze of experimental data plotted in dimensional form. For instance, Equation (16) may be rewritten in dimensionless form through solving for f and combining with Equation (12):

$$f = -2 \frac{dp}{dL} \frac{D}{\rho V^2} = \frac{C''}{\mathrm{R}^{2-n}} \qquad (31)$$

This expression for f as a function of the Reynolds number, another dimensionless quantity, at once suggests the use of these two flow characteristics as ordinates and abscissa for plotting on a single dimensionless graph the variation of the coefficient over the widest possible range of pipe diameter, velocity, viscosity, and density. The form of such a curve for smooth pipes (Fig. 4) is probably already quite familiar to the majority of engineers, for its efficacy in co-ordinating the results of many investigators is undeniable.

Despite the many points in favor of this method, engineers are wont to protest that although such a curve is excellent for very smooth pipes, almost no pipes used in engineering projects are smooth enough to fall within this class. Moreover, the few attempts that have been made to bring commercial rough pipes into such a general relationship have not met with complete success[4]. As a result, the treatment of roughness by engineers has of necessity remained almost purely empirical.

In order to answer such an argument emphatically, it is only necessary to cite the progress that has been made in the present century in this very attempt at generalization. Although the results are quite well known, so far as smooth pipes are concerned, it should prove encouraging to the Engineering Profession to know that progress in the study of rough pipes is continuing successfully at a fully equivalent rate. Research of the present day is emphasizing more and more the general nature of the problem, in an attempt to determine universal relationships which will include every type of pipe that is known, under all possible conditions. It is with the present status of this research that the remainder of this paper will deal.

Physical Characteristics of Turbulence

Attention has already been called to the fact that the Reynolds number is a direct indication of the relationship between the inertial qualities of the flow, which tend toward instability, and the viscous qualities, which have a stabilizing influence. Reynolds' original visual experiments to determine the upper critical velocity—that point at which laminar motion changes to turbulent motion—were splendid illustrations of the growth of instability. Reynolds' equipment consisted of a large tank of still liquid, from which led a glass tube with well-rounded entrance, at the end of which was a valve to regulate the discharge. By introducing a thin filament of dye at the entrance of the tube during discharge, the condition of the flow could be

[4] "Elemente der technischen Hydromechanik", von R. von Mises, I. Teil, B. G. Teubner, Leipzig und Berlin, 1914; "Die Messung der hydraulischen Rauhigkeit", von L. Hopf, *Zeitschrift für angewandte Mathematik und Mechanik*, Band 3, S. 329, 1923; and "A Study of the Data on the Flow of Fluids in Pipes", by E. Kemler, *Transactions*, A. S. M. E., Hydraulics Div., August 31, 1933.

observed by eye over the entire length of the liquid column. So long as the flow remained laminar, the ribbon of color continued as a straight line without diffusing; but the moment the velocity passed above the critical, the ribbon began to waver and finally to diffuse over the entire cross-section.

At the point of initial wavering of the colored filament Reynolds found a mean value of R ranging from 12 000 to 14 000. It is very important to note that later experimenters managed to increase this value of the Reynolds number by improving the entrance, eliminating all vibration, and allowing the liquid in the tank to stand for a much longer period—for several days, in fact. With Reynolds' original equipment, for instance, a value of more than 40 000 has been obtained[5]. The obvious conclusion to be drawn from these experiments is that for perfectly smooth pipes the limiting upper critical point is indeterminate (see Fig. 3), for it depends largely upon the care with which the experiments are conducted. In every case the initial turbulence was a result of some irregularity of flow that was too minute to be discovered beforehand, yet which gradually upset the equilibrium within the fluid.

On the other hand, below a fairly well established point called the lower critical velocity—the point of change from turbulent to laminar flow—the viscous forces are sufficiently large to quell any disturbances that may be present and thus prevent general instability of the flow. Above this lower critical point, which has been almost universally accepted to be about $R = 2\,000$, the slightest disturbance in the oncoming flow is enough to cause a rapid growth of that irregularity of motion called turbulence.

The word "turbulence" has its distinct meaning to those scientists who are now responsible for its analytical investigation, yet it has various independent and often conflicting connotations in the engineering world. To the practical hydraulician engaged in irrigation and power development, for instance, the word instantly suggests the picture of large swirls and eddies which have no relation whatever in his mind with the tiny irregularities of flow in Reynolds' glass tube. Because of this apparently ambiguous usage of the word, the writer submits the following brief picturization of the turbulent phenomenon.

On the small scale of Reynolds' experiments, or on the large scale of the hydraulician's practical experience, fully developed turbulence is basically the same. Superimposed upon the translatory movement of the fluid is a complex internal agitation of the fluid mass, differing from the kinetic motion of gaseous molecules, however, in that finite portions of the fluid rather than infinitesimal particles are involved in the mixing process. Although the action is apparently fully disordered, a statistical treatment of the conditions at any point in a "steady" flow will yield a temporal mean value of the velocity which is invariable so long as the general conditions of flow remain unchanged.

In addition to this temporal mean, the statistical method introduces the conception of instantaneous velocity fluctuations at a given point, as components to be added to the temporal mean velocity measured at the point in

[5] "On the Change from Steady to Turbulent Motion of Liquids," by V. W. Ekman, *Arkiv für matematik, astronomi och fysik*, 6, Nr. 12, 1911.

question; that is, at any instant there may be superimposed upon the translatory movement of the fluid past that point either positive or negative velocity components in each of the three co-ordinate directions. Thus, there is a variable movement of small fluid masses in a direction normal to the general flow, these masses carrying into other regions increments of momentum or energy from the region from which they came—as a result, the turbulent mixing process involves a constant transfer of energy among the various portions of the flow.

Although this statistical interpretation of the turbulence phenomenon is of advantage in the mathematical treatment of energy distribution, only to the mathematicians can it offer a sufficiently complete picture of the internal fluid mechanism. In order to broaden the viewpoint, recourse is often taken to the concept of vortex motion as the root of fluid turbulence. The vortex—briefly, a fluid mass rotating about a central axis and inducing a velocity field in the surrounding fluid medium—is often the source of turbulence, and its rotational motion is fairly typical of the swirls and eddies in a moving stream[6]; yet while turbulent agitation might be thought of as an intricate system of vortices, large and small—some spinning violently and some very slowly, and each influencing the velocity of the neighboring fluid—such a schematic representation gives somewhat too ideal an impression of true turbulence.

Perhaps the best picture is a combination of the two extremes, in which from the statistical representation is taken the notion of continuous—but not abrupt—fluctuation at a given point, and from the vortex conception the visualization of irregular rotational movement of small masses of the fluid in addition to the general movement of the stream. As illustrative of the final picture, imagine dense smoke clouds issuing from a chimney; the motion is obviously changing from instant to instant, but it exhibits on the other hand a very typical sequence of rolling billows of smoke, the general movement of which is by no means the individual helter-skelter of tiny particles of soot; that is, one must not draw from the statistical method the conclusion that each fluid particle describes its own irregular path irrespective of the motion of its neighbors; instead, the behavior of every particle is completely dependent upon that of the others in its immediate vicinity. Free flight and resulting collision between gaseous molecules, furthermore, is not the basic movement in turbulent agitation of fluid masses; nor may the notion of molecular impact, or even of intermittent impact of fluid masses, be considered generally typical of turbulence. On the contrary, the swirling masses are always in complete contact with neighboring masses, and the consequent energy losses are entirely viscous in nature as a result of the variable velocity gradient across any section of the agitated fluid.

A fact commonly ignored at the present time is the existence of considerable energy of turbulence in a moving fluid. The familiar Bernoulli theorem includes only a single kinetic term, velocity head, which is computed from the mean velocity of flow over the entire cross-section. Needless to say, the

[6] Refer to the photographs at the end of the Engineering Societies Monograph, "Applied Hydro- and Aeromechanics", by Prandtl-Tietjens, McGraw-Hill, 1934.

existence of velocity fluctuations indicates further kinetic energy in the fluid, which, unlike the components of fluctuation, has by no means a temporal mean value of zero. This energy of turbulence is perhaps best illustrated by referring once again to the notion of vortices superimposed upon the general flow; however much the individual vortices may be distorted in the actual flow pattern, it is apparent that each single vortex represents a certain amount of rotational energy in addition to its kinetic energy of translation.

The hydraulic engineer has long been familiar with such turbulent energy, under perhaps a different name. The so-called "energy loss" in the hydraulic jump, at "stilling" racks, in tumble bays, at pipe valves, and in various other devices of a similar nature, is really a conversion from the energy of flow embodied in the three terms of the Bernoulli theorem into energy of turbulence. That this transformation is not directly into heat is shown by the fact that the resulting turbulence, of however fine a type (that just after a stilling rack, for instance) is still apparent quite some distance down stream. Eventually, of course, viscous action produced by the turbulent mixing process accomplishes the mechanical transformation into heat, but this is a gradual and not an abrupt process; consider, as illustration, the time necessary to still the water in Reynolds' experiments, or the distance down stream the spiral effect of elbows makes itself known. To be sure, such energy of turbulence is lost to the engineer, for it can never be regained in useful form; but as turbulent energy it can still play insidious havoc as it proceeds down the pipe or channel. C. Camichel[7], for instance, produced artificial turbulence in normal laminar motion by placing a screen in the path of the flow. The resistance then followed the turbulent law until the stabilizing viscous action had restored the flow to its original character some distance down stream. Thus, the presence of abnormal turbulence can change completely the general characteristics of flow.

The causes of turbulence are several in number, a clear understanding of which would depend upon a finer perception of the physics of fluid motion than can be presented in this paper[8]. Mention has already been made of the steady growth of any small irregularity of the flow at Reynolds numbers above the critical, resulting eventually in fully developed turbulence. Furthermore, under certain conditions, roughness of the boundary surface may produce a turbulent "wake" in much the same fashion as will the motion through the air of a vehicle that has not been stream-lined; thus, the action of wall roughness may serve to augment the normal turbulence of the flow. In the latter case the action at the wall will be in effect a constant transformation of potential energy into turbulent energy, which produces as a result an apparent shearing stress between wall and fluid.

Many investigations to determine the "friction factor" for different types of pipe have been of little direct value to the Engineering Profession because insufficient effort was made to distinguish between actual wall resistance and induced resistance caused by turbulence resulting from valves, pipe-joints, or by too great proximity of the measured section to entrance or exit.

[7] "Notice sur les Travaux Scientifiques", Toulouse, 1929.
[8] See, for instance, "Entstehung der Turbulenz", von L. Prandtl, *Zeitschrift für angewandte Mathematik und Mechanik*, Band 11, 1931.

Although the total loss in commercial piping is of direct interest to the designing engineer, it is futile to attempt an analysis of each separate influence if these influences cannot be isolated one at a time. Hence all mention of normal pipe turbulence in this paper refers only to that fully developed turbulent state which will result from the interaction between the fluid itself and the walls of a uniform pipe. It is possible experimentally to make joints of such a nature that they will have no appreciable effect upon the flow, and it has been found that a distance of about 50 pipe diameters from a symmetrical entrance (short elbows or valves may cause so great a disturbance as to require a longer approach section) will be sufficient to permit the full development of normal turbulence.

Resistance as a Function of the Reynolds Number

According to the principle of dynamic similarity, which has had sufficient experimental justification to warrant the complete confidence of both the scientist and the engineer, any single Reynolds number denotes a very definite state of turbulence. Although the flow picture may change from instant to instant because of the complexity of the vortex pattern superimposed upon the general translatory movement, a dimensionless temporal average of velocity conditions at any given section of flow will yield identical results for a given Reynolds number, regardless of fluid properties and pipe diameter. At the same time, it must be remembered that dynamic similarity is dependent upon geometrical similarity, which signifies that the roughness must play a definite part in similitude. Despite the prevalent custom of distinguishing between smooth and rough pipes, it is obvious that roughness is purely a relative characteristic, for even the smoothest surface is rough under the microscope. Recent experimental studies have very clearly demonstrated this fact.

As a general example for the following discussion, assume a pipe that is relatively smooth, remembering that its walls still possess finite surface irregularities. As a given fluid, whether it is a liquid or a gas, flows at a very low Reynolds number through this pipe, the velocity will vary parabolically from zero at the wall to a maximum at the center of the pipe. The fact that the wall velocity is zero is purely a viscous—not an adhesive—effect; for mercury, which does not "wet" the wall, will have just the same flow characteristics as air or water[*].

As the discharge through this pipe is increased, the velocity distribution will remain parabolic, varying only in scale; the shearing stress at the wall will increase in direct proportion to the average velocity (one-half the maximum velocity), as will also the pressure gradient in the direction of flow. Hence, for the given fluid and the given pipe, the frictional factor, f, will be in inverse ratio to the average velocity. Generally speaking, for any fluid and any pipe, so long as the flow is laminar, this friction factor is equal to $f = \frac{64}{R}$. This condition holds until the critical zone is reached (where the

[*] "Unsere Kenntnis der Zähigkeit von Quecksilber", von S. Erk, *Zeitschrift für Physik*, Bd. 47, 1928.

Reynolds number is approximately 2 000), at which point the viscous forces are no longer sufficiently great to counterbalance completely the inertial tendency toward instability. Since these viscous stresses are greatest near the walls of the pipe where the velocity gradient attains its highest value, and lowest in the central regions where the velocity gradient approaches zero, it is reasonable to presume that the first signs of instability will appear at some distance from the wall; this presumption may be vindicated experimentally. That wall roughness (when not excessive) is not the cause of the initial turbulence, will be seen from the following discussion of the boundary layer.

Within the critical zone (from $\mathsf{R} = 2\,000$ to about $\mathsf{R} = 3\,000$), under normal conditions a state of complete equilibrium is difficult to produce. The initial turbulence is so closely dependent upon slight disturbances within the pipe (sharp entrance, elbows, a valve, etc.), that it is difficult to distinguish a definite transition curve among the numerous plots of data that exist. Generalized transition curves (after Schiller) are shown in Fig. 5

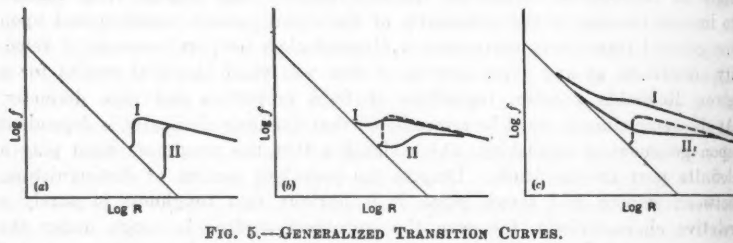

FIG. 5.—GENERALIZED TRANSITION CURVES.

in which the initial disturbance is extremely far away (Fig. 5(*a*)), a short distance away (Fig. 5(*b*)), and, finally, very close to the measured section (Fig. 5(*c*)). Curves marked I represent a large disturbance and II, a small disturbance. Obviously, the smaller and more remote the existing disturbances, the higher the value of R at which the change takes place.

However, once the critical zone has been passed, the curve of f against R assumes a very definite trend. The earliest measurements of lasting importance are those by Augustus V. Saph, Assoc. M. Am. Soc. C. E., and Ernest W. Schoder, M. Am. Soc. C. E.[10]—the true value of which was realized only after analysis by H. Blasius[11]. When plotted by the latter in the now customary form of log f against log R, all results in the turbulent region for the relatively smooth (drawn brass) pipes of different diameters lay very close to a straight line with the slope, $-\frac{1}{4}$ (see Fig. 6). Hence, f may be written as inversely proportional to the fourth root of R, or, as determined by Blasius:

$$f = \frac{C''}{\mathsf{R}^{(2-n)}} = \frac{0.3164}{\mathsf{R}^{\frac{1}{4}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

[10] *Transactions*, Am. Soc. C. E., Vol. LI (1903), p. 253.

[11] "Das Aehnlichkeitsgesetz bei Reibungsvorgängen in Flüssigkeiten", *Forschungsarbeiten* auf dem Gebiete des Ingenieurwesens, 131, 1913.

This relationship thus corresponds to the exponential form—for a given pipe and a given fluid—of $\tau_0 \propto V^{1.75}$. The logical conclusion to be drawn from this apparently simple result was that all very smooth pipes have an identical

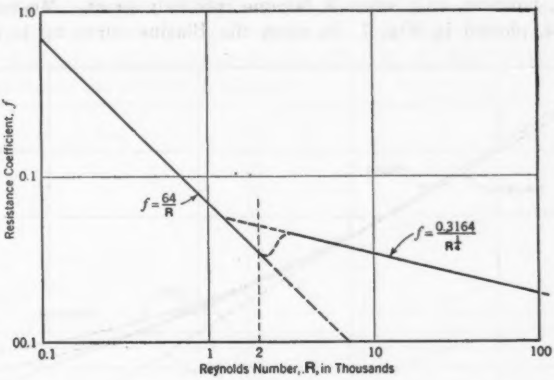

FIG. 6.

effect upon fluid motion, regardless of the degree of turbulence, and that such flow may always be expressed as an exponential function in which $n = 1.75$. (It is to be noted that Reynolds had previously determined this value as 1.732, within surprisingly close range of that of Blasius.)

Nevertheless, research by Messrs. T. E. Stanton and J. R. Pannell[12] soon exceeded the range covered by the curve of Blasius (up to about $\mathsf{R} = 105\,000$) by attaining a maximum Reynolds number greater than 400 000, using both air and water. Based upon these results, C. H. Lees[13] developed the following formula, which differs from that of Blasius in the upper range:

$$f = 0.00714 + \frac{0.6104}{\mathsf{R}^{0.35}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

About fifteen years later, R. Hermann, after reaching a Reynolds number of nearly 2 000 000, in which range both the Blasius and the Lees formulas were found to deviate from experimental results, proposed the more accurate empirical relationship[14]:

$$f = 0.0054 + \frac{0.396}{\mathsf{R}^{0.3}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

This limit has since been surpassed by J. Nikuradse[15], who attained a value of $\mathsf{R} = 3\,240\,000$. These investigations have proved conclusively that the magnitude of n is not constant even for very smooth pipes, but that beyond the Blasius range ($\mathsf{R} = 105\,000$) it increases slowly with increasing

values of R. Thus, flow through an absolutely smooth pipe—which may never be realized—would probably become less and less dependent upon the Reynolds number as the latter increased, attaining complete independence ($n = 2$), however, only when R became infinitely great. Measurements by Nikuradse, plotted in Fig. 7, lie upon the Blasius curve up to a Reynolds

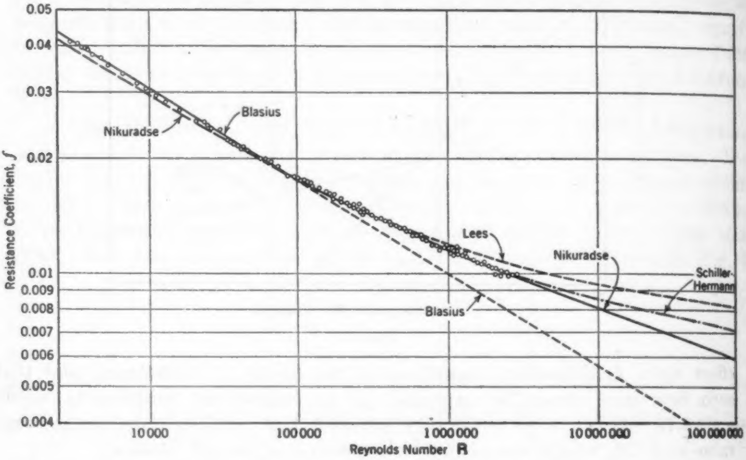

FIG. 7.

number of about 100 000, beyond which point they follow well the curve of Schiller-Hermann. For reasons which will be explained subsequently, Nikuradse has proposed the relationship,

$$f = 0.0032 + \frac{0.221}{\mathsf{R}^{0.237}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

which may be expected to apply to Reynolds numbers as high as 10 000 000. For purposes of comparison, the extrapolated curves of Blasius, Lees, Schiller-Hermann, and Nikuradse are all shown in Fig. 7.

Whereas in laminar flow the resistance was seen to be directly proportional to the average velocity, the turbulent state entails far greater resistance than such a function would provide, since the stress at the walls is now proportional to the average velocity raised to a power varying between 1.75 and 2. It is at once obvious that a redistribution of energy must occur within the flow to cause this change in resistance, since a complete parabolic curve of velocity will no longer provide a sufficiently high value of τ_0. Attention has already been called to the fact that turbulence within the moving body of fluid, schematically illustrated by innumerable vortices superimposed upon the translatory movement, causes a continuous transfer of fluid matter between neighboring layers. Thus, fluid masses from the central regions, possessing a higher velocity in the direction of flow, are whirled into regions in which the velocity is lower, and *vice versa*. In other words, there is a

steady passage of energy from the inner regions of flow in the direction of the pipe walls, resulting in a more uniform velocity distribution over the central portion of the pipe. Hence, the temporal mean velocity curve in turbulent flow, as compared with that of laminar flow, is much flatter at the pipe axis, and accordingly much steeper near the walls (see Fig. 8(*a*)). Obviously, the greater the degree of turbulent mixing (that is, the higher the Reynolds number) the flatter the curve will become.

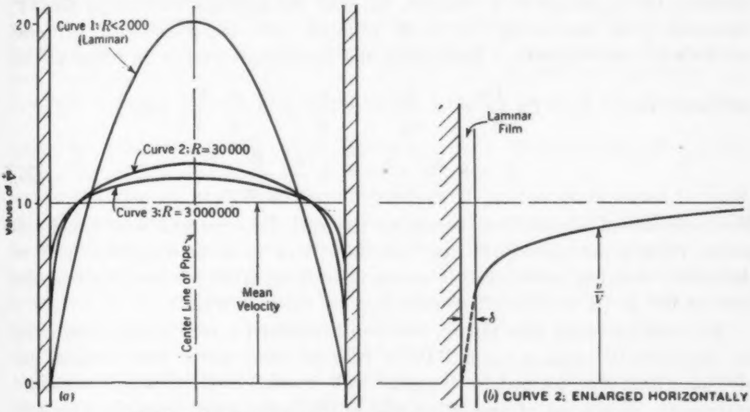

FIG. 8.—VELOCITY DISTRIBUTION IN A VERY SMOOTH PIPE.

Careful measurements of the velocity distribution have long seemed to indicate that the velocity at the wall is by no means zero, as in laminar flow. However, continued improvements in the design of Pitot tubes, enabling a closer approach to the wall, have lowered repeatedly the apparent wall velocity. Despite this indication of a finite velocity at the boundary, analytical investigators have always claimed that the velocity curve must pass through zero at a smooth wall. Based upon this hypothesis, Prandtl developed the theory of the laminar boundary film to account for the high shearing stress at the wall, at which point there is obviously no further turbulent interchange of momentum.

This theory of the boundary layer assumes not only that the wall velocity is zero, but also that the layer of fluid next to the wall contains only a laminar movement of the fluid particles. Since the velocity gradient here will be high —that is, of such magnitude as to provide the shearing stress required by the existing conditions of flow ($\tau_0 = \mu \dfrac{dv}{dy}$)—the error in assuming a linear velocity distribution, rather than a parabolic distribution, will be quite negligible (see Fig. 8(*b*)). It is evident that the boundary layer must become increasingly thin with ascending values of **R**, so that when the Reynolds number is high a rough idea of its thickness may be found from the following simple approximation. The shearing stress at the wall for turbulent flow

may be written: $\tau_0 = f\rho\frac{V^2}{8}$ (see Equation (13)). This stress must be equivalent to the viscous stress at the wall caused by the velocity gradient, which is assumed to be linear over the small normal distance, δ, denoting the thickness of the laminar film. As an arbitrary value for the velocity at the edge of this film may be taken the apparent wall velocity as noted in measurements. Needless to say, the magnitude of this value is open to debate, since the ratio between the apparent wall velocity, v_w, and the average velocity of flow, V, increases with increasing Reynolds number and decreases with improved methods of measurement. Expressing the foregoing equality in terms of this arbitrary ratio: $\tau_0 = f\rho\frac{V^2}{8} = \mu\frac{dv}{dy} = \mu\frac{v_w}{\delta} = \mu\frac{v_w}{V}\frac{V}{\delta}$, and,

$$\delta = 8\frac{v_w}{V}\frac{\mu}{fV\rho} = 8\frac{v_w}{V}\frac{D}{f\mathsf{R}} \qquad (36)$$

For purposes of illustration, assuming the ratio of apparent wall velocity to mean velocity as about 0.5, the boundary film in a smooth pipe 1 ft in diameter, carrying water at an average velocity of 10 ft per sec at a temperature of 60° F (R = 840 000) would then be about 0.0004 ft.

In order to verify this theory, Stanton conducted a very painstaking series of experiments[16] with a special Pitot tube of rectangular cross-section, one side of which was formed by the pipe wall itself. Since this side remained stationary, movement of the outer side of the tube away from the pipe wall simply increased the size of the opening and changed the position of its center. The tube was rated first in laminar flow, in which the velocity distribution was definitely known, these corrections then being applied to measurements in the neighborhood of the wall under turbulent conditions. Nikuradse has found similar values through use of Pitot tubes of several different diameters[15], thus determining the error as a function of tube diameter; by extrapolation, the correct velocity (as would be measured with a tube of zero diameter) was readily available. The results of these experiments served as a striking verification of the theory of the laminar boundary film, as have also more recent tests conducted in wind tunnels of large diameter.

It is erroneous, of course, to consider the laminar film as adjacent to the turbulent region, yet sharply divided from it. Actually there is only an arbitrary limit to the boundary layer, for a transition zone must exist between the two regions, in which zone the motion is neither laminar nor completely turbulent. Thus, while within the laminar film the resistance is purely viscous, it is not until well within the turbulent region (where the velocity gradient is low) that the action of viscous shear finally becomes secondary.

It is now possible to draw a valuable comparison between the laminar and the turbulent régimes. In the former case, the laminar boundary film extends to the very center of the pipe; as the critical zone is reached, this laminar portion of the flow decreases rapidly in radial dimension, and then

[16] "On the Conditions at the Boundary of a Fluid in Turbulent Motion", by T. E. Stanton, D. Marshall, and C. N. Bryant, *Proceedings*, Royal Soc. of London, (A) 97, 1920.

continues to diminish gradually with increasing values of the Reynolds number. The thickness, δ, becomes infinitesimal, if the pipe is extremely smooth, only as n approaches the limit 2 (that is, as $R \to \infty$). The previous statement that initial turbulence in relatively smooth pipes does not occur at the walls now becomes clear, since the wall region, except in very rough pipes, is the last stronghold of laminar conditions.

With the realization that a laminar boundary layer actually exists even in turbulent flow, a comprehension of the part roughness plays in influencing turbulent resistance becomes greatly simplified. Roughness may be described in part by comparing with the radius, r_0, the average distance, ϵ, over which the individual projections extend into the flow section from the pipe wall; thus, the term "relative roughness" signifies the ratio of ϵ to the pipe radius, $\frac{\epsilon}{r_0}$. Obviously, this ratio approaches—but never attains—the limit zero in the case of extremely smooth pipes, and on the other hand in rare instances may approach unity for badly corroded surfaces in which the pipe has become almost completely choked through age; the former class comprises very smooth commercial piping (glass, drawn brass, and lead), but the latter case is so extreme as to make its inclusion in such a paper quite reasonless. In other words, normal relative roughness of pipes can be assumed to vary from nearly zero to perhaps one-fifteenth.

With this partial definition of roughness, it now is possible to subdivide the turbulent region into two distinct zones, separated by a region of transition. It has often been proved that in the laminar régime slight surface roughness has no effect whatever upon either velocity distribution or wall resistance. Similarly, it may be reasoned that so long as the laminar boundary film is of such thickness as to cover all roughness protuberances at the wall, such roughness will continue to have no effect upon the conditions of flow. Thus it is that smooth pipes—despite the fact that they are actually rough to a certain degree—appear to follow a different resistance law from that of commercial rough pipes, for the relative roughness is so slight that the unevennesses are still enveloped in the thin laminar film; yet many pipes, ordinarily classed as smooth, behave as such only for comparatively low Reynolds numbers, since the relative roughness is such that the boundary layer at high Reynolds numbers is not sufficiently thick to cover the roughness particles. Other pipes, in which the relative roughness is high, at no time follow the curve of resistance for smooth pipes beyond the critical zone, because the thickness of the boundary film is never great enough to include all roughness particles in a continuous enveloping layer.

The data plotted by Kemler, previously cited[4], are not in general sufficiently systematic to warrant more than broad statements as to the nature of the absolute action of roughness in the sense already defined. Two conclusions are of great importance, however. One, long since recognized, is that once roughness extends inside the laminar film, the resistance to flow is greatly increased; the second is that roughness may not be defined completely by a ratio of radial dimension to pipe radius, for the plots of certain rough pipes

show complete independence of R, whereas others run approximately parallel to the minimum curve for smooth pipes (Fig. 9).

The conditions which must exist for dynamic similarity, already stated in this paper, include first that of strict geometrical similarity. Thus, in

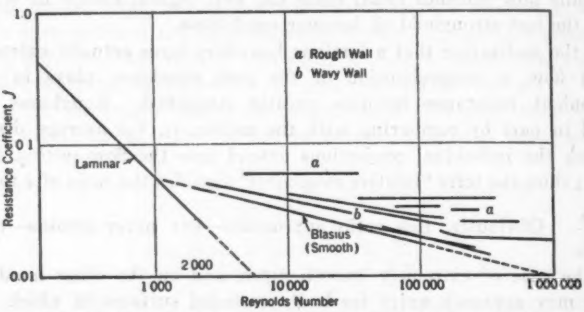

FIG. 9.—TYPICAL RESISTANCE CURVES FOR COMMERCIAL PIPE.

order for flow through any two pipes to be dynamically similar, not only must the Reynolds numbers be identical, but the entire physical character of the inside of one pipe must be similar geometrically to the other; yet this means that not only the relative roughness, but also the general form and spacing of the irregularities themselves, must be the same in each case. Obviously, the relative roughness of rivets inside a penstock may equal the relative roughness of rust tubercles or that of unevennesses in commercial asphalt-lined pipe; yet there is no reason whatever to suppose that the action of all such forms of roughness should be the same. As a matter of fact, a surface may be further defined (refer to Hopf[4]) by distinguishing between waviness and actual jagged roughness; whereas jagged roughness that breaks the continuity of the laminar film results in a constant resistance coefficient for all values of R, the waviness (corrugated, asphalt, or galvanized lining) serves to increase the resistance in such a way that it is still a function of R. Of course, it is not always possible to differentiate between the two forms, as the wall material in some cases may be a combination of both, the resistance curves then lying between the two extremes. Typical plots may be seen in Fig. 9.

As a suggested explanation of the difference in behavior between rough and wavy surfaces, the writer offers the following: When bodies of very angular profile are tested in a wind tunnel, their resistance coefficients are found to be nearly independent of the Reynolds number characterizing the flow; the turbulent wake behind such a body is then determined in size largely by the form and position of the outermost irregularities of the profile. As the angles of the body are softened, approaching the ideal stream-line form, a profile is reached for which the turbulent wake is smaller and not of constant form, actually decreasing in size with increasing Reynolds number, the resistance factor thereby dropping appreciably in magnitude. This phenomenon is explained by the fact that an increase in velocity decreases the thick-

ness of the laminar film surrounding the front of the body to such an extent that the point of separation (now a function of velocity distribution along the softened curves rather than of abrupt angularity) moves toward the rear of the body. In the completely stream-lined profile, separation and the formation of a wake are obviated. Whereas the body of irregular profile corresponds to the projections on a very rough wall and the stream-line profile typifies the smooth wall, there may be irregularities in pipe surface between the two extremes which exhibit much the same variation in turbulent "wake" as the transition profile in the foregoing illustration.

What is considered by several authorities to be a more scientific viewpoint than the notion of relative thickness of laminar film and roughness particles is the following: Every roughness protuberance may be considered to act as an individual body, to which a lower critical Reynolds number may be assigned in much the same way as is done for the plate or sphere; this number is composed of the dimension, ϵ, the kinematic viscosity of the fluid, and the velocity existing at the outermost part of the roughness projection. The latter may be computed on the basis of a linear velocity gradient in the boundary layer, with a velocity of zero at the wall itself. Thus, when the critical number for the projection in question is exceeded, separation occurs, with a resulting turbulent wake. Although it is doubtful whether roughness particles may behave in such an independent fashion unless their spacing is relatively great, several investigators have been able to compute, with fair approximation, the point at which roughness projections of known magnitude will begin to produce wall turbulence.

A great advantage of this viewpoint is the clarity it lends to the action of roughness in the laminar régime. Although the fact has already been mentioned that slight roughness has no influence in purely laminar flow, it is still possible that the local critical velocity for projections of large magnitude may be reached shortly before the critical value of R for the entire pipe. Although such individual disturbances may be dampened out before affecting the general flow, it is obvious that roughness of large magnitude may provide the initial disturbance leading to fully developed turbulence in the critical zone.

It has been stated that the resistance in the case of either roughness or waviness is a function not only of relative roughness, but also of the form and spacing of the individual particles. Not only is this complex general function still to be determined, but it is also difficult to classify the wide variety of commercial pipes accurately without further knowledge of the function itself. Such knowledge cannot come from the plentiful existing data on commercial pipes, because of the lack of systematic investigation already mentioned. However, a commendable start has been made by Nikuradse[17] and others in the investigation of controlled, artificial roughness. By means of uniform sand grains attached to the pipe wall with a thin coat of varnish, Nikuradse studied not only the similarity of flow with different pipe diameters and a constant relative roughness, but also the variation of f with roughness

[17] "Strömungsgesetze in rauhen Rohren", V. D. I., *Forschungsheft* 361, 1933.

of six different relative magnitudes, over a wide range of the Reynolds number. So systematic was his investigation that the flow behavior in all the different zones discussed previously was clearly demonstrated. Reference to the plot (Fig. 10) taken from Nikuradse's experiments will show distinctly

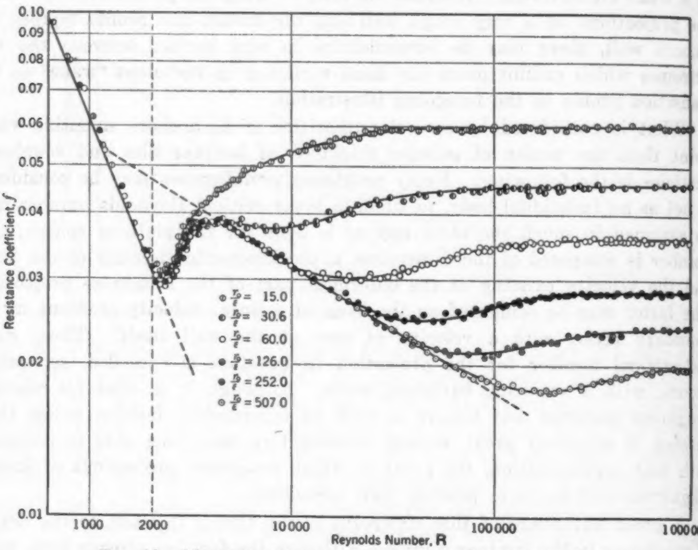

FIG. 10.—MEASUREMENTS ON ARTIFICIALLY ROUGHENED PIPE.

the regions in which the roughness particles were enveloped by the laminar film, the flow then being similar to that through a very smooth pipe. Just as distinct is the transition region, wherein the roughness particles begin to disrupt the boundary layer. Finally, Fig. 10 shows the zone in which the continuous laminar film has disappeared entirely, the friction coefficient then being dependent upon the relative roughness alone. For the last of the three zones Nikuradse has found the relationship:

$$f = \frac{1}{\left(2 \log_{10} \frac{r_0}{\epsilon} + 1.74\right)^2} \qquad (37)$$

It is to be noted that Equation (37) may be expected to apply generally only in the event that the roughness in question is geometrically similar to that of the sand coatings in Nikuradse's investigation. Any departure in the form of roughness will most certainly require different constants in this relationship, and in some cases (waviness) even a different form of equation.

Although, to a certain extent, Fig. 10 shows the systematic variation of the coefficient with a change in relative roughness, Nikuradse has indicated their very close relationship by plotting them in such a way that all points

in the third region (where f is independent of R) are superposed. As Equation (37) may be changed to read,

$$\frac{1}{\sqrt{f}} - 2\log_{10}\frac{r_0}{\epsilon} = 1.74 \quad (38)$$

which is simply a statement of the constant relationship between f and $\frac{\epsilon}{r_0}$ in this range, the use of the left-hand side of this equation as ordinates for all three regions would result in a series of points which might be expected to coincide only in the region of constant f. As abscissa was selected the quantity, $\sqrt{\frac{\tau_0}{\rho}}\,\frac{\epsilon}{\nu}$, which indicates as a dimensionless number of the Reynolds type the flow characteristics in the vicinity of the wall; that is, $\sqrt{\frac{\tau_0}{\rho}}$ has the dimension of a velocity (see Equation (13)) while ϵ is the appropriate length parameter.

A glance at this plot as reproduced in Fig. 11 will indicate at once that within the range of experimental error the resistance coefficient will lie upon

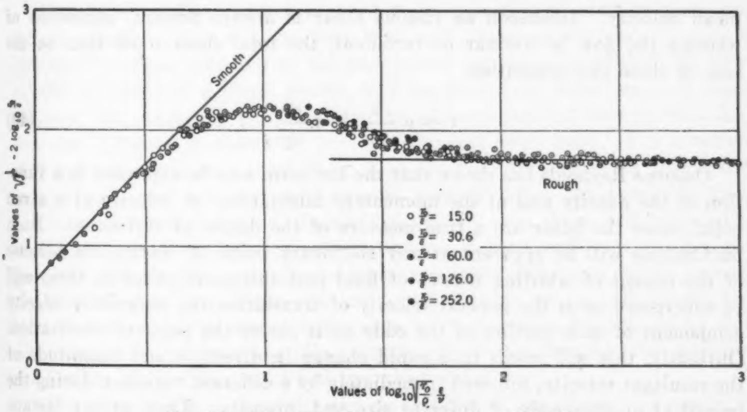

FIG. 11.—COMPOSITE PLOT OF CURVES IN FIG. 10.

a single dimensionless curve, regardless of relative roughness, so long as the roughness is of a similar nature. It is with the investigation of other types of roughness in this systematic fashion that laboratories are now engaged, with the ultimate goal of determining the proper functional relationship for major types of commercial pipe.

VELOCITY DISTRIBUTION AND THE MIXING LENGTH

Notwithstanding the fact that numerous attempts have been made during the past hundred years to formularize the velocity distribution in turbulent flow, very few expressions have been derived which apply correctly to much

more than the limited range of Reynolds numbers for which they were developed. Moreover, nearly all such empirical attempts have included only the central portions of the flow, disregarding entirely the region in the immediate neighborhood of the wall. By far the most scientific approach to the problem of energy distribution in turbulent flow is that proceeding from a general relationship developed by J. Boussinesq[18]; since the shearing stress at any point in purely laminar motion may be expressed as the product of the fluid viscosity and the velocity gradient (Equation (21)), Boussinesq reasoned that the intensity of shear in purely turbulent motion may be written in a closely parallel form,

$$\tau = \eta \frac{dv}{dy} \quad \text{.......................(39)}$$

In Equation (39), however, the factor, η, unlike μ, is not a constant for a given fluid, for it expresses the dynamic quality of the turbulent process at a given point; η will thus depend not only upon the fluid density, but upon the general state of flow and upon the point in the flow which is being considered. The gradient, $\frac{dv}{dy}$, as shown by Boussinesq, will now be that of the temporal mean velocity. Inasmuch as viscous shear is always present, regardless of whether the flow is laminar or turbulent, the total shear must then be the sum of these two quantities:

$$\tau = \mu \frac{dv}{dy} + \eta \frac{dv}{dy} \quad \text{.....................(40)}$$

Osborne Reynolds has shown that the last term may be expressed as a function of the density and of the momentary fluctuations in velocity at a given point, since the latter are a true measure of the degree of turbulence. Such fluctuations will be apparent at any stationary point of observation because of the transit of whirling masses of fluid past this point; that is, there will be superposed upon the general velocity of translation the tangential velocity component of each portion of the eddy as it passes the point of observation. Obviously, this will result in a rapid change in direction and magnitude of the resultant velocity, followed immediately by a different variation during the transit of another eddy of different size and intensity. Thus, at any instant there must be added, vectorially, to the temporal mean velocity, v, at the point in question the velocity of fluctuation, v', which varies constantly in magnitude and direction, having two essential components, v'_x, parallel to, and v'_y, normal to, the pipe wall; the third component, normal to the other two, is of no consequence in this development. It is evident that both v'_x and v'_y must yield a temporal mean value of zero; the temporal mean of the product of the two essential components, $\overline{v'_x v'_y}$, however, will always have a finite value, except at the pipe wall and pipe axis, because of a certain correlation which exists between the two components in the normal turbulent pattern.

[18] "Essai sur la théorie des eaux courantes", Mémoires présentés par divers savants à l'Académie des Sciences de l'Institut de France, Tome 23, 1877.

As a result of these velocity fluctuations, at any instant through a small increment of area, Δa, normal to the pipe radius, there will be a rate of flow equal in magnitude to $\Delta a\, v'_y$. A positive magnitude of this value denotes an instantaneous rate of flow toward the pipe axis—that is, into a region where the velocity is higher—and *vice versa*. Because of this movement into a region of different velocity, at that instant there is being transported into the neighboring region of flow either a positive or a negative increment of momentum. The component of this increment in the direction of average flow is proportional to the density, ρ, and to the velocity fluctuation in this direction, v'_x. The rate of passage in the y-direction of this axial component of the increment of momentum is then given by the quantity, $-\Delta a\, v'_y\, \rho\, v'_x$, which has the dimension of a force. The negative sign signifies that fluid moving in the negative y-direction (toward the wall) into a region of lower velocity exerts a positive force. Hence, the force per unit of area, or the apparent shearing stress due to turbulence, must have a temporal mean value of $-\rho\, \overline{v'_x\, v'_y}$, and,

$$\tau = \mu \frac{dv}{dy} - \rho\, \overline{v'_x\, v'_y} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(41)$$

Since viscous shear within a given fluid must depend entirely upon the velocity gradient, it will be evident that such viscous action has two quite different functions: Owing to the presence of innumerable eddies, the local velocity gradient at a given section may be quite high across each of these eddies at the instant of transit, the curve of instantaneous velocity distribution then differing considerably from its temporal mean form. The function of this relatively intense local shear is to dissipate the energy of turbulence as rapidly as it forms, for only through viscous action can energy of flow finally be converted into heat. In addition to such local stress within the eddy itself, however, there must be a continuous viscous resistance to general translatory movement through the pipe, the latter resistance being proportional to the gradient of the temporal mean velocity curve. Obviously, the local dissipation of energy of turbulence is of secondary importance in this discussion, however vital the rôle it must play in maintaining the essential equilibrium of the fully developed turbulent state.

It so happens, moreover, that the magnitude of the viscous resistance to the general translatory motion becomes, at high Reynolds numbers, of inappreciable magnitude in comparison with that resulting from turbulent transfer of momentum. This will be seen from Fig. 12, in which are plotted, against dimensionless co-ordinates, data found by Nikuradse for smooth pipes at Reynolds numbers ranging from slightly above the critical to a maximum of more than 3 000 000. Not only does the slope of the velocity curve in the turbulent portion of the flow decrease with increasing Reynolds number, but the total resistance as evidenced by the slope at the wall becomes ever greater as the average viscous shear in the central regions diminishes. This trend is shown in a somewhat different form by Fig. 13, in which is plotted the ratio of the average velocity to the maximum velocity as a function of the

Reynolds number, based upon the results obtained by various investigators for smooth pipes; as is readily apparent from Fig. 13, the higher the values of R, the more nearly equal the average and maximum velocities become.

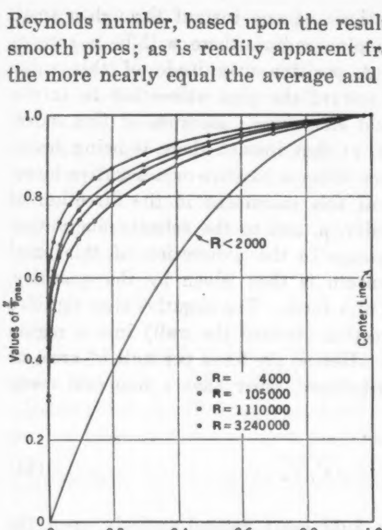

FIG. 12.—VELOCITY CURVES FOR SMOOTH PIPES.

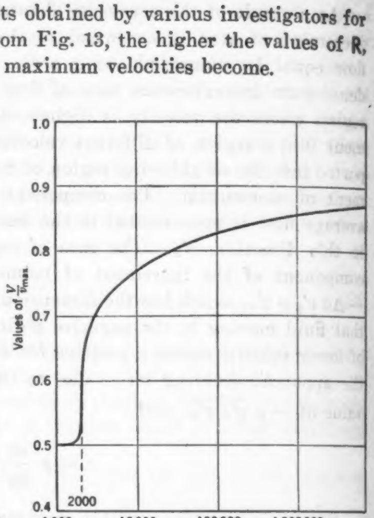

FIG. 13.—RATIO OF MEAN TO MAXIMUM VELOCITY AS A FUNCTION OF R.

Experimental results show that beyond the range of the Blasius equation for smooth pipes the term for average viscous shear may be omitted entirely without introducing noticeable error, the region of predominant viscous influence being restricted entirely to the vicinity of the pipe wall. In the case of rough pipes in the range of constant f, the turbulent action is so excessive that viscous resistance as a function of the mean velocity gradient is completely negligible in all parts of the flow. Thus, the Boussinesq concept of purely turbulent resistance in the central regions of flow is practically realized throughout the realm of high Reynolds numbers for smooth and rough pipes alike.

Before general use can be made of the Reynolds relationship for shear, it is necessary to find a means of expressing the quantity, $\overline{v'_x \, v'_y}$, in terms of known characteristics of flow. Prandtl made the first essential step in this direction by assuming a certain mixing length—analogous to the mean free path in the kinetic theory of gases—to denote the average transverse distance, in any region of the flow, over which a small fluid mass is carried by the turbulent mixing process. It then follows that the difference in average velocity between the beginning and the end of this distance (approximately equal to the product of the mixing length and the velocity gradient, $l \dfrac{dv}{dy}$) must be a measure of the component of fluctuation, v'_x, in the axial direction; furthermore, the existence of correlation between v'_x and v'_y denotes a general

proportionality between these two components; that is, the difference between the original average velocity of the particle and that of the region into which it comes must be proportional to the magnitude of the velocity fluctuations involved in this transverse motion. This proportionality may be written: $l \frac{dv}{dy} \backsim v'_x \backsim v'_y$, and $\tau \backsim \rho\, l^2 \left(\frac{dv}{dy}\right)^2$. By changing this proportionality to an equality, l will absorb the proportionality factor, and will then be completely defined:

$$\bar{\tau} = \rho\, l^2 \left(\frac{dv}{dy}\right)^2 \quad (42)$$

At this point it is interesting to note that Boussinesq's coefficient of turbulence, η, through division by the density, ρ, will take on dimensional characteristics similar to those of the kinematic viscosity, ν, the ratio then denoting the kinematic characteristics of the turbulent process in a manner quite independent of the fluid properties. By combining Equations (39) and (42), there results the following significant expression for this kinematic parameter:

$$\frac{\eta}{\rho} = l^2 \frac{dv}{dy} \quad (43)$$

Since the shearing stress at any point within the flow is inversely proportional to the distance from the wall (Equation (20)), Equation (42) then becomes:

$$\tau_0 \left(1 - \frac{y}{r_0}\right) = \rho\, l^2 \left(\frac{d\bar{v}}{dy}\right)^2 \quad (44)$$

It is to be noted that Equations (42) and (44) do not include viscous shear; hence, they cannot be expected to apply to those conditions of flow in which viscous resistance is appreciable.

Nikuradse has computed the magnitude of l from measured values of wall resistance and measured curves of velocity gradient for smooth pipes[16] over a great range of R, and for rough pipes[17] with various values of $\frac{\epsilon}{r_0}$ within the region of constant f; these values are plotted in dimensionless form in Fig. 14. In every case the mixing length has a value of zero at the wall (actually at the edge of the boundary layer, for at this point there is no further velocity fluctuation), rising to a maximum at the center. As is to be expected, the computed mixing length for smaller values of R is greater in magnitude than is actually the case, since Equation (44) ignores the viscous influence, which is still appreciable in this range of R. Beyond the limit of $\mathsf{R} = 105\,000$, however, l is practically independent of R, apparently depending only upon the relative distance from the wall. Comparison with the single curve drawn through the points for rough pipes would seem to indicate that this function is invariable, regardless of the magnitude of the relative roughness.

Thus, although viscous shear still plays an important rôle throughout the moving fluid even well past the critical zone, influencing the internal mechanism of motion (and, hence, the velocity distribution and wall resistance) this

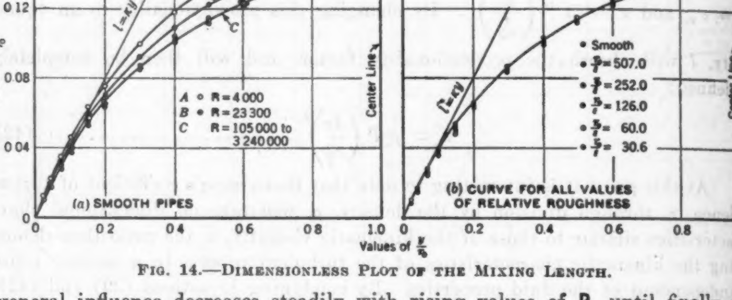

FIG. 14.—DIMENSIONLESS PLOT OF THE MIXING LENGTH.

general influence decreases steadily with rising values of R, until finally a limit is reached beyond which viscous resistance to flow is completely negligible throughout the greater portion of the pipe, being restricted to a relatively thin boundary region. Furthermore, experiments indicate that the variation of the mixing length for smooth pipes beyond this limit is identical with that for rough pipes in a corresponding range of R, showing that the internal mechanism of flow must be quite similar in all such cases.

UNIVERSAL CHARACTERISTICS OF TURBULENT FLOW

Through a statistical analysis of the velocity fluctuations at any point within turbulent movement past a fixed surface, Theodor von Kármán[19], M. Am. Soc. C. E., has concluded that (where viscous resistance to flow is negligible) there must exist a certain correlation between the components, v'_x and v'_y, regardless of the distance from this surface (excluding, of course, the boundary region). Without venturing into a detailed discussion of the theory of correlations, the following reasoning will serve to illustrate this relationship: Particles of fluid moving away from the wall into a region of higher velocity as the result of a positive v'_y-fluctuation will have an average velocity, v, smaller than that of this new region. Since this difference will appear as a negative v'_x-fluctuation at this point, it is obvious that positive values of v'_y are generally associated with negative values of v'_x and *vice versa*. Experiments made in the United States and in Europe with a hot wire anemometer capable of recording rapid fluctuations have verified von Kármán's conclusion that correlation must exist, these investigations indicating a constant correlation factor from the wall region almost to the center of the pipe.

As was shown herein under the heading "Velocity Distribution and the Mixing Length", there exists experimental evidence that the ratio of the mixing length to the pipe radius is a definite function of relative distance from

[19] "Mechanische Aehnlichkeit und Turbulenz", *Göttinger Nachrichten*, Math. Phys. Kl., 1930; see, also, by the same author, "Turbulence and Skin Friction", *Journal of the Aeronautical Sciences*, January, 1934.

the wall, and of no other characteristic of the flow. Hence, there appears to be a certain relationship between the turbulent patterns in any two pipes, regardless of pipe diameter, relative roughness, velocity, and fluid properties. As pointed out by von Kármán, the constant correlation of the components of velocity fluctuation indicates, furthermore, a similarity of the turbulent mechanism over the larger part of the cross-section of any given pipe; that is, not only should corresponding regions in two pipes show similar movement, but flow in any region in the one pipe should be similar to that in any region in the other pipe, the turbulent pattern differing only in time and length scales. (The variation in the length scale, for instance, may be typified by the variation of the mixing length, while the time scale is associated with the ratio, $\frac{dv}{dy}$.) Moreover, because of this similarity of the turbulent pattern, the conditions at any point of any flow may be expressed entirely in terms of their variation with y in the immediate vicinity of the point in question.

von Kármán has thus expressed the mean velocity, v, at a given point in terms of its variation with increments of y through expansion in a series, omitting, however, all terms after the second derivative. Then writing a general stream function in terms of this velocity series and introducing the proper time and length scales, by means of certain principles of classical hydrodynamics he has deduced the following relationship for the mixing length in terms of a universal constant:

$$l = \kappa \frac{\frac{dv}{dy}}{\frac{d^2v}{dy^2}} \quad \text{(45)}$$

The merit of this expression lies in the fact that the value of l may now be written for any point in the turbulent region without regard for distance from the wall or center line of the pipe. It is to be noted that A. Betz[20] has developed an identical equation in a different manner, working in terms of the spacing and rotational speed of an ideal group of vortices superimposed upon the general translatory motion of the fluid. This fact is quite significant in correlating the statistical method with the physical picture of the turbulent mixing process.

A simple schematic digest of the complex mathematical reasoning leading to Equation (45) is given in the following development presented by B. A. Bakhmeteff, M. Am. Soc. C. E., in his lectures on fluid mechanics. The mean velocity, v, at any two points of the flow, expressed in terms of variation with increments of y according to Taylor's theorem, will be as follows:

$$v = \phi\,(y + \Delta\, y)$$

$$v_{(y_1+\Delta y)} = v_1 + \frac{dv_1}{dy}\,\Delta\, y + \frac{d^2v_1}{d\,y^2}\,\frac{\overline{\Delta y}^2}{2} + \frac{d^3v_1}{dy^3}\,\frac{\overline{\Delta y}^3}{6} + \ldots$$

[20] "Die v. Kármánsche Aehnlichkeitsüberlegung für turbulente Vorgänge in physikalischer Auffassung", *Zeitschrift für angewandte Mathematik und Mechanik*, Band 11, 1931.

and,

$$v_{(y_2+\Delta y)} = v_2 + \frac{dv_2}{dy}\Delta y + \frac{d^2v_2}{dy^2}\frac{\overline{\Delta y}^2}{2} + \frac{d^3v_2}{dy^3}\frac{\overline{\Delta y}^3}{6} + \cdots$$

Owing to the similarity of the flow pattern at Points 1 and 2, the following proportionality must exist between corresponding derivatives of the expansion:

$$\frac{\dfrac{dv_1}{dy}}{\dfrac{dv_2}{dy}} \propto \frac{\dfrac{d^2v_1}{dy^2}}{\dfrac{d^2v_2}{dy^2}}; \quad \frac{\dfrac{d^2v_1}{dy^2}}{\dfrac{d^2v_2}{dy^2}} \propto \frac{\dfrac{d^3v_1}{dy^3}}{\dfrac{d^3v_2}{dy^3}}; \text{ etc.}$$

Omitting all terms of higher order than the second, this proportionality may then be written:

$$\frac{\dfrac{dv_1}{dy}}{\dfrac{d^2v_1}{dy^2}} \propto \frac{\dfrac{dv_2}{dy}}{\dfrac{d^2v_2}{dy^2}}$$

Obviously, each ratio has the dimension of a length, which means only that the magnitude of the ratio varies directly with the length scale of the pattern; that is, the mixing length is equal to a universal constant times the ratio of the first and second derivatives of the velocity with respect to y, as in Equation (45). In the wall region where y is very small, increments of y will be of the same order as y itself; in this region the mixing length will vary directly with y, as may be seen from Fig. 14; thus $l = \kappa y$.

The magnitude of the universal constant has been found experimentally to lie between the limits of 0.36 and slightly more than 0.40, the small discrepancy resulting to some extent from unavoidable experimental error. Variation within such narrow limits is surely sufficient reason to recognize the existence of a universal characteristic of the flow.

Darcy was probably the first to notice the resulting similarity between curves of velocity distribution in turbulent flow. Such similarity is strikingly displayed in the group of curves shown in Fig. 15(a), taken from measurements by Nikuradse. Each of these curves represents a different magnitude of relative roughness, the similarity arising from the fact that the dimensionless ordinates have been reduced to a common denominator, $\sqrt{\frac{\tau_0}{\rho}}$. The physical significance of this method of plotting is as follows: Equation (13) may be rewritten in the form:

$$\sqrt{\frac{\tau_0}{\rho}} = V\sqrt{\frac{f}{8}} \text{ and } \frac{1}{\sqrt{f}} \propto \frac{V}{\sqrt{\frac{\tau_0}{\rho}}}$$

in which the term, $\sqrt{\frac{\tau_0}{\rho}}$, has the dimension of a velocity and is known in fluid mechanics as the "friction velocity". The foregoing proportionality shows that the dimensionless ratio of mean velocity to friction velocity will

vary inversely with the square root of f, regardless of whether the wall resistance is caused by viscous shear in the laminar film of smooth pipes or by the turbulent "drag" along the walls of rough pipes. In the case of smooth pipes this ratio will increase with decreasing values of f; referred to a common friction velocity, this would mean that the central portion of the distribution curve would merely shift in one direction or the other, the velocity gradient at the walls thereby remaining constant. In the case of rough pipes in the range of constant f, this ratio would of necessity be constant for any given relative roughness, but would decrease with increasing values of $\frac{\epsilon}{r_0}$.

Furthermore, the use of the friction velocity to indicate average conditions at once establishes a similar common denominator for all portions of the flow: Mention has already been made of the fact that since the pressure is statically distributed over the pipe cross-section, the intensity of shear must be a linear function of relative distance from the wall (see Fig. 15(b)). In flow at high Reynolds numbers, in which viscous resistance in the central portion of the flow is negligible, the shearing stress must be due entirely to the turbulent exchange of momentum—and this turbulent exchange of momentum at the same time determines the velocity distribution in all regions except the immediate vicinity of the wall. Thus, regardless of what the distribution curve may be in the wall region, the ratio of velocity to friction velocity must display a similar variation over the entire central region of

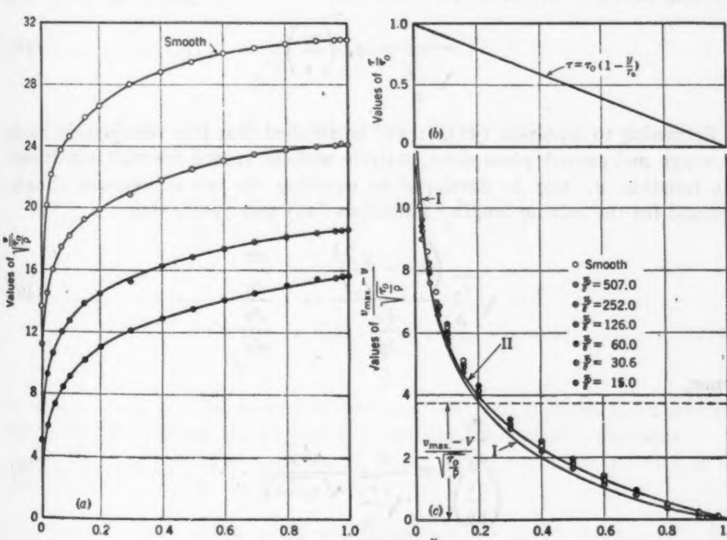

FIG. 15.—DIMENSIONLESS PLOT OF VELOCITY DISTRIBUTION FOR VARIOUS VALUES OF RELATIVE ROUGHNESS.

the flow, for smooth pipes as well as for all values of relative roughness. Hence, if the central portions of all curves in Fig. 15(a) are superposed, a single curve will result.

In other words, within the purely turbulent portion of the movement, the difference between the maximum velocity at the center and that at any other point (that is, the "velocity defect"), divided by the friction velocity, is purely a function of the relative distance from the wall. Stanton was the first to formulate this universal function:

$$\frac{v_{max} - v}{\sqrt{\frac{\tau_0}{\rho}}} = \phi_1\left(\frac{y}{r_0}\right) \qquad (46)$$

The conditions near the wall, however, are still dependent upon other influences. The velocity near a smooth surface, where viscous shear predominates, depends upon τ_0, ρ, μ, and y. A completely general expression for this universal relationship must, for dimensional reasons, have the form,

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = \phi_2\left(\sqrt{\frac{\tau_0}{\rho}}\,\frac{y}{\nu}\right) \qquad (47)$$

Similarly, the velocity in the vicinity of a rough wall, where viscous influences do not exist, will depend entirely upon τ_0, ρ, y, and ϵ. The corresponding universal function must then be:

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = \phi_3\left(\frac{y}{\epsilon}\right) \qquad (48)$$

Returning to Equation (44), it will be recalled that this relationship holds for rough and smooth pipes alike, entirely without regard for wall conditions. The function, ϕ_1, may be developed by equating the two expressions already obtained for the mixing length (Equations (44) and (45)), thus:

$$l = \sqrt{\frac{\tau_0}{\rho}}\,\frac{\left(1 - \frac{y}{r_0}\right)^{\frac{1}{2}}}{\frac{dv}{dy}} = \kappa\,\frac{\frac{dv}{dy}}{\frac{d^2v}{dy^2}} \qquad (49)$$

Hence,

$$\frac{\frac{d^2v}{dy^2}}{\left(\frac{dv}{dy}\right)^2} = \frac{\kappa}{\sqrt{\frac{\tau_0}{\rho}}}\,\frac{\sqrt{r_0}}{\sqrt{r_0 - y}} \qquad (50)$$

Equation (50) may be integrated directly, the constant of integration being found by assuming an infinite velocity gradient at the wall (this is of no

serious consequence, as the wall conditions play no part in the central regions for which the relationship is valid):

$$\frac{dv}{dy} = \frac{1}{2\kappa} \frac{\sqrt{\frac{\tau_0}{\rho}}}{\sqrt{r_0}} \frac{1}{\sqrt{r_0 - y} - \sqrt{r_0}} \qquad (51)$$

Integrating once again between the limits, $y = y$ and $y = r_0$, the final relationship is obtained, in accord with Equation (46):

$$\frac{v_{max} - v}{\sqrt{\frac{\tau_0}{\rho}}} = -\frac{1}{\kappa}\left[\log_e\left(1 - \sqrt{1 - \frac{y}{r_0}}\right) + \sqrt{1 - \frac{y}{r_0}}\right] \qquad (52)$$

A plot of the velocity defect divided by the friction velocity yields a general curve (I in Fig. 15(c)) which fits fairly well all measured values of the velocity within the central regions of flow. In order to take into consideration the outer regions, it is necessary to return to Equations (47) and (48); the only relationship commensurate with these expressions and the similarity of the turbulent pattern must be the following, first derived by von Kármán:

For smooth pipes,

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = C_1 + \frac{1}{\kappa} \log_e \left(\sqrt{\frac{\tau_0}{\rho}} \frac{y}{\nu}\right) \qquad (53)$$

and, for rough pipes,

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = C_2 + \frac{1}{\kappa} \log_e \frac{y}{\epsilon} \qquad (54)$$

With Constants C_1 and C_2 determined from Nikuradse's measurements, Equations (53) and (54) become:

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = 5.5 + 5.75 \log_{10} \left(\sqrt{\frac{\tau_0}{\rho}} \frac{y}{\nu}\right) \qquad (55)$$

and,

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = 5.85 + 5.75 \log_{10} \frac{y}{\epsilon} \qquad (56)$$

in which the value, 5.75, corresponds to $\kappa = 0.40$, and includes the conversion factor, 2.3026, between the natural and common systems of logarithms.

Writing each of these equations in terms of the maximum velocity at the distance, $y = r_0$, from the wall:

$$\frac{v_{max}}{\sqrt{\frac{\tau_0}{\rho}}} = 5.5 + 5.75 \log_{10} \left(\sqrt{\frac{\tau_0}{\rho}} \frac{r_0}{\nu}\right) \qquad (57)$$

and,

$$\frac{v_{max}}{\sqrt{\frac{\tau_0}{\rho}}} = 5.85 + 5.75 \log_{10} \frac{r_0}{\epsilon} \quad \ldots\ldots\ldots\ldots\ldots\ldots (58)$$

and subtracting Equations (55) and (56), respectively, there results the single general relationship for the velocity defect,

$$\frac{v_{max} - v}{\sqrt{\frac{\tau_0}{\rho}}} = 5.75 \log_{10} \frac{r_0}{y} \quad \ldots\ldots\ldots\ldots\ldots\ldots (59)$$

which is valid for the wall regions in either case, and, moreover, gives good results over the entire central portion of the flow (see Curve II in Fig. 15(c)).

The full significance of Equation (55) will be revealed by careful study of Figs. 16 and 17 based upon measurements by Nikuradse. In Fig. 16 the ratio

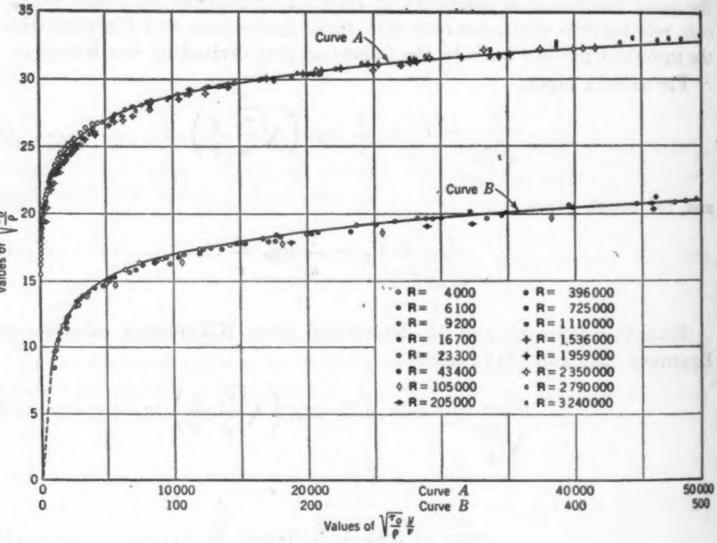

FIG. 16.

of velocity to friction velocity has been plotted as a function of the "friction-distance parameter", $\sqrt{\frac{\tau_0}{\rho}}\frac{y}{\nu}$, which is structurally equivalent to the Reynolds number; Fig. 17 is the same plot in semi-logarithmic form. In Fig. 16 the wall itself is represented by the ordinate axis, whereas the distance to the pipe center, $y = r_0$, is different for each different set of conditions, and depends entirely upon the magnitude of the friction-distance parameter. The horizontal scale of this plot has been given two different values, showing twice

the same general curve drawn through the plotted points; the more extended scale shows to good advantage the existence of the laminar film, in which the velocity distribution is practically linear.

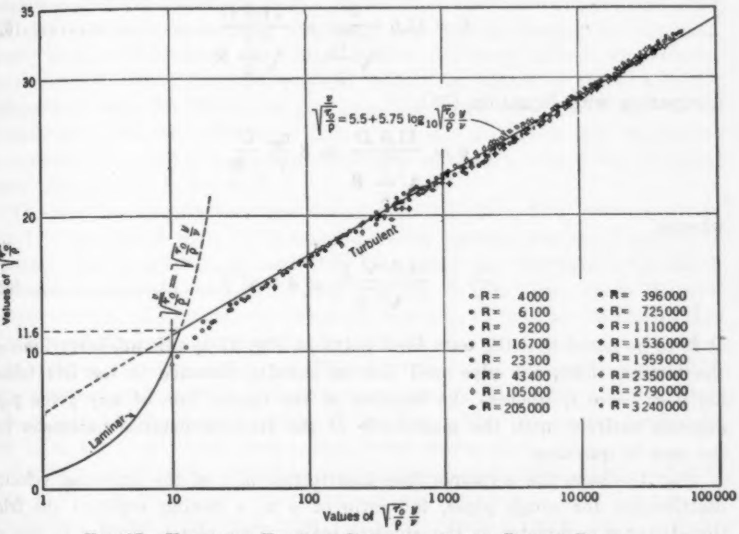

FIG. 17.—UNIVERSAL VELOCITY DISTRIBUTION FOR SMOOTH PIPES.

Equation (55) plotted in semi-logarithmic form (Fig. 17) must obviously be a straight line. Points measured by Nikuradse on smooth pipes for various values of R are seen to fall upon this linear plot throughout an extreme range of the friction-distance parameter. Even at the pipe centers (the last groups of plotted points) only a slight deviation is noticeable. The departure in the wall region is obviously the result of viscous action as the boundary film is approached; this may be further clarified by constructing the curve of laminar distribution in this film, in which the following equality will be seen to hold:

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = \sqrt{\frac{\tau_0}{\rho}}\,\frac{y}{\nu} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(60)$$

since $v = \frac{\tau_0 y}{\mu}$. Thus, the lowest measured points are seen to be in the transition zone between the laminar and the turbulent regions. Not only may the approximate thickness of the laminar film be found from this plot, but also the extent of the viscous influence in the turbulent region. By combining Equations (55) and (60), at the point of intersection,

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = \sqrt{\frac{\tau_0}{\rho}}\,\frac{y}{\nu} = 11.6 \quad \ldots\ldots\ldots\ldots\ldots\ldots(61)$$

Since this intersection of the laminar and turbulent velocity distribution curves may be chosen arbitrarily as the border of the laminar film, y will then equal δ, and the thickness of the laminar film will be given by,

$$\delta = 11.6 \frac{\nu}{\sqrt{\frac{\tau_o}{\rho}}} = \frac{11.6\ D}{\sqrt{\frac{f}{8}}\ \mathsf{R}} \quad \ldots\ldots\ldots\ldots\ldots\ldots(62)$$

Comparing with Equation (36),

$$\delta = \frac{11.6\ D}{\sqrt{\frac{f}{8}}\ \mathsf{R}} = 8\,\frac{v_w}{V}\,\frac{D}{f\ \mathsf{R}}$$

whence,

$$\frac{v_w}{V} = \frac{11.6\sqrt{f}}{\sqrt{8}} = 4.1\sqrt{f} \quad \ldots\ldots\ldots\ldots\ldots\ldots(63)$$

It is to be noted that the only fixed point in Fig. 17 is this arbitrary limit of the laminar film; the pipe wall lies an infinite distance to the left (since $\log 0 = -\infty$), whereas the location of the center line of any given pipe depends entirely upon the magnitude of the friction-distance parameter for the case in question.

Fig. 18 shows the corresponding logarithmic plot of the universal velocity distribution for rough pipes, the ratio of y to ϵ having replaced the friction-distance parameter as the abscissa scale. This plot is similar to that of Fig. 17 in all respects, except for the absence of the laminar boundary film

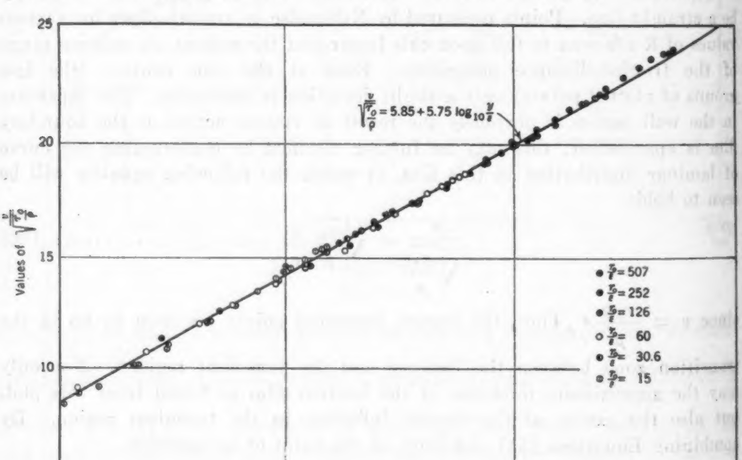

FIG. 18.—UNIVERSAL VELOCITY DISTRIBUTION FOR ROUGH PIPES.

and the accompanying viscous influence in the wall region. It will be noted that points determined by Nikuradse for various values of relative roughness fall upon a straight line even as close to the wall as the outer edges of the roughness particles (where $y = \epsilon$). Moreover, inspection of Equations (55) and (56) will show a striking similarity between the respective constants. It will be seen that, since the factor, 5.75, is the same in both expressions, the two curves have identical slopes and are simply shifted on the plot by the difference between 5.5 in the one case and 5.85 in the other. Different forms of roughness, however, will surely require a change in one or both constants; at any rate, the term, ϵ, must then denote far more than merely the extent of linear projection from the wall.

The fact has already been mentioned that the value, 5.75, corresponds to $\kappa = 0.40$ (combined with the conversion factor between the two logarithmic systems). If Equations (52) and (59) are correct for the regions for which they were developed, then they must coincide in the zone where the two regions overlap. This they will never do, however, so long as the same value of κ is used for both—as must be done if this is a true universal constant. This explains more fully why von Kármán found that κ must be about 0.36 for the central regions, and Nikuradse was forced to choose the higher magnitude of 0.40 for the outer portions of the flow. The two curves plotted in Fig. 15(c) are based upon these two different values of κ.

Furthermore, owing to the linear characteristics of Equations (55) and (56) when plotted in semi-logarithmic form, it will be evident that the velocity distribution curves computed from these relationships must have a finite slope at the pipe axis, although actual velocity curves all reach a zero slope at this point. While the discrepancy is so slight as to be entirely negligible in practice, it points to a fallacy in the fundamental assumptions upon which these expressions were based. That is, the application of Equation (45) to the entire central region of flow presumes a constant correlation of the two essential components of velocity fluctuation; actually, there is no reason to expect such correlation near the pipe axis, for points in this vicinity are practically equi-distant from either side of the pipe wall. If the assumed variation of the mixing length as expressed in Equation (45) is plotted after the manner of Fig. 14, these computed values will follow the actual curve over the greater portion of the abscissa scale, but near the center line will drop away rapidly, approaching the value of zero at the axis. Obviously, the analytical study of the velocity distribution has not quite reached perfection.

Since similarity of the turbulent mechanism has been found to result in a general function for the velocity distribution, the close relation existing between velocity distribution and shear would indicate that there is also a universal function for the resistance coefficient. Equation (55) written for the maximum velocity at the distance, $y = r_0$, and in terms of the universal constant, κ, will have the form:

$$\frac{v_{max}}{\sqrt{\frac{\tau_0}{\rho}}} = 5.5 + \frac{1}{\kappa}\log_e\left(\sqrt{\frac{\tau_0}{\rho}}\,\frac{r_0}{\nu}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (64)$$

As shown in Fig. 15(*c*), furthermore, the general nature of the velocity-defect curve must permit a direct computation of the difference between the maximum and mean velocities in terms of the common denominator, $\sqrt{\frac{\tau_0}{\rho}}$. This is nothing more than the average ordinate of the velocity-defect curve, when the latter is considered the cross-section of a surface of revolution about the center line of the pipe. The average ordinate of Curve II, therefore, may be determined as follows, as shown by Professor Bakhmeteff, through integration of Equation (59):

$$\frac{v_{max} - V}{\sqrt{\frac{\tau_0}{\rho}}} = \frac{\int_{r_0}^{0} 2\,\pi\,(r_0 - y)\,\frac{1}{\kappa}\log_e \frac{r_0}{y}\,dy}{\pi\,r_0^2} = \frac{3}{2\,\kappa} = 3.75 \quad \text{. . (65)}$$

Although Nikuradse found that a value of 4.07 would better fit experimental measurements of v_{max} and V, Equation (65) will be used without modification in the following development; it is this value which has been plotted as the mean in Fig. 15(*c*).

Subtracting Equation (65) from Equation (64), there results an expression for the average velocity of flow as a function of the friction velocity, the universal constant, and the friction-distance parameter:

$$\frac{V}{\sqrt{\frac{\tau_0}{\rho}}} = -3.75 + 5.5 + \frac{1}{\kappa}\log_e\left(\sqrt{\frac{\tau_0}{\rho}}\,\frac{r_0}{\nu}\right) \quad \text{. . . . . (66)}$$

Equation (66) may now be reduced to a more significant form through introduction of Equation (13) in the forms,

$$\frac{V}{\sqrt{\frac{\tau_0}{\rho}}} = \sqrt{\frac{8}{f}} \text{ and } \sqrt{\frac{\tau_0}{\rho}} = V\sqrt{\frac{f}{8}}:$$

$$\frac{\sqrt{8}}{\sqrt{f}} = 1.75 + \frac{1}{\kappa}\log_e\left(\frac{\sqrt{f}}{\sqrt{8}}\,\frac{VD}{2\,\nu}\right)$$

$$= 1.75 + \frac{l}{\kappa}\log_e \frac{1}{4\sqrt{2}} + \frac{1}{\kappa}\log_e(\mathsf{R}\sqrt{f})$$

Hence,

$$\frac{1}{\sqrt{f}} = -0.91 + 2.03\log_{10}(\mathsf{R}\sqrt{f}) \quad \text{. . . . . (67)}$$

Thus, a very simple relationship for the resistance factor in terms of the universal constant and the Reynolds number has been developed directly from the general expression for the velocity distribution. This basic relationship was first derived by von Kármán in terms of the maximum velocity, and

later put into the form of Equation (67) by Prandtl. With slight modification of constants according to the experimental data of Nikuradse, this basic equation finally becomes:

$$\frac{1}{\sqrt{f}} = -0.8 + 2 \log_{10} (\mathsf{R} \sqrt{f}) \quad \ldots\ldots\ldots\ldots\ldots (68)$$

Inasmuch as Equation (68) is based upon physical analysis, it might be expected to be valid (with correct constants) from $\mathsf{R} = 100\,000$ to extremely high, if not to infinite, values of R. The only drawback to its use for general purposes is the appearance of the square root of f on both sides of the equation. Although this disadvantage may be offset through use of a plotted curve, Nikuradse has suggested the empirical Equation (35), which is quite accurate for all ordinary values of R above the Blasius range, and which, moreover, may be extrapolated safely a considerable distance beyond the present limit of experimental measurements. As seen from Fig. 19, in which

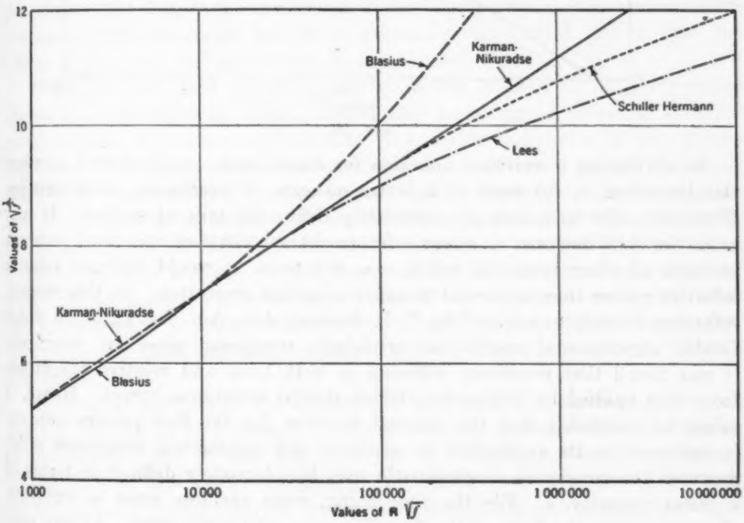

FIG. 19.

the curves of Equations (68) and (35) are practically identical, previous empirical curves deviate considerably from the linear form.

A similar operation performed on Equation (56), with slight correction of constants to conform with Nikuradse's data, results in the expression already given for the resistance in rough pipes (see Equation (38)):

$$\frac{1}{\sqrt{f}} = 1.74 + 2 \log_{10} \frac{r_0}{\epsilon}$$

The excellent agreement between Nikuradse's measurements and the linear quality of the analytical expression is shown in Fig. 20. Once again the

curves for smooth and rough pipes are seen to have the same slope, differing only in position as determined by the constants, − 0.8 and 1.74, at least for the type of roughness studied by Nikuradse.

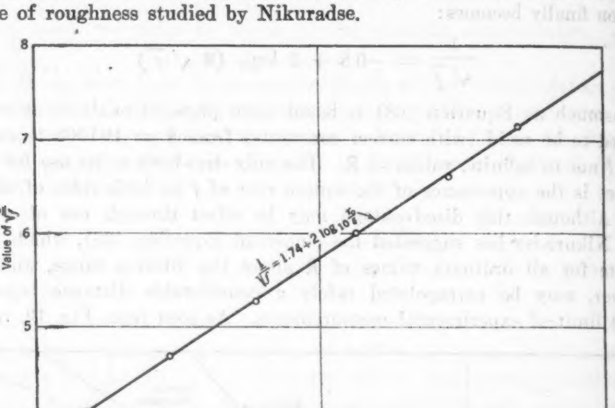

FIG. 20.

In developing a universal function for rough pipes, one is forced to adopt the dimension, ε, for want of a better measure of roughness characteristics. Obviously, this term does not completely define the type of surface. It may prove feasible, however, to adapt a linear characteristic of this kind to rough surfaces of other types, in which case the term, ε, would indicate relative behavior rather than an actual measure of radial projection. In this respect, reference is made to a paper[21] by V. L. Streeter, Jun. Am. Soc. C. E., in which further experimental results for artificially roughened pipes are described; it was found that roughness differing in both form and relative magnitude from that studied by Nikuradse yielded similar resistance curves. Hence, it might be concluded that this general function for the flow pattern actually is universal in its application to artificial and commercial roughness alike, provided the roughness characteristic may be adequately defined in terms of a linear quantity, ε. For the time being, wavy surfaces must be excepted, of course, since the form of the function may not be the same. At any rate, it has been proved conclusively that roughness dimensions alone are not sufficient indication of the resistance to flow, but must always be considered with relation to the dimensions of the pipe.

Mention must be made of the fact that, whereas the mathematical genius of von Kármán was first responsible for the development of these universal functions, several other scientists of note have deduced similar relationships in various ways; Prandtl[22] has continued to hold a foremost place in this field and it was under the latter's directorship of the Kaiser Wilhelm Institut für

[21] "Frictional Resistance in Artificially Roughened Pipes", *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 681.

[22] "Neuere Ergebnisse der Turbulenzforschung", *Zeitschrift* des Vereines Deutscher Ingenieure, Band 77, Nr. 5, 1933.

Strömungsforschung, in Göttingen, that Nikuradse conducted his extensive and systematic measurements of turbulent flow in pipes. Also from the Prandtl school has come the latest effort to study the problem of turbulence in the light of probability and statistical physics.[28]

Although such experimental data as herein cited were limited by laboratory conditions so far as wall surface and pipe diameter are concerned, a splendid beginning has been made in the experimental verification of such broad analytical deductions.

Research of the Future

Throughout this paper constant emphasis has been laid upon the necessity of systematic, physically sound investigation of fluid motion. Various schools in Europe and several of note in the United States are engaged upon such fluid research of an advanced nature, but both co-operation and correlation of effort are essential to continued progress. It is noteworthy that within the past year (1934–35), at the instigation of the World Power Conference, a committee on fluid resistance has been created in the United States with the object of planning and sponsoring organized research in this field.

What problems still remain unsolved in the domain of fluid resistance should be quite apparent. Fluid motion may no longer be classified satisfactorily simply as laminar or turbulent flow, since turbulence is not always free from appreciable viscous resistance to flow. Whereas on the one hand laminar or purely viscous motion is practically a closed book so far as general pipe resistance is concerned, on the other hand, the problem of purely turbulent motion at very high Reynolds numbers is not yet fully solved; a complete rational analysis of the inner mechanism of turbulent movement is still to be achieved, despite the success of the methods herein described; and no successful attempt has been made as yet to analyze the combined effect of viscous and turbulent shear within the lower range in which the Blasius equation applies.

Of primary interest to the engineer, of course, is the correlation between artificial roughness as produced in the laboratory, and the actual roughness of commercial pipe, if only for the range of constant resistance coefficient. Not only does this leave unexplained the entire transition region between the smooth and rough régimes, but it fails completely to consider that type of pipe of which the behavior does not fall in either category—the pipe with "wavy" surface. It is obvious that neither the existing data on commercial pipe nor the recent experiments on a few types of artificial roughness provides sufficient evidence for the formulation of general relationships including every type of roughness under every possible condition of flow.

Once the realm of pipe resistance is left, the problem becomes even more complex. Open channels present a further variable in the form of the free surface, and the question of geometrical similarity of the profile and cross-section becomes of major importance; it is still a debatable question whether the hydraulic radius may continue to prove satisfactory as a general length

[28] "Turbulenz". von H. Gebelein, Springer, Berlin, 1935.

parameter. Doubtless, however, open channel flow is of so highly turbulent a nature that viscous influences are probably quite negligible; yet this again introduces a question in the mind of the experimenter, for open flow is often simulated in the laboratory by small-scale models, in which the viscous action is most assuredly of appreciable magnitude—even far above the laminar régime.

In other fields of engineering similar problems must be encountered, for the designers of air and water craft are in much the same difficult situation in their efforts to understand the complexities of skin and form resistance. This very universality of resistance phenomena may well continue to prove an impetus toward the advancement of knowledge in this field.

Acknowledgment

For many hours of stimulating discussion and criticism during the preparation of this paper, the writer expresses his sincere gratitude to Boris A. Bakhmeteff, M. Am. Soc. C. E.

APPENDIX

List of General Symbols

$\left.\begin{matrix} M \\ L \\ T \end{matrix}\right\}$ = mass, length, and time as general dimensional terms.

F = any acting force.

I = generally, the inertial reaction to any acting force; specifically, the inertial character of flow; that is, the momentum passing a section per unit of time.

m = mass.

t = time.

V = the average velocity of flow for the entire cross-section.

v = in general, any instantaneous velocity vector; for pipe study, the temporal average velocity at any point in the cross-section.

$v_{max.}$ = the maximum value of v, occurring at the pipe axis.

p = pressure intensity.

R = Reynolds number.

f = resistance coefficient for pipes.

n = exponent in the general equation, $f = C\ \mathsf{R}^{(n-2)}$.

h = manometric head.

L = length of pipe.

D = diameter of pipe.

r_0 = radius of pipe.

r = radial distance from pipe axis.

y = normal distance from pipe wall.

ρ = density of fluid, or mass per unit of volume.

γ = specific weight of fluid, or weight per unit of volume.

g = gravitational acceleration; $g = \dfrac{\gamma}{\rho}$.

μ = viscosity of a fluid.

ν = kinematic viscosity of a fluid; $\nu = \dfrac{\mu}{\rho}$.

τ = intensity of shear at any point in the cross-section.

τ_0 = intensity of shear at the pipe wall.

ϵ = radial dimension of roughness particles.

δ = thickness of the boundary layer.

l = the mixing length.

κ = a universal constant relating to flow at high values of **R**.

ϕ = a function of.

DISCUSSION

Chesley J. Posey,[24] Jun. Am. Soc. C. E. (by letter).—In publishing this excellent paper the author has performed a service to the Engineering Profession. It summarizes, in a lucid manner, the progress made upon the important problem of fluid turbulence. The writer has recently developed an analytical approach to certain of the unsolved phases of the problem to which the author calls particular attention. Although the writer's studies are as yet in a tentative stage, it seems worth while to outline them briefly in discussion.

The author points out that one of the chief difficulties in the study of fluid resistance in rough pipes is the lack of a satisfactory measure of the roughness. The measure, ϵ, representing the radial dimension of roughness particles, is apparently only satisfactory when the particles are geometrically similar. The curves shown in Fig. 10, for artificially roughened pipe, cannot be expected to apply to other pipe as the friction factor, at large values of R, is a function not only of $\frac{r_0}{\epsilon}$, but also of other unknown factors dependent upon the geometry of the roughness. In mathematical terms:

$$f = \Phi\left(\mathsf{R}, \frac{r_0}{\epsilon}, ?, ?, ..\right) \qquad (69)$$

It is the writer's intention to point out what may be the nature of the unknown factors. The form of the function must remain to be determined experimentally.

Fig. 21 is a diagrammatic longitudinal section through the wall of the pipe, showing the inside surface. The section is long enough to include a representative sample of the "roughness." The dimension, ϵ, is of the extreme

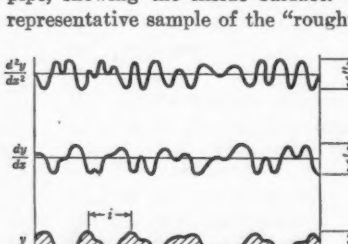

Fig. 21.—Longitudinal Section Through Pipe Wall, Showing Roughness, and Derivative Curves.

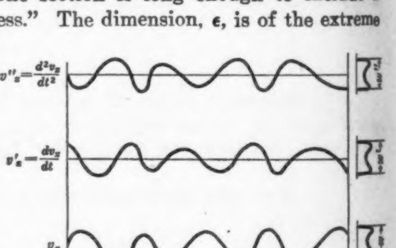

Fig. 22.—Instantaneous Velocity as a Function of Time, and Derivative Curves.

radial variation in the pipe's inner surface. Two curves are plotted above the "roughness" curve, representing its first and second derivatives with respect to the distance along the pipe. The maximum ranges of the two curves may be termed ϵ' and ϵ'', as shown. The first is obviously dimensionless, whereas

[24] Asst. Prof. of Mechanics and Hydraulics, State Univ. of Iowa; and Assoc. Engr., Iowa Inst. of Hydr. Research, Iowa City, Iowa.

the second must be multiplied by a length parameter to be dimensionless. The appropriate parameter would seem to be the average distance between successive roughness particles. Higher derivatives might be taken, but when it is noted that ϵ' is a measure of the maximum slopes of the roughness, and that ϵ'' is a measure of the sharpness of its points, it seems unlikely that higher derivatives will be needed to characterize the roughness satisfactorily. Thus:

$$f = \Phi\left(\mathsf{R}, \frac{r_o}{\epsilon}, \epsilon', i_{\infty}\, \epsilon'' \right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (70)$$

It is questionable whether experiments to determine the form of Φ should include unnatural geometrical roughnesses, but whether artificial or natural roughnesses are investigated the experiments should include a measurement of the roughness as outlined herein. The technique of making such a measurement would require taking a precise profile along a longitudinal section of the pipe by use of the recently developed "profilograph", or by other means. The derivative curves could then be constructed graphically. In commercial pipes the roughness measured in a transverse direction might be different from that measured in a longitudinal direction. It is to be hoped that the transverse roughness, where different, will have a comparatively minor effect upon the frictional resistance to flow in the pipe.

In the more general problem, there is a need for a definite measure of turbulence. It is evident that the complete picture of velocity distribution in a turbulent region at any instant can never be exactly repeated; yet the turbulent stream may be "steady" in the sense that certain measures do remain constant, statistically. For example, the average velocity at a point during successive intervals of time may remain constant if the intervals of time are long enough. The average velocity, however, is unsatisfactory as a measure of the turbulence. To arrive at a definition of the statistical measures which may be expected to provide a sufficiently precise measure of the turbulence, consider the variation of the x-component of the velocity at a point in a turbulent stream. The x-direction is understood to be the direction of the mean velocity. Fig. 22 shows an imaginary curve for v_x as a function of t. Above it are the first two derivative curves, v'_x and v''_x. At the right end of each curve is represented the frequency distribution of ordinates during equal infinitesimal increments of time. The x-component of the turbulence at one point may be said to be identical with that at another if these distributions of v_x, v'_x, and v''_x are identical at each. Distributions from higher order curves are omitted arbitrarily; perhaps that of the second order is unnecessary. The same procedure can be applied to v_y and v_z. The use of six or nine frequency distributions to measure the turbulence at a single point seems hopelessly complicated, but in many cases correlations will reduce the number, and it may be that the double-moded distributions of Fig. 22 can be represented with sufficient accuracy for experimental work by the ranges, w, w', and w''. These ranges can be reduced to dimensionless form by dividing by appropriate parameters, but this should not be done except in comparisons of geometrically similar cases.

The measure of turbulence suggested by the writer bears somewhat the same relation to von Kármán's universal relation for the mixing length as does the Eulerian viewpoint to the Lagrangian viewpoint in classical hydrodynamics. The concept of mixing length is perhaps better adapted to studies of energy loss than that of the writer, but the writer's concept would seem susceptible to more direct experimental application. Study of each may yield information valuable in the development of the other.

S. Franz Yasines,[28] Assoc. M. Am. Soc. C. E. (by letter).—An excellent résumé of the investigations that have been made in this field of fluid turbulence since the middle of the Nineteenth Century, is contained in this paper.

Because the current mathematical, as well as the physical, knowledge of many fluid-flow problems is limited, present-day investigators are forced to idealize the conditions in such problems, in order to save time and labor in actual research in the laboratories; and in this manner they find at least a partial solution of a problem in an empirical form. When an attempt is made to imitate Nature in the laboratory, in performing tests on models, the investigator frequently resorts to such guides as Froude's or Reynolds' numbers. Often he finds that they fail to perform their functions. Is this because their true meanings (and hence their limitations in application to actual problems) are not understood?

Some hydraulicians maintain that Reynolds' number is the ratio of inertial force to that of frictional force in a given flow. Such a definition is confusing when flow in a straight pipe of uniform cross-section is under consideration. The Newtonian principle of momentum may be applied to a flow confined in such a conduit, but at a constant rate of flow the rate change of momentum is zero; hence, the inertial force in this particular flow must also be zero. Therefore, if Reynolds' number is to be defined as the ratio of inertial force to frictional force, it must be zero for any constant rate of flow in a conduit of uniform cross-section.

The brief derivation of Reynolds' number, presented by the author, leads to the conclusion that the only forces governing the flow of fluids in pipes are frictional and a certain fictitious force which he terms "the rate of passage of momentum." What is the latter force? Why not consider pressure force, since it is known definitely that the governing forces in the problem of motion under consideration are friction and pressure? The rigorous mathematical derivation of Reynolds' number is by no means easy when a physical conception of the problem is to be formulated. Considering, for example, the application of dimensional analysis (π-theorem) to the flow (at constant rate) in a conduit of uniform cross-section, it is possible to obtain the proper relation among the variables which indicates the presence of Reynolds' number, provided the independent variables are properly selected. On the other hand, how is one to know at the beginning of the analysis what variables are to be considered as being independent if no experimental data are available?

---

[28] Instr. in Civ. Eng., Coll, of Eng., New York Univ., New York, N. Y.

By using the Navier-Stokes equation of motion and the Newtonian principle of dynamic similarity, it can be proved that the ratio of inertial force to that of frictional force may be equal to zero or to unity (depending upon the assumption made in the physical analysis of the flow), and yet Reynolds' number does appear as a governing factor for similarity of flow.

The reliability of investigations of the boundary layer with a thickness of 0.001 ft, by means of specially designed Pitot tubes, is questionable. Instruments based on electrical rather than physical principles would be more reliable in the study of such complex problems.

The writer agrees with the author that a more specific definition of surface roughnesses should be established. This can be done since apparatus for this purpose is already available.

Since the contemporary hydraulician has inherited a large amount of information from his predecessors and has the opportunity of resorting to efficient physical tools for the study of various types of fluid flow, there is good reason to believe that he may solve many intricate problems; but, in order to do so, a closer co-ordination among hydraulicians and physicists is essential.

BENJAMIN MILLER,[26] ESQ. (by letter).—The study of turbulent flow in commercial pipe has been conducted along both analytical and empirical lines. The author has referred to work of both types, and gives the impression that whereas great strides have been made on the analytical side, the empirical studies have not been of much help, and that as yet the engineer cannot use the results of recent work for design. The writer feels that the picture is rather different, that the analytical methods described are far from satisfactory, but that fluid-flow rate can now be predicted with great accuracy by means of the empirical relationship given in the paper. That empirical relationship is due entirely to experiment, and owes nothing to analytical work. A rational analysis of turbulent flow should lead to the same relationship as that found empirically. The methods described in the paper do not, but improved methods of the future may.

Before giving reasons for these statements, the writer wishes to point out that the law of viscous flow was discovered by Hagen in 1839 and established beyond doubt by Poiseuille in 1842, but it was not until 1856 that Wiedemann derived the law analytically. The law of turbulent flow was first published in 1932, although experimental work was available previously on which it might have been based. Perhaps, by 1946, an analytical derivation of it may have been developed.

The law of turbulent flow to which the writer refers is the author's Equation (68). Mr. Rouse states that the appearance of the square root of f on both sides of the equation is a drawback to its use for general purposes; but this is a drawback only because of the habit of thinking in terms of f, which in turn, comes about through thinking of the pressure drop required to maintain a given flow rate. If, however, one thinks in terms of the flow rate

[26] With Cities Service Co., New York, N. Y.

which can be maintained by a given pressure drop, one may transform Equation (68) into,

$$\frac{m}{t} = \frac{\pi}{\sqrt{8}}\left(D^5 \rho \frac{dp}{dL}\right)^{0.5}\left(\log_{10} \frac{D^3 \rho \frac{dp}{dL}}{\mu^2} - 0.5\right) \quad \ldots\ldots(71)$$

Introducing the following symbols:

For the flow rate,

$$Q = \frac{m}{\rho t} \quad \ldots\ldots(72)$$

for the pressure gradient,

$$G = \frac{dp}{dL} \quad \ldots\ldots(73)$$

and, for the von Kármán number[37],

$$K = \frac{D^{1.5} \rho^{0.5} G^{0.5}}{\mu} \quad \ldots\ldots(74)$$

Equation (71) becomes,

$$Q = \frac{\pi}{\sqrt{2}}\left(D^5 \frac{G}{\rho}\right)^{0.5} (\log_{10} K - 0.25) \quad \ldots\ldots(75)$$

Equation (75) is suitable for general use. It describes, accurately, the turbulent flow in commercial steel pipe. The flow through pipe lines will be less because of the pressure drops at joints, bends, fittings, etc.

The development of Equation (75) is detailed in the paper previously cited.[37] The author's Equation (8) may be used as a starting point, but it is written instead,

$$V = \phi_1 (D, \rho, \mu, \tau_0) \quad \ldots\ldots(76)$$

Since Q is proportional to V,

$$Q = \phi_2 (D, \rho, \mu, \tau_0) \quad \ldots\ldots(77)$$

By dimensional analysis Equation (77) transforms to,

$$Q = \left(D^5 \frac{G}{\rho}\right)^{0.5} \phi_3 (K) \quad \ldots\ldots(78)$$

and Equation (78) is put into the explicit form of Equation (75) by the empirical method of plotting the results of the various investigators, such as Stanton and Pannell, Nikuradse, etc.

Equation (75) is represented well by the author's Equation (35) between Reynolds numbers of 10^5 to 10^7, but it is not restricted to this region. Actually, it coincides with experiment down to the beginning of the turbulent régime. As mentioned previously, it applies to pipe, and not necessarily to pipe lines. However, there are commercial pipe lines in which the flow is more than 95% of that calculated by Equation (75), and it is an unusual line in which the flow is less than 90% of that so calculated.

[37] *Transactions*, Am. Inst. Chem. Engrs., Vol. 32 (1936), p. 1.

The author does not consider that the methods of analysis described in the paper are perfect. He does indicate that, although there is a fallacy in the fundamental assumptions, the discrepancy thus introduced is so slight as to be entirely negligible in practice. Rather than pick out the discrepancies, the writer suggests that the problem be re-examined in the light of what is known.

In turbulent flow, as in viscous flow, there must be maximum velocity at the center and zero velocity at the wall. Furthermore, there must be a viscous drag proportional to the rate of change of velocity.

These statements may be expressed as follows: $v = 0$ at $r = r_0$; $\frac{dv}{dr} = 0$ at $r = 0$; $\mu \frac{dv}{dr} = \tau_0$ at $r = r_0$; and,

$$\tau = \mu \frac{dv}{dr} + f(r) = \frac{\tau_0 r}{r_0} \qquad (79)$$

The law of turbulent flow (Equation (75)), is:

$$2\pi \int_0^{r_0} r\, v\, dr = \frac{\pi}{\sqrt{2}} \left(D^5 \frac{G}{\rho} \right)^{0.5} (\log_{10} K - 0.25) \qquad (80)$$

Any analytical expression for v as a function of r must meet all these conditions. Assumptions which lead to infinite velocity gradient at the wall and infinite velocity at the center may be interesting, but they can not be correct.

Ralph W. Powell,[28] M. Am. Soc. C. E. (by letter).—The title of this paper is perhaps too broad, as it scarcely covers the entire subject of fluid turbulence. The question of turbulence as it affects problems in aeronautics[29] and the transportation of sediment in streams[30], for instance, is scarcely touched upon. As a résumé of present knowledge on the flow in pipes, however, the paper is excellent. The only other adequate treatment of the subject in English, as far as the writer knows, is that given by Prandtl and Tietjens[31], and the author has improved upon this study at several points. (However, he has not included all the interesting material given therein as, for instance, the "length of transition" at the entrance, the intermittent occurrence of turbulence in the critical range, the effect of convergent and divergent flow, and the seventh-root law of velocity distribution.)

In studying through parts of the paper with a graduate class in fluid mechanics, one idea has occurred to the writer which is perhaps worth noting. In the paragraphs following Fig. 8 the author assumes a linear distribution of velocity in the boundary layer. This simplifies the mathematics, but is contrary to the fact shown in Equation (25) that for stream-line flow the velocity distribution is parabolic. As a matter of fact, the assumption is unnecessary.

[28] Assoc. Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

[29] See, for example, "Applied Hydro- and Aeromechanics", by Prandtl and Tietjens, Chapters IV, V, and VI, N. Y., McGraw-Hill Pub. Co., 1934.

[30] "Review of the Theory of Turbulent Flow and Its Relation to Sediment Transportation", by Morrough P. O'Brien, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Geophysical Union, April, 1933, pp. 487–491.

[31] "Applied Hydro- and Aeromechanics", Chapters III and IV, N. Y., McGraw-Hill Pub. Co., 1934.

One can assume that the flow in the boundary layer obeys exactly the same laws as in the case of laminar flow, but that τ_0, the intensity of shear at the pipe wall, has the value of turbulent flow. Combining Equations (13) and (25):

$$v = \frac{f \rho V^2}{16 \mu} \left(\frac{r_0^2 - r^2}{r_0} \right) \qquad (81)$$

which will hold within the boundary layer only. Taking, as the author does, v_w as the velocity at the inner surface of the boundary layer, and δ as the thickness of the boundary layer, and substituting $v = v_w$, $r = \frac{D}{2} - \delta$, and $r_0 = \frac{D}{2}$ in Equation (81), and solving for δ:

$$\delta = \frac{D}{2} \left\{ 1 - \left(1 - \frac{32}{f \mathsf{R}} \frac{v_w}{V} \right)^{\frac{1}{2}} \right\} \qquad (82)$$

Expanding Equation (82) by the binomial theorem and dropping all except the first term gives Equation (36). The difference between the two expressions will be largest when $f \mathsf{R}$ is smallest; that is, just above the critical region, say, when $\mathsf{R} = 3\,000$. Then Equation (32) gives $f = 0.0428$ and $f \mathsf{R} = 128$. If $\frac{v_w}{V} = \frac{1}{2}$, as assumed by the author in his example, Equation (36) gives $\delta = 0.03125\, D$ and Equation (82) gives $\delta = 0.03229\, D$, or 3.3% greater thickness of boundary layer. For larger values of R the relative error is less, and the absolute error very much less. Thus, the author's assumption is satisfactory for purposes of calculation, but it is not necessary to think of the velocity in the boundary layer as varying uniformly.

One other fact may be added. If Equations (32) and (35) are solved simultaneously, $\mathsf{R} = 117\,500$; that is, Equation (32) may be taken as the law of fluid friction in smooth pipes up to a Reynolds' number of 117 500 and Equation (36) beyond that point. As both these equations are empirical, it is probable that there is actually no sudden change of law.

JOE W. JOHNSON,[32] JUN. AM. SOC. C. E. (by letter).—An extremely timely summary of the modern conceptions and theories of the mechanics of fluid turbulence is offered in this paper. The presentation is clear and orderly and contains a consistent and logical system of notation. The application of these principles affords new methods of approach to many complex hydraulic problems.

One such application, for example, is the problem of silt transportation advanced by W. Schmidt[33] and outlined by Morrough P. O'Brien[34], Assoc. M. Am. Soc. C. E., in 1932, in a review of the theory of turbulent flow and its

[32] Care, SCS, U. S. Dept. of Agriculture, Washington, D. C.

[33] "Die Massenaustauch in freien Luft und verwandte Erscheinungen", von W. Schmidt, H. Grand, Hamburg, 1925.

[34] "Review of the Theory of Turbulent Flow and Its Relation to Sediment Transportation", by Morrough P. O'Brien, *Transactions*, Am. Geophysical Union, Hydrology Section, 1933.

relation to silt transportation in open channels. In later papers, Messrs. J. B. Leighly[35] and J. E. Christiansen[36] discussed Professor O'Brien's paper and reported encouraging results in comparing measured silt distribution and theory. The silt referred to is the solid matter transported in suspension, but not that which moves as bed-load. It is recognized, of course, that there is no dividing line between the classifications. Therefore, in view of the fact that the difference between suspended load and bed-load is purely arbitrary, it is fairly reasonable to believe that the theories discussed by the author and by Professor O'Brien may ultimately provide an adequate and accurate relation between bed-load transportation and certain hydraulic elements.

The Prandtl-von Kármán theory of velocity distribution in turbulent flow can also be applied to open channels of great widths where the lines of equal velocity are parallel to the channel bed and viscous resistances are assumed to be negligible. Equation (52) as developed for pipes, is a general equation for turbulent flow in either tubes or open channels. For open channels, the expression for the distribution of velocity in the central region of the flow is:

$$\frac{v_{max} - v}{\sqrt{\frac{\tau_0}{\rho}}} = -\frac{1}{\kappa}\left[\log_e\left(1 - \sqrt{1 - \frac{y}{d_0}}\right) + \sqrt{1 - \frac{y}{d_0}}\right] \ldots\ldots (83)$$

or,

$$\frac{v_{max} - v}{\sqrt{\frac{\tau_0}{\rho}}} = \phi_1\left(\frac{y}{d_0}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (84)$$

in which τ_0 is the intensity of shear at the channel bottom; d_0, the depth of flow, or the distance from the bottom to the point of maximum velocity when the maximum velocity is below the water surface; and y, the distance of the velocity measurement, v, from the channel bottom (see Fig. 23).

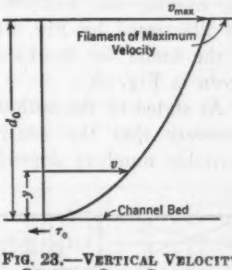

FIG. 23.—VERTICAL VELOCITY CURVE IN OPEN CHANNEL.

Equation (84), derived without regard to wall conditions, gives a theoretical velocity distribution only in the central regions of flow. Another equation must now be derived for the velocity distribution near the wall. Substitution of Prandtl's mixing length as given by the relation,

$$l = \kappa\, y \ldots\ldots\ldots\ldots\ldots (85)$$

into Equation (44) gives the expression,

$$\frac{dv}{dy} = \frac{1}{\kappa\, y}\sqrt{\frac{\tau_0}{\rho}}\sqrt{\frac{d_0 - y}{d_0}} \ldots\ldots\ldots\ldots\ldots\ldots (86)$$

[35] "Turbulence and Transportation of Rock Débris by Streams", by J. B. Leighly, *The Geographical Review*, Vol. XXIV, No. 3, July, 1934.

[36] "Distribution of Silt in Open Channels", by J. E. Christiansen, *Transactions*, Am. Geophysical Union, Hydrology Section, 1935, p. 478.

Integration of Equation (86) with the condition that $v = 0$ when $y = 0$, gives,

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = \frac{2}{\kappa}\left[4 + \sqrt{1 - \frac{y}{d_0}} - \tan h^{-1}\sqrt{1 - \frac{y}{d_0}}\right] \ldots\ldots\ldots (87)$$

or,

$$\frac{v}{\sqrt{\frac{\tau_0}{\rho}}} = \phi_2\left(\frac{y}{d_0}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (88)$$

Of primary interest to the hydraulic engineer, of course, is the agreement between the foregoing theoretical formulas and experimental data. For illustration in this respect, vertical velocity curves will be used, that were measured by the writer in connection with research work at the U. S. Waterways Experiment Station, at Vicksburg, Miss. These experiments consisted of complete velocity traverses at a section near the center of a tilting rectangular flume, 45 ft long, 2.313 ft wide, and 1.3 ft deep, with smooth cement lining. The flume was given slopes of 0.0002, 0.0005, 0.0010, 0.0015, 0.0020, and 0.0040. At all times the water-surface slope was maintained parallel to the channel bottom. Velocities were measured by an accurately calibrated Pitot tube, which was mounted on the lower end of an ordinary laboratory gage which, in turn, was mounted on a rack that traveled upon a horizontal bar. The horizontal bar support was graduated along the top side to 0.01-ft intervals, and the laboratory gage read to 0.001 ft. With this precise horizontal and vertical control, it was possible to place the Pitot tube at identical locations for all tests and check measurements. The number and location of velocity observations in a typical cross-section are illustrated by Fig. 24. Average vertical velocity curves in the center of the flume for depths of 0.10 ft and 0.20 ft and for various slopes are shown in Fig. 25.

As stated by the author in referring to straight tubes, it was an important discovery that the relative motion of the particles at moderately large Reynolds numbers depends on the fall in pressure and not at all on the

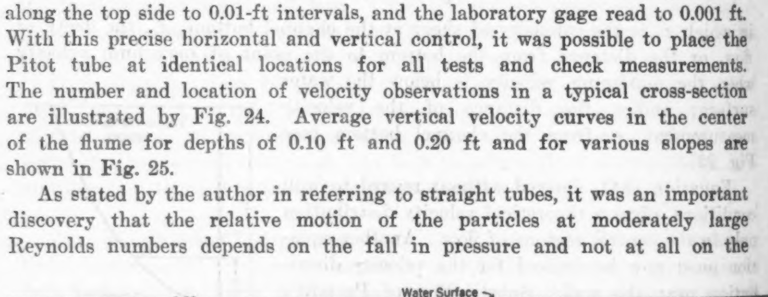

FIG. 24.—DISTRIBUTION OF VELOCITY AND

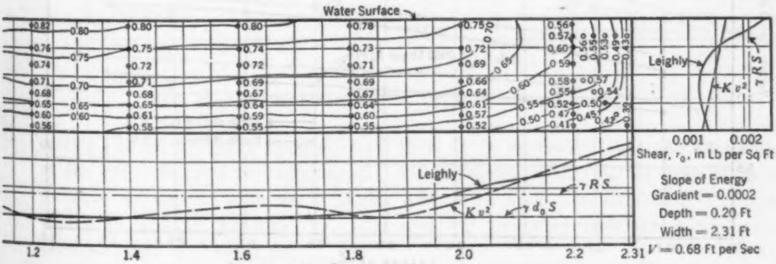
character of the wall, so that, therefore, with constant fall in pressure, the velocity distribution curves in tubes with different values of relative roughness can be brought into conformity by shifting them along the velocity axis. The single curve resulting from superimposing the central parts of the curves in Fig. 15(a) of the paper is evidence of this fact; but it is not true, of course, for the layer in immediate contact with the wall, where the velocity increase is greater on a smooth surface than on a rough one. Comparable to this for open channels would be the vertical distributions in channels of infinite width in which surface roughness, depth of flow, and the slope of the energy gradient have been adjusted so that the bottom shearing force given by $\gamma\, d_0\, S$ is a constant. In channels of finite width, however, the question of the effect of shearing force along the side walls, as well as the bottom, becomes important. In this case the bottom shear is no longer equal to $\gamma\, d_0\, S$. Where flow resistance at the side walls is appreciable, the average shearing force on the side walls and bottom is given by $\gamma\, R\, S$, in which R is the hydraulic radius and S = slope of the energy gradient. As illustrated by Fig. 24, the shearing force on the bottom exceeds the average value in most cases and approaches, but should not equal, $\gamma\, d_0\, S$. A dimensionless plot similar to Fig. 15(a) is not attempted in this discussion, but a plot of velocity distribution is presented (Fig. 26) for those cases in which the bottom shearing force, as given by equal values of $\gamma\, d_0\, S$, is approximately constant. These velocity distribution curves differ slightly due to the fact, no doubt, that the bottom shearing forces may be (and are, perhaps, not) constant for any two pair of curves (analogous to this in pipe flow would be the condition in which fall in pressure is not constant); nevertheless, by superimposing those curves in which the values of the bottom shearing forces are approximately equal, it is evident that similar flow conditions will occur in the central region of the flow when the value of the bottom shearing force is a constant.

As a means of further comparison, the dimensionless plot defined by Equation (84), and presented in Fig. 27, is made for the same velocity distribution curves as those in Fig. 26. Since the value of the bottom shearing force, τ_0, is not accurately known, the mean value, $\gamma\, R\, S$, is used for illustrative purposes; also included in Fig. 27 for comparison are plots of the theoretical formulas, Equations (83) and (59). It is obvious from an exami-



SHEARING FORCES IN RECTANGULAR FLUME.

nation of Fig. 27 that the experimental curves differ from the theoretical curves by amounts too large to be attributed to experimental errors. This difference is due to several fundamental and important factors. The assump-

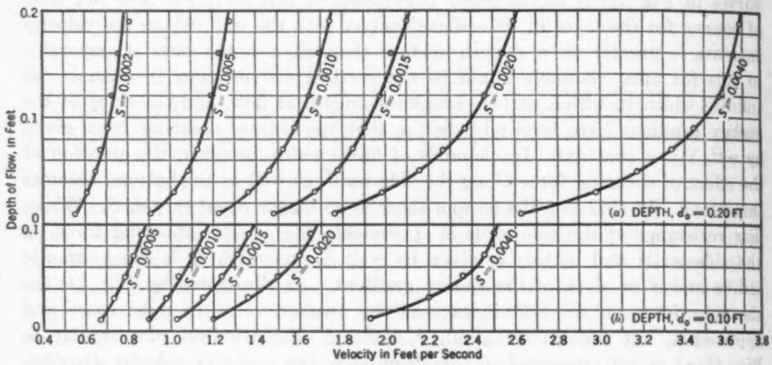


FIG. 25.—VERTICAL VELOCITY CURVES ALONG THE CENTER LINE OF A RECTANGULAR FLUME, 2.31 FEET WIDE.

tion that the bottom shearing force, τ_0, is equal to $\gamma R S$, or the fact that the value of the universal constant may be different from 0.40, does not alone account for the departure of the experimental velocity distribution from the theoretical one. Of perhaps more importance is the fact that the velocity distributions presented in Fig. 25 were observed in a channel of finite width, where the frictional resistance exerted by the side walls is appreciable.

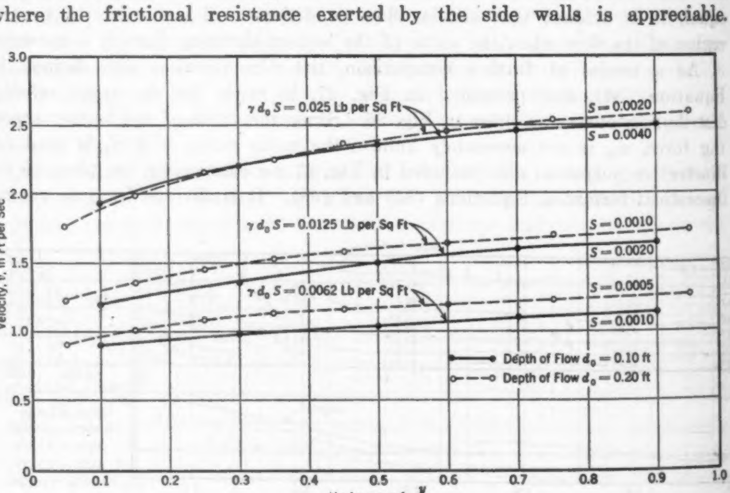

FIG. 26.—VELOCITY DISTRIBUTION IN OPEN CHANNELS WHERE BOTTOM SHEARING FORCES ARE APPROXIMATELY CONSTANT.

Therefore, the curves are the resultant of shearing forces exerted by both the bottom and the side walls and are not the velocity distributions resulting from shearing forces exerted only by the bottom. It is to be anticipated that frictional forces exerted by side walls tend to present experimental curves that are more erect than theoretical curves.

Although not considered in the foregoing discussion, it is of primary importance to recognize that the energy of water flowing in open channels is not dissipated by frictional resistances only. In the general case energy is used in several different ways, the most important of which are: (*a*) In overcoming frictional resistances of drag along the channel walls; (*b*) in overcoming resistances due to purely viscous shearing forces; (*c*) in transporting solids; (*d*) in the alteration of the channel cross-section; (*e*) in creating and maintaining waves on the surface of the stream; and (*f*) in creating and maintaining sand ripples. Although Factor (*a*) is perhaps the most important

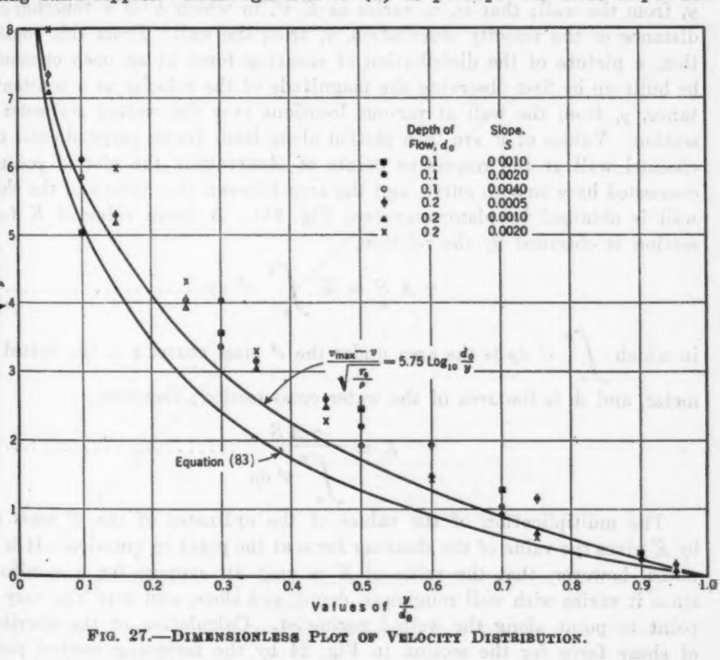

FIG. 27.—DIMENSIONLESS PLOT OF VELOCITY DISTRIBUTION.

energy loss in ordinary open-channel flow, it is necessary that the existence of the other factors be recognized. An example in this latter respect is a movable-bed model with sand banks and sand bed. In this case the loss of energy due to Factors (*c*), (*d*), and (*f*) probably assumes a value in excess of that of Factor (*a*).

The assumption that the bottom shearing force is evenly distributed over the wetted perimeter (that is, $\tau_0 = \gamma R S$) is merely an approximation

as is shown by the irregularities in the isovels. That the trace of the isovels in a stream cross-section and the distribution of shearing force over the wetted perimeter are inextricably related was recognized by Leighly[27]. In 1932, he described a European method of approximating the distribution of shearing force, which consists in dividing the wetted perimeter into equal lengths and drawing from the dividing points between these areas, lines, perpendicular to the equi-velocity lines. The areas bounded by the perimeter, the line of maximum velocity, and the orthogonal lines are proportional to the shear at the bottom. The result of such an analysis for the cross-section shown in Fig. 24 is plotted below the section. For comparison, a plot of the average distribution of shear, as given by $\gamma\ R\ S$, and the bottom shear, as given by $\gamma\ d_0\, S$, are also given. Another approach to approximating the distribution of shear along the wetted perimeter is from the consideration that the shear is proportional to the square of the velocity measured at a distance, y, from the wall; that is, τ_0 varies as $K\ v^2$, in which K is a function of the distance of the velocity observation, v, from the wall. From this consideration, a picture of the distribution of shearing force in an open channel can be built up by first observing the magnitude of the velocity at a constant distance, y, from the wall at various locations over the wetted perimeter of a section. Values of v^2 are then plotted along lines drawn perpendicular to the channel wall at the respective points of observation, the plotted points are connected by a smooth curve, and the area between the curve and the channel wall is obtained by planimeter (see Fig. 24). A mean value of K for the section is obtained by the relation,

$$\gamma\ A\ S = K \int_0^p v^2\ dp \qquad (89)$$

in which $\int_0^p v^2\ dp$ is the area under the v^2 mass curve, p is the wetted perimeter, and A is the area of the water cross-section; therefore,

$$K = \frac{\gamma A S}{\int_0^p v^2\ dp} \qquad (90)$$

The multiplication of the values of the ordinates of the v^2 mass curve by K gives the value of the shearing force at the point in question. It is to be noted, however, that the value of K is only an average for a specific case since it varies with wall roughness, depth, and slope, and may also vary from point to point along the wetted perimeter. Calculation of the distribution of shear force for the section in Fig. 24 by the foregoing method yields a distribution that compares quite well with the distribution obtained by applying Leighly's method. Of particular interest is the variation in shearing force distribution resulting when various depths and slopes were introduced into the flume, calculation of shearing force being made by the v^2 mass-curve method. The total shearing force exerted by the side walls is equal to

[27] "Toward a Theory of the Morphologic Significance of Turbulence in the Flow of Water in Streams", by J. B. Leighly, Univ. of California, *Publications in Geography*, Vol. 6, No. 1, 1932, Univ. of California Press, Berkeley, Calif.

the areas under those parts of the shearing-force distribution diagram which have the side walls as bases. The percentage of the total shearing force exerted by the two side walls was found to vary with depth and to be a constant for a particular depth, regardless of slope. Fig. 28 shows a plot of the percentage of shearing force exerted by the side walls for various depths of flow in the flume.

The information presented in Fig. 28 gives a picture of the magnitude of the error introduced when it is assumed that the total energy of a flowing stream is dissipated in frictional resistances along only the channel bottom. This erroneous assumption is particularly serious in flume studies of the transportation of bed-load material. The usual procedure in such work has been to attempt to correlate the rate of bed-load movement (in pounds per hour per foot width of flume) with the tractive force (in pounds per square foot) as calculated by the term, $\gamma\ d_0\ S$.

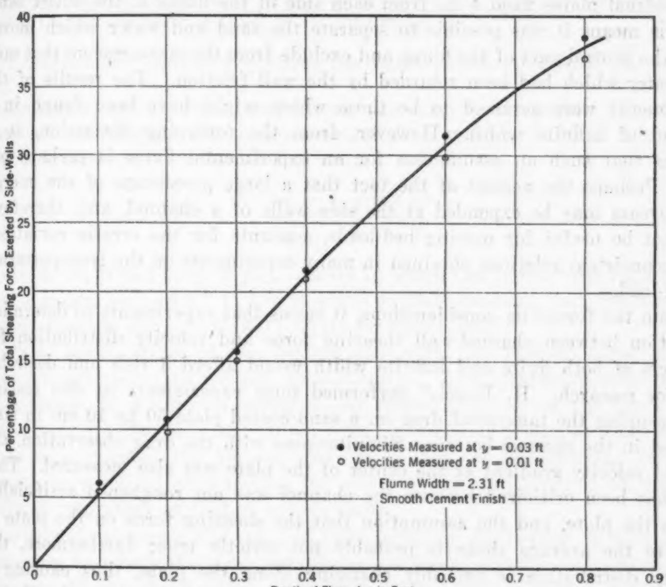

FIG. 28.—RELATION OF DEPTH OF FLOW AND SHEARING FORCE EXERTED BY SIDE WALLS.

Examination of Fig. 28 shows clearly that the difference between the true value of the bottom shearing force and the value of $\gamma\ d_0\ S$ varies with the depth of flow. Of particular importance is the fact that for a certain depth, d_0, this difference becomes less than is shown in Fig. 28 if the bottom roughness is made rougher than the side walls; that is, for example, in the case of the sand bed in the ordinary, smooth-wall, experimental flume the bed roughness increases with increased height of sand ripple, the result being a decrease in the percentage of the total shearing force exerted by the side walls

(depth and slope, of course, are held constant as sand ripples change form). In his experiments on the transportation of bed-load, Hans Kramer, M. Am. Soc. C. E.[38], attempted to correct the condition of unequal bottom and wall roughness by roughening the side walls artificially with sand sprinkled on a coat of wet oil paint to which the grains adhered after the paint dried. Although this procedure is fundamentally sound, it is doubtful whether this type of roughness is effective in reducing the percentage of the shearing force that is exerted on the side walls to the value where the bottom shear can be considered equal to $\gamma\ d_0 S$ as in a channel of infinite width. In this case the use of the average shearing force, as given by the term, $\gamma\ R\ S$, perhaps, gives a better approximation of the value of the bottom shear. Another method of reducing the effect of frictional resistances at the side walls is an arrangement used by C. H. MacDougall[39] for diverting the sand and the water which flowed adjacent to the walls of the channel. This was done by two longitudinal plates fixed 4 in. from each side of the flume at the outlet tank. By this means it was possible to separate the sand and water which moved down the central part of the flume and exclude from the measurement that sand and water which had been retarded by the wall friction. The results of the experiments were assumed to be those which might have been found in a channel of infinite width. However, from the foregoing discussion, it is obvious that such an assumption for an experimental flume is perhaps not true. Perhaps the neglect of the fact that a large percentage of the energy of a stream may be expended at the side walls of a channel, and, therefore, may not be useful for moving bed-loads, accounts for the erratic variations and inconsistent relations obtained in many experiments on the transportation of bed-load.

From the foregoing considerations, it seems that experiments to determine a relation between channel-wall shearing force and velocity distribution for channels of both finite and infinite width would afford a rich and desirable field for research. H. Engels[40] performed some experiments in this respect by measuring the tangential drag on a sand-coated plate 50 by 10 cm in size, recessed in the channel bottom. Simultaneous with the drag observation, the vertical velocity gradient at the center of the plate was also measured. This work has been criticized because the channel was not roughened artificially, as was the plate, and the assumption that the shearing force on the plate is equal to the average shear is probably not strictly true; furthermore, the velocity distribution is probably changing along the plate, thus causing a non-uniform distribution of shear. Simultaneous observation of velocity gradient by accurate Pitot tubes and of distribution of shearing force with an instrument perhaps of the type recently used by Fage[41] would prove of great value to a better understanding of the mechanics of flow in open channels.

WARREN E. WILSON,[42] JUN. AM. SOC. C. E. (by letter).—In presenting a useful summary of many of the modern developments of fluid mechanics the author has performed a valuable service to the Engineering Profession.

In the analysis of data on flow in open channels the Reynolds' number has been used to some extent and is expressed thus,

$$\mathsf{R} = \frac{V R}{\nu} \qquad (91)$$

in which the nomenclature is that of the paper. The author quite rightly questions the use of the hydraulic radius in this case.

The success which has been reported in such usage may be due in part at least to the fact that most experimental work on open channels covers a comparatively limited depth range. Furthermore, most experiments have been conducted with a small depth-width ratio, thereby giving a flow which approximates that in an open channel of infinite width.

Lindquist has suggested[43] plotting the dimensionless quantities, $\frac{V^2}{R g}$ and $\frac{V R}{\nu}$, as ordinates and abscissas, respectively, on logarithmic paper. The results obtained for several sets of experimental data, notably those of Darcy and Bazin, indicate an equation of the form:

$$\frac{V^2}{R g} = C \left(\frac{V R}{\nu}\right)^n \qquad (92)$$

However, if one were to plot a series in which the depth-width ratio varied over a range, such as 0.1 to 1.0, it seems entirely probable that the foregoing simple relation (Equation (92)) would no longer hold.

With small values of the depth-width ratio, the problem involves wide channels approximately similar, geometrically. With successive cross-sections of a stream in a series covering widely differing values of the depth-width ratio there are channels that do not even approximate a similar cross-section. In a wide channel the bottom shear is by far the predominant retarding force. In a square cross-section the effect of side-wall shear is of the same order of magnitude as that of bottom shear.

For wide channels the ratio of unit shear on the bottom to that on the sides may be nearly the same throughout a series of experiments. Such is not the case if the depth-width ratio is increased to any great extent, thus leaving the range of wide channels.

It is impossible, therefore, to express the unit shearing stress at the boundary as a simple function of the velocity and, until a completely satisfactory theory of turbulent flow is available, an experimental approach to the problem seems in order. A determination of the distribution of shearing stress in the boundary surface as a function of the depth-width ratio would provide useful information for a further analysis of the flow in open channels.

[43] "Hydraulic Laboratory Practice", by the late John R. Freeman, Past-President and Hon. M. Am. Soc. C. E., p. 819.

THEODOR VON KÁRMÁN,[44] M. AM. SOC. C. E. (by letter).—It appears that this paper has two main objectives: First, to present the results of a series of experimental and theoretical investigations on the mechanism of turbulent flow to practical engineers; and, second, to suggest the use of rational formulas resulting from those investigations in design problems.

As far as the first objective is concerned, even the most practical engineer will agree that a better understanding of the underlying phenomena is useful also for the practical work. The only question is, whether in some cases total ignorance of some facts is not better than half-knowledge. Authorities disagree, however, on the second point. The writer has often been asked: "Are the new formulas free from any empirical element—that is, empirical assumptions and empirical constants? Why not use purely empirical formulas which have been carefully adjusted to the real conditions by experimental determination of the coefficients involved?" From a very competent source the writer learns that the formulas used for fluid resistance in actual practice are so exact that predictions agree with final results within 3 to 5%, whereas, unavoidable changes in the condition of the structures cause even larger differences.

Assuming that this statement is correct, nevertheless it appears to the writer that the rational formulas have at least three strong points:

First.—The rational formula is always dimensionally correct. This means that, in so far as the underlying assumptions are satisfied, it will give correct results independent of scale, absolute magnitude of speed, etc. Quite a few of the empirical formulas used in hydraulics are dimensionally incorrect. It seems that their success is based on the fact that experienced engineers use them only within a relatively narrow range.

Second.—Empirical formulas are good for interpolation, whereas rational formulas offer a fair chance for extrapolation. There is no reason why an empirical formula will give correct results beyond the limits of actual experiments. If, for instance, the friction coefficient, which is supposed to be a function of Reynolds number, was found, within a certain range, proportional to a certain power of that number, there is no justification to continue this law beyond the maximum Reynolds number used in the experiments. It is a common experience that almost every empirical function plotted in a suitable chosen scale on a logarithmic paper appears as a straight line within a small range. The theoretical formula for fluid friction in a smooth pipe suggested by the writer and given in the paper is deduced under the assumption that the influence of viscosity is negligible, except within a small range near the walls. Hence, it is probable that the formula will agree with the facts more and more, the larger the Reynolds number corresponding to the actual construction.

Third.—The theoretical formulas facilitate the transfer of results from one field to other related fields of research. Fluid friction and heat transfer in fluids are good examples for this point. Both phenomena are affected by

[44] Director, Daniel Guggenheim Aeronautical Laboratories, California Inst. of Technology, Pasadena, Calif.

the same mechanism of the turbulent flow. The problem of heat transfer is much more complex than the problem of friction. For instance, the friction coefficient for a smooth plate is a function of one parameter (Reynolds number) only, whereas the heat transfer depends on two parameters—namely, in addition to the Reynolds number, the ratio between the heat conduction coefficient and the product of heat capacity and viscosity. Hence, the flow conditions in oil and water will be similar if the corresponding Reynolds numbers are the same; but the heat flow will be different due to the relatively much smaller heat conduction coefficient of the oil. For this reason the heat transfer problem appears confusingly complicated from the standpoint of pure empirical research, and very elaborate series of research work in the past have yielded only information relating to a small section of the entire problem.

The use of the results of the turbulence theory determines the general shape of the heat transfer formula, indicates the manner in which the Reynolds number will enter into the formula, and reduces the problem to the determination of one single function of one variable which is the ratio involving the aforementioned physical constant. In a similar manner the writer believes that the turbulence theory and the use of its results will facilitate the systematic solution of many other complex problems, as, for instance, that of silt transportation, which is now the center of interest.

For the reasons presented herein, papers such as that by Mr. Rouse are extremely useful, also, from a merely practical standpoint. The difficulty is to decide at which stage a certain theory is ripe enough to be injected into the pulsating veins of engineering routine practice. Handicapped, perhaps, by the fact that he had some opportunity to work on the theory presented, the writer has been somewhat cautious about making such a proposition. However, the results obtained in aeronautical practice, with the corresponding skin-friction formulas, are so satisfactory that it now seems to the writer that the introduction of rational formulas in hydraulics should be encouraged.

Hunter Rouse,[45] Assoc. M. Am. Soc. C. E. (by letter).—Offered primarily as an interpretative review for hydraulic engineers of present-day knowledge of fluid turbulence, the paper was at the same time an attempt to emphasize basic methods of attack that have proved invaluable in the applied science of fluid mechanics. The interest that readers have shown for this subject through printed discussion, correspondence, and verbal comment is indeed encouraging. In this closing discussion, therefore, the writer seeks to clarify certain aspects of the problem that were questioned in the discussions, introducing as further illustration of the basic thesis several related phases having direct bearing upon the contents of the paper.

Professor Posey's statistical approach to the study of turbulent fluctuations is well adapted to research of a fundamental nature, but it would seem to the writer to be of questionable practical value. Evidently the behavior of the three components of fluctuation is a sufficient measure of the degree of turbulence and hence of all phenomena depending upon the mixing

[45] Asst. Prof. of Fluid Mechanics, California Inst. of Technology, SCS, Pasadena, Calif.

process. Although leading surely to a more thorough understanding of the turbulence mechanism, such analysis, divorced as it is from the basic pattern of mean flow, would scarcely tend to relate the degree of turbulence to flow characteristics readily measurable. The fact must be emphasized that the success of von Kármán's method lies in proving the existence of correlation at every point and in recognizing the similarity of the turbulent pattern from point to point, but above all in determining the degree of mixing as a universal function of the mean velocity gradient.

Although it is not altogether likely to provide a simple mathematical statement of commercial pipe resistance, the analysis of roughness suggested by Professor Posey would surely help to clarify the basic action of surface irregularities. Systematic experimentation on controlled artificial roughness of an elementary nature, to which this type of analysis is admirably suited, may well replace such hit-and-miss investigations of internally threaded pipe as have been conducted in past decades. The roughness parameters used by Professor Posey—ϵ, ϵ', and $i_{av}\ \epsilon''$—are excellent criteria on which to base such research.

For the present, however, it would seem not only necessary but practicable to rely upon experimental determination of a single characteristic length parameter to designate the effective absolute roughness of a surface, whether referred to the sand grains used by Nikuradse or to some standard otherwise determined. Nikuradse was the first to make systematic studies of artificial roughness covering a sufficient range to be generally significant and, therefore, his studies would seem to merit use as a reference for comparative rating of other roughness types. Nevertheless, such adoption would be regrettable if only for the fact that the sand grains in his analysis, and his method of applying them to the surface, do not lend themselves to ease in reproduction. Sand of a given mean grain diameter undeniably varies greatly in shape and hence in roughness action; and even a change in the grade of lacquer used as binder might alter the absolute roughness appreciably. It would be better for one to select arbitrarily, as a standard reference, a numerical relative roughness yielding some convenient resistance coefficient; for instance, fix $\frac{r_0}{\epsilon}$ at 500 for a value of $f = 0.02$. This point lies close enough to Nikuradse's values to provide ease in comparison, but its arbitrary selection renders it forever independent of a standard sand, lacquer, and technique of application. This value is then readily convertible to a single length parameter, ϵ, designating the effective absolute roughness of commercial surfaces; the sole drawback lies in the unavoidable fact that this length parameter is not dimensionless, and hence tables of effective absolute roughness of different materials must necessarily vary among the several dimensional systems.

In this connection, a paper by H. Schlichting[46] that appeared almost simultaneously with the writer's paper, describes further research on artificial roughness which merits notice at this point. In an endeavor to develop a

[46] "Experimentelle Untersuchungen zum Rauhigkeitsproblem", *Ingenieur-Archiv*, Band VII, Heft 1, 1936.

means of testing actual samples of commercial surfaces for effective absolute roughness, Schlichting modified Nikuradse's apparatus to include a wide, shallow, rectangular test section of considerable length, one side of which was composed of the surface to be investigated, the remaining three sides being very smooth. Piezometer openings at frequent intervals were located along only the wide smooth side, and the test specimen was of sufficient length to permit full establishment of flow before the sections of pressure measurement were reached; Pitot tube traverses were possible at several locations.

Beginning, for purposes of comparison, with sand surfaces similar to those of Nikuradse, Schlichting thereby proved that combined measurements of longitudinal pressure gradient and transverse velocity gradient were sufficient to determine the intensity of shear along the rough surface. This was accomplished through use of the expression for the universal velocity gradient near a smooth wall (Equation (55)), and the relationship:

$$(\tau_0)_s + (\tau_0)_r = -b\frac{dp}{dL} \qquad \text{(93)}$$

in which b is the distance between the smooth wall and the rough test specimen, and $(\tau_0)_s$ and $(\tau_0)_r$ designate the intensity of shear at the smooth and rough walls, respectively.

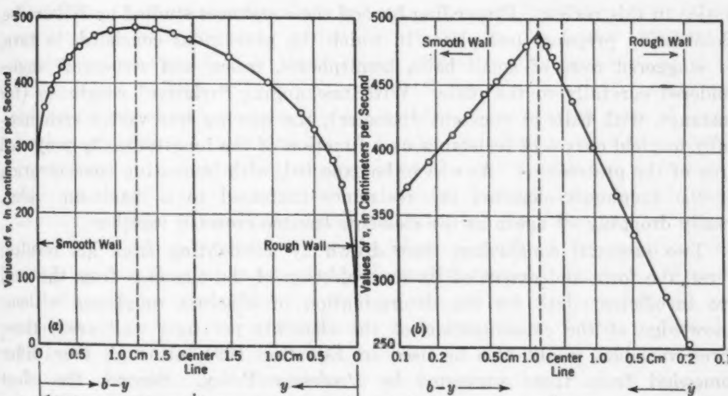

FIG. 29.—VELOCITY DISTRIBUTION BETWEEN SMOOTH AND ROUGH WALLS.

Referring to the paper it will be recalled that the universal velocity distribution curves for both smooth and rough walls were based upon the fact that the entire pattern of turbulent flow in the vicinity of the wall is a function of distance from the wall and hence is completely independent of any effect of the wall on the other side of the center line. Thus, even if the two opposite walls are of a different nature, it is still to be expected that only in the centermost regions of flow will the influence of both walls be felt. Fig. 29(b), taken from Schlichting's paper, is excellent vindication of this reasoning,

the velocity distribution on either side of the maximum following a logarithmic function corresponding to the universal plots of Figs. 17 and 18. Furthermore, the constants of the several distribution curves for sanded surfaces determined in this way checked Nikuradse's measured values within a few per cent.

Use of such an apparatus for practical purposes (in Schlichting's case primarily for investigation of the roughness of ship hulls) is straighforward and simple: The test specimen in the form of a long flat plate is mounted in the rectangular conduit; measurements are made of pressure gradient and velocity distribution at several different flow rates (only one, however, being necessary theoretically). From the semi-logarithmic distribution curves Equation (55) enables the direct determination of $(\tau_0)_s$, and $(\tau_0)_r$ is then found at once from Equation (93). Equation (56), finally, provides a means of determining the effective absolute roughness referred to the sand used by Nikuradse; it is evident that to standardize some arbitrary value of ϵ requires simply a change in the constant, 5.85, of Equation (56). It should also be apparent that this procedure is correct only for that type of roughness which results in a resistance coefficient that is independent of the Reynolds number.

Other salient features of Schlichting's paper are equally deserving of notice in this review. Proceeding beyond the roughness studied by Nikuradse, Schlichting prepared test plates in which the projections consisted, in turn, of staggered rows of small balls, hemispheres, cones, and structural angles soldered carefully to the plate. With unchanging "relative" roughness (for instance, with balls of constant diameter), the spacing was varied systematically to yield curves of resistance as a function of the longitudinally projected area of the protrusions. As was to be expected, with increasing concentration of the roughness elements the resistance increased to a maximum value, finally dropping off again as the elements became crowded together.

Two essential conclusions were drawn by Schlichting from his results: First, the form and extent of linear projection of the elements from the wall are insufficient data for the determination of absolute roughness without knowledge of the concentration of the elements per unit wall area; these three variables might also be used in Equation (69), although they differ somewhat from those suggested by Professor Posey. Second, the effect of the roughness elements is equivalent to the formation of a wake during flow past an immersed body because the limiting resistance of each individual element investigated was of practically the same magnitude as that of a similar body moving through a fluid with a velocity equal to that at the outer edge of the roughness element (by "limiting resistance" is meant that of a single element as the concentration approached a minimum). As the elements become more crowded, it is clear that their effectiveness as individuals should decrease, the over-all effect still increasing until mutual interference finally results in a gradual reduction of the total resistance. Obviously, the limit of crowding is reached when the elements are packed so closely as to produce, in effect, a smooth wall.

The relative ease of experimentation, once such an apparatus for commercial testing is made available, and the evident dependability of results for widely different types of roughness, lead the writer to believe that such a method may lend itself to other purposes than simply the testing of commercial plate material. For instance, since the effect of roughness on turbulent resistance is identical for both closed and open conduits, such technique is easily adapted to the study of canal linings, whether of timber, concrete, or brick. Simply by building a test section of the material in question, and sealing the apparatus on top of it in inverted position, a conduit is formed exactly as in Schlichting's original tests. This would necessitate rebuilding the Chezy equation into a form such as that of Equation (16) or Equation (17) since the Kutter and Manning n used to determine the Chezy C is not a length parameter equivalent to the effective absolute roughness, ϵ. The idea has also occurred to the writer that similar methods might possibly be extended to the case of movable beds, eliminating the free surface by means of a smooth upper boundary. This might well permit investigation of the true shear and mean velocity distribution in the vicinity of the bottom, for through Schlichting's method both may be determined by indirect measurement.

Mr. Miller's comments on empirical *versus* analytical investigation must be examined more closely, for there are actually four, rather than two, methods of arriving at expressions for fluid motion. One must distinguish, first, between experimental measurement (which the writer by no means scorns) and empirical formulation of working rules for design—two processes which Mr. Miller seems to bulk as one. Experimental measurement is the mechanical determination of one or more flow characteristics for a given state of motion. Pure empiricism, on the other hand, includes the effort to develop a practical generalization of the results of experimental measurement for a number of different conditions; it may provide simple working formulas for design within the range of available data—but, although the data may be accurate, there is no guaranty whatever for the physical truth of the empirical statement, for only by chance are natural laws discovered in this way. Were this still the only recourse of the hydraulician, the subject of pipe resistance would probably be in the same jumbled state as it was before Blasius published his analysis of Schoder's experimental data.

On a considerably higher plane is the second method, that of Blasius and actually that which Mr. Miller is upholding—one which is partly analytical in character since it is based upon physically sound dimensional analysis; although experimental measurements are still necessary to determine the type of function and the numerical constants relating the several dimensionless parameters, the investigator is well beyond the chance of pure empiricism when he interprets his results. Still further advanced, it would seem to the writer, is the method of fluid mechanics presented in the paper, because it combines with dimensional analysis a reasonable and closely approximate physical analysis, thus determining the probable form of the function and leaving only the numerical constants to experimental investigation. The

fourth method—complete rational analysis—leaves nothing to be found experimentally; it is the ultimate goal of every field of science, but as yet only in isolated cases has it been fully a success.

Although Mr. Miller looks forward to the attainment of this goal, he seems to frown upon present efforts in that direction. He must remember that the "law of turbulent flow" which he uses to emphasize the advantages of "empirical" relationships, and which "might" have been discovered earlier from experimental data, actually was far more the result of careful physical analysis than of empirical luck. Mr. Miller evidently attributes the law to Nikuradse's experimental work published in 1932,[15] whereas the latter was an outgrowth of von Kármán's original analysis published in 1930[19],[47]. As Mr. Miller finally remarks, an "infinite velocity at the center" would indeed be interesting, but the writer can recall no mention of such an assumption. The infinite velocity gradient at the wall, on the other hand, was not assumed to portray wall conditions, but to provide the necessary mathematical limit for a curve of which the characteristics are used only in the central regions of the flow. If ever found, a single analytic function to include both the laminar film and the zone of highly turbulent mixing would very likely prove too complex to serve any practical purpose.

As Mr. Yasines looks upon the application of dimensional analysis with such apparent skepticism, further discussion to supplement the original statements involving Equations (8) to (17) and (46) to (48) may possibly prevent future misunderstanding of this basic factor in the investigation of fluid motion. Mr. Yasines asks what means the investigator has of knowing which characteristics to include in the original expression. Briefly stated, the only variables belonging in any correct statement of flow conditions at constant temperature are as follows: The several linear and angular dimensions describing the geometry of the flow; two flow characteristics, a pressure gradient (or a shearing stress), and a velocity; and the fluid properties of density, specific weight, absolute viscosity, surface tension, and elastic modulus. Of these, either pressure gradient or velocity is usually considered the dependent variable. Use of the Π-theorem will group these variables in a number of dimensionless terms, each including four variables, three of which appear in every Π-term. It is most reasonable to select velocity, density, and a significant length as the three repeating variables, since this grouping yields as Π-terms the Froude, Reynolds, Weber, and Cauchy numbers.

If the flow is completely enclosed, specific weight and surface tension (and, hence, the Froude and Weber numbers) will disappear from the relationship. For cases of constant density, the modulus of elasticity (and, hence, the Cauchy number) may also be dropped. It is evident that use of wall shear instead of pressure gradient is perfectly sound, since the two are definitely related through Equation (15); although pressure is more easily measured, intensity of shear is often more significant. In open-channel flow the pressure gradient must be replaced by either boundary shear or surface slope. Little experience is necessary to reach these conclusions. However, if experience is completely lacking, the infallible method is to include every one of these

[47] "Mechanische Aehnlichkeit und Turbulenz", Verhandlungen des III. Internationalen Kongresses für technische Mechanik, Stockholm, 1930.

variables in the basic statement, afterward eliminating from the equation those Π-terms which, through experimental trial, prove to have no effect upon the dependent variable.

It must be remarked at this point that the Froude and the Reynolds numbers cannot "fail to perform their functions", despite Mr. Yasines' remark to the contrary. Only when they are misused will the investigator be disappointed, and then only he is to blame. It is futile, for instance, to expect the Froude number to bear the brunt of boundary roughness and viscous action without any assistance whatever from roughness and viscosity parameters, a condition too often encountered in model studies. "'Scale effect" and "limitations of similitude" are expressions often used to imply that correction factors are necessary to compensate for inherent weakness in theory. Such is by no means true; scale effect is fully covered by the several dimensionless parameters, and the limitations are not analytical, but practical.

Although the foregoing choice of the three repeating variables is the most logical, in that it separates the fluid force characteristics (specific weight, viscosity, surface tension, and elastic modulus) and thus leads to the most fundamental dimensionless parameters, it is sometimes expedient to use other groupings for the purpose of emphasizing some significant functional relationship not otherwise apparent. For example, the study of turbulence in smooth pipes involves only the measurable variables, V, D, ρ, $\frac{dp}{dL}$, and μ. Customary grouping leads to the expression,

$$\phi\left[\frac{\rho V^2}{D\frac{dp}{dL}}, \frac{V D}{\frac{\mu}{\rho}}\right] = 0 \quad \text{.................... (94)}$$

which yields the familiar equation,

$$\frac{dp}{dL} = \phi' (\mathbf{R}) \frac{\rho V^2}{D} \quad \text{.................... (95)}$$

Mr. Miller has shown, implicitly, that by choosing D, ρ, and $\frac{dp}{dL}$ as the three repeating characteristics there will result,

$$\phi\left[\frac{\rho^{\frac{1}{2}} V}{D^{\frac{1}{2}}\left(\frac{dp}{dL}\right)^{\frac{1}{2}}}, \frac{D^{\frac{3}{2}} \rho^{\frac{1}{2}}\left(\frac{dp}{dL}\right)^{\frac{1}{2}}}{\mu}\right] = 0 \quad \text{.............. (96)}$$

or, using more familiar parameters (see Equation (16)),

$$\phi\left(\frac{1}{\sqrt{f}}, \mathbf{R}\sqrt{f}\right) = 0 \quad \text{.............. (97)}$$

A plot of $\frac{1}{\sqrt{f}}$ against log $\mathbf{R}\sqrt{f}$ yields a straight line, thereby disclosing the

apparent fact that this line may be extrapolated without probable error. The writer cannot refrain from pointing out, however, that a logarithmic plot of Equation (95), first published by Blasius, also led to a straight line, and only after further research was it proved that extrapolation would introduce serious error. Assurance that Equation (75) may safely be extrapolated beyond the range of experimental data is not the outcome of Mr. Miller's dimensional analysis but of Professor von Kármán's analytical determination of the fact that the functional relationship actually is linear as long as viscous shear has a negligible effect upon the turbulent pattern. Since Equation (75) submitted by Mr. Miller states the same relationship as Equation (68), it does not eliminate the drawback mentioned in the text preceding Fig. 19—one can conveniently solve for **R** (or Q), with $f\left(\text{or } \frac{dp}{dL}\right)$ given, but not *vice versa*.

Mr. Yasines' use of the Navier-Stokes equations to illustrate his remarks on the dubious significance of the Reynolds number surely warrants further investigation. These equations are as follows:

$$\frac{\partial v_x}{\partial t} + v_x \frac{\partial v_x}{\partial x} + v_y \frac{\partial v_x}{\partial y} + v_z \frac{\partial v_x}{\partial z} = -\frac{1}{\rho}\frac{\partial}{\partial x}(p + \gamma h) + \frac{\mu}{\rho}\nabla^2 v_x \quad (98)$$

$$\frac{\partial v_y}{\partial t} + v_x \frac{\partial v_y}{\partial x} + v_y \frac{\partial v_y}{\partial y} + v_z \frac{\partial v_y}{\partial z} = -\frac{1}{\rho}\frac{\partial}{\partial y}(p + \gamma h) + \frac{\mu}{\rho}\nabla^2 v_y \quad (99)$$

and,

$$\frac{\partial v_z}{\partial t} + v_x \frac{\partial v_z}{\partial x} + v_y \frac{\partial v_z}{\partial y} + v_z \frac{\partial v_z}{\partial z} = -\frac{1}{\rho}\frac{\partial}{\partial z}(p + \gamma h) + \frac{\mu}{\rho}\nabla^2 v_z \quad (100)$$

in which v_x, v_y, and v_z, are the components of the instantaneous velocity vector, and,

$$\nabla^2 v_x = \frac{\partial^2 v_x}{\partial x^2} + \frac{\partial^2 v_x}{\partial y^2} + \frac{\partial^2 v_x}{\partial z^2}, \text{ etc.} \quad (101)$$

The left side of each equation denotes the component of acceleration at any point with time and with distance in three-dimensional space; the right side represents the sum of all force components per unit mass which produce this acceleration. If the first term at the left of each equation is zero, the flow is steady (that is, unchanging with time); if the second, third, and fourth terms are zero, the flow is uniform (that is, unchanging with distance in the direction of motion). If the flow is both steady and uniform, there is no acceleration; the terms at the left disappear, and the terms at the right then indicate the equilibrium of pressure, weight, and viscous shear.

Obviously, only in this last case can the term for fluid density be dropped. Hence, Mr. Yasines' statement that in viscous flow the density plays no part holds true only if the flow is both uniform and steady. Under these conditions the density should not be included in the original group of variables for dimensional analysis; since there are then only four variables (pressure gradient, velocity, diameter, and viscosity), there will be only one Π-term, as seen from Equation (29); only the numerical constant, 32, cannot be found by this

method. Equation (30) is derived by introducing the density at two compensating points, which produces a useful equation without altering the fundamental expression. Laminar flow, however, is uniform only if the stream lines are parallel, and it must be remembered that any boundary curvature or rapid change of flow section will involve mass acceleration, under which conditions appreciable velocity will make the density of decided importance.

The Navier-Stokes equations, contrary to popular opinion, apply just as accurately to turbulent flow as to laminar, for the velocity components used in the equations refer to the actual instantaneous velocity at any point in question. Whether the flow is laminar or turbulent, viscous action is the only means of reducing the total energy of flow, through conversion into heat. Although it is possible for laminar flow to be both uniform and steady, turbulent flow is always unsteady and non-uniform in the strict sense of the word, for the velocity fluctuations vary at a given point with time, and at a given instant with distance in any direction. Therefore, it is evident that, however correct the Navier-Stokes equations may be, it is futile to use them for a practical study of turbulence as long as they remain in their present form.

Statistically speaking, it is reasonable to consider each velocity component to be composed of a temporal mean value and a secondary fluctuating value:

$$v_x = \overline{v_x} + v'_x \qquad (102a)$$

$$v_y = \overline{v_y} + v'_y \qquad (102b)$$

and,

$$v_z = \overline{v_z} + v'_z \qquad (102c)$$

Turbulent flow is then considered both steady and uniform if the values of the mean components do not vary with either time or space. By substituting these values for the velocity components in the original Navier-Stokes equations, one obtains parallel expressions for the Newtonian acceleration-force-mass equilibrium. Remembering that, while the temporal mean of any component of fluctuation is zero, the product of any two components (owing to the existence of correlation) will have a temporal average of finite magnitude, these parallel expressions may be written in terms of the mean velocity components and mean products of the components of fluctuation, as follows:[48]

$$\frac{\partial \overline{v_x}}{\partial t} + \overline{v_x}\frac{\partial \overline{v_x}}{\partial x} + \overline{v_y}\frac{\partial \overline{v_x}}{\partial y} + \overline{v_z}\frac{\partial \overline{v_x}}{\partial z}$$

$$= -\frac{1}{\rho}\frac{\partial}{\partial x}(p + \gamma h) + \frac{\mu}{\rho}\nabla^2 \overline{v_x} - \left(\frac{\partial \overline{(v'_x)^2}}{\partial x} + \frac{\partial \overline{v'_x v'_y}}{\partial y} + \frac{\partial \overline{v'_x v'_z}}{\partial z}\right) \qquad (103)$$

$$\frac{\partial \overline{v_y}}{\partial t} + \overline{v_x}\frac{\partial \overline{v_y}}{\partial x} + \overline{v_y}\frac{\partial \overline{v_y}}{\partial y} + \overline{v_z}\frac{\partial \overline{v_y}}{\partial z}$$

$$= -\frac{1}{\rho}\frac{\partial}{\partial y}(p + \gamma h) + \frac{\mu}{\rho}\nabla^2 \overline{v_y} - \left(\frac{\partial \overline{(v'_y)^2}}{\partial y} + \frac{\partial \overline{v'_y v'_z}}{\partial z} + \frac{\partial \overline{v'_y v'_x}}{\partial x}\right) \qquad (104)$$

[48] "Turbulente Strömungen", by W. Tollmien, Handbuch der Experimentalphysik, Band IV, Teil 1, Leipzig, 1931.

and,

$$\frac{\partial \bar{v}_z}{\partial t} + \bar{v}_x \frac{\partial \bar{v}_z}{\partial x} + \bar{v}_y \frac{\partial \bar{v}_z}{\partial y} + \bar{v}_z \frac{\partial \bar{v}_z}{\partial z}$$

$$= -\frac{1}{\rho} \frac{\partial}{\partial t} (p + \gamma h) + \frac{\mu}{\rho} \nabla^2 \bar{v}_z - \left(\frac{\partial \overline{(v'_z)^2}}{\partial z} + \frac{\partial \overline{v'_z v'_x}}{\partial x} + \frac{\partial \overline{v'_z v'_y}}{\partial y} \right) \quad \text{..(105)}$$

Under these circumstances, the differential equation for steady uniform turbulent flow in a pipe will become, from Equation (103),

$$\frac{\partial (p + \gamma h)}{\partial x} = \mu \frac{\partial^2 \bar{v}}{\partial y^2} - \rho \frac{\partial \overline{v'_x v'_y}}{\partial y} \quad \text{..............(106)}$$

Mr. Yasines will note that, contrary to steady uniform laminar flow, there is now no possible way of eliminating the fluid density. In other words, once turbulent flow is described in terms of the mean, rather than instantaneous, velocity components (similar to the mean velocity, V, in the Reynolds number), then density must play a very essential rôle in any correct expression. (It is to be remarked that, for simplicity, the bar denoting temporal mean velocity was consistently omitted in the paper.)

From these considerations, Mr. Yasines' query about the writer's "rate of passage of momentum" should find a satisfactory answer. Since the components of fluctuation vary directly with the average velocity of flow, the rate of passage of momentum is a convenient means of representing, in measurable quantities, the magnitude of the momentum transport in the mixing process; and since the effect of viscous shear in terms of the mean velocity gradient varies inversely with the average velocity of flow, the Reynolds number for turbulent flow in pipes really denotes the ratio between the shearing intensity due to momentum transport, on the one hand, and that due to viscous shear in terms of the mean velocity gradient, on the other.

Similar conclusions will result from the following reasoning: In the Navier-Stokes equations the three components of the shearing stress, τ, are simply those due to viscous action, regardless of whether the flow is laminar or turbulent:

$$\tau_{xy} = \tau_{yx} = \mu \left(\frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x} \right) \quad \text{..............(107)}$$

$$\tau_{yz} = \tau_{zy} = \mu \left(\frac{\partial v_y}{\partial z} + \frac{\partial v_z}{\partial y} \right) \quad \text{..............(108)}$$

and,

$$\tau_{zx} = \tau_{xz} = \mu \left(\frac{\partial v_z}{\partial x} + \frac{\partial v_x}{\partial z} \right) \quad \text{..............(109)}$$

Once the instantantous velocity gradient is replaced by the mean velocity gradient, if the flow is turbulent there must exist additional terms to express the high viscous stresses in the turbulent eddies—that is, the effective

shear of the momentum transport; introducing Boussinesq's turbulence coefficient, η, these become:

$$\bar{\tau}_{xy} = \bar{\tau}_{yx} = \mu \left(\frac{\partial \bar{v}_x}{\partial y} + \frac{\partial \bar{v}_y}{\partial x} \right) - \rho \, \overline{v'_x v'_o} = (\mu + \eta) \left(\frac{\partial \bar{v}_x}{\partial y} + \frac{\partial \bar{v}_y}{\partial x} \right) \quad \ldots (110)$$

$$\bar{\tau}_{yz} = \bar{\tau}_{zy} = \mu \left(\frac{\partial \bar{v}_y}{\partial z} + \frac{\partial \bar{v}_z}{\partial y} \right) - \rho \, \overline{v'_y v'_z} = (\mu + \eta) \left(\frac{\partial \bar{v}_y}{\partial z} + \frac{\partial \bar{v}_z}{\partial y} \right) \quad \ldots (111)$$

and,

$$\bar{\tau}_{zx} = \bar{\tau}_{xz} = \mu \left(\frac{\partial \bar{v}_z}{\partial x} + \frac{\partial \bar{v}_x}{\partial z} \right) - \rho \, \overline{v'_z v'_x} = (\mu + \eta) \left(\frac{\partial \bar{v}_z}{\partial x} + \frac{\partial \bar{v}_x}{\partial z} \right) \quad \ldots (112)$$

It must be realized that Equations (107) to (109) and (110) to (112) are merely different ways of stating the same basic effect of viscous shear.

Reducing Equation (110) to the case of flow in a pipe:

$$\bar{\tau} = \mu \frac{d\bar{v}}{dy} - \rho \, \overline{v'_x v'_y} = (\mu + \eta) \frac{d\bar{v}}{dy} \quad \ldots\ldots\ldots\ldots (113)$$

In the paper it was shown that with increasing Reynolds number the magnitude of η becomes increasingly greater than that of μ, and that above the approximate Reynolds number of 100 000, the magnitude of μ is comparatively insignificant. In the light of the foregoing discussion, the Reynolds number might also be considered to denote the relative magnitude of η and μ, the former being averaged over the flow section.

Since in highly turbulent motion $\mu \frac{d\bar{v}}{dy}$ is generally negligible when compared with $\eta \frac{d\bar{v}}{dy}$, Equation (113) may then be written in the form,

$$\bar{\tau} = - \rho \, \overline{v'_x v'_y} = \eta \frac{d\bar{v}}{dy} \quad \ldots\ldots\ldots\ldots\ldots\ldots (114)$$

Introducing the expression, $| v'_x | = l \frac{d\bar{v}}{dy}$ (refer to the development of Equation (42)):

$$\frac{\eta}{\rho} = | v'_y | \, l \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (115)$$

in which the vertical bars denote mean absolute magnitude, regardless of sign.

Equation (115) is of very basic importance, for it not only lends added clarity to Boussinesq's coefficient of turbulence, but is a direct measure of the transporting power of the mixing process. The writer stressed only the transport of momentum by this means, but the fact must be appreciated that it is the same mechanism which results in a transportation of heat, salinity, or suspended matter from one region of turbulent flow to another. The rate of transport of momentum has been shown to depend upon only the

factor, $\frac{\eta}{\rho}$. and the mean velocity gradient, thus producing an effective shearing stress:

$$\bar{\tau} = \rho \mid v'_y \mid l \frac{d\bar{v}}{dy} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (116)$$

The problem of suspended load in a stream may be attacked in similar fashion. If at any depth of flow there are n particles per unit volume of fluid, the concentration gradient being written $\frac{dn}{dy}$, then, due to the transverse fluctuations, fluid masses bearing n particles per unit volume will be carried the mean distance, l, across the flow to regions where the concentration differs by the amount, $l \frac{dn}{dy}$. Thus, the temporal rate of passage of sediment per unit area, N, will be the product of the rate per unit area of transverse flow, $\mid v'_y \mid$, and the difference between the sediment concentration in the traveling fluid mass and that of the region into which it comes, $- l \frac{dn}{dy}$ —in other words, the product of $\frac{\eta}{\rho}$ and the sediment gradient:

$$N = - \mid v'_y \mid l \frac{dh}{dy} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (117)$$

Identical reasoning applies to the transportation of salinity, and similar considerations show that the rate of heat transfer per unit area, q, will depend only upon $\frac{\eta}{\rho}$, the specific heat, c, and the mean temperature gradient across the flow, $\frac{d\,\theta}{dy}$:

$$q = - \mid v'_y \mid l\, c \frac{d\,\theta}{dy} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (118)$$

Such heat transfer is purely convective, and must be distinguished from the process of conduction in the laminar film.

The parallel development and structure of Equations (116) to (118) was shown to excellent advantage by von Kármán in a résumé of turbulence theories[49]. Since the problem of suspended load in a stream is of paramount interest in river hydraulics, amplification of this method of treatment should be of value at this time. If the sediment transportation of the stream as a whole is in a uniform state of equilibrium, the rate of upward transfer by the mixing process must equal the downward movement due to settling. Designating the settling velocity of a given particle size by w, then N, the temporal rate of transportation per unit area, must equal the number of particles per unit volume multiplied by their rate of fall:

$$N = w\, n = - \mid v'_y \mid l \frac{dn}{dy} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (119)$$

[49] "Some Aspects of the Turbulence Problem", *Proceedings*, Fourth International Congress for Applied Mechanics, Cambridge, England, 1934.

This expression may be integrated in the form,

$$\log_e \frac{n}{n_a} = - w \int_a^y \frac{dy}{|v'_y|\, l} \text{ .... (120)}$$

in which $\frac{n}{n_a}$ is the relative concentration at any point, referred to some arbitrary elevation, a, above the bottom. The evaluation of the last term in the expression depends only upon knowledge of the kinematic turbulence factor, $\frac{\eta}{\rho} = |v'_y|\, l$, as a function of the depth.

As shown by von Kármán, introduction of Equation (116) yields an integrable expression,

$$\frac{dy}{|v'_y|\, l} = \frac{dy}{\dfrac{\tau}{l\dfrac{d\bar{v}}{dy}}} = \frac{l\dfrac{d\bar{v}}{dy}}{\tau_0\left(1-\dfrac{y}{d}\right)}\, dy \text{ .... (121)}$$

in terms of the mean velocity gradient. If the latter is of the universal logarithmic type, then from Equation (59),

$$\frac{d\bar{v}}{dy} = \frac{1}{\kappa}\sqrt{\frac{\tau_0}{\rho}}\,\frac{1}{y} \text{ .... (122)}$$

and Equation (120) becomes:

$$\frac{n}{n_a} = \left[\frac{1-\dfrac{y}{d}}{\dfrac{y}{d}} \times \frac{\dfrac{a}{d}}{1-\dfrac{a}{d}}\right]^z = \left[\frac{1-\dfrac{y'}{d'}}{1+\dfrac{y'}{a}}\right]^z \text{ .... (123)}$$

in which $z = \dfrac{w}{\kappa\sqrt{\dfrac{\tau_0}{\rho}}}$. Two pertinent facts are to be noted in Equation (123):

The relative sediment distribution, for a given particle size (that is, for a given settling velocity), is a function of relative depth only. It cannot, however, be extended to the channel bottom, but only to some arbitrary depth, $d' = d - a$, and then only if the concentration at that depth is not so great as to change either the density of the fluid mixture or the assumed velocity distribution. If the bottom is smooth, the logarithmic velocity curve does not extend to the bottom, and there is no mixing in the final layer of fluid at the boundary. If the bottom is rough, knowledge of the total suspended load would permit complete solution of the sediment distribution (provided the logarithmic law could be extended to the free surface), but this expression in no way permits determination of the total transporting capacity of the stream. The latter probably depends upon conditions in the transition region between movable bed-load and completely suspended matter, a problem still awaiting a satisfactory physical analysis.

On the assumption that the logarithmic velocity curve actually extends to the free surface of a very wide stream, Equation (123) enables one to construct a plot of sediment distribution curves (Fig. 30) for various values of the suspended load parameter, $z = \dfrac{\dot{w}}{\kappa \sqrt{\dfrac{\tau_0}{\rho}}}$, indicating, for a given state of flow, the relative distribution of the different particle sizes based upon their settling velocities. Such a diagram was first developed by Arthur T. Ippen, Jun. Am. Soc. C. E., at the suggestion of Professor von Kármán. An interesting comparison may be made with a group of measured curves published by L. G. Straub[50], Assoc. M. Am. Soc. C. E.

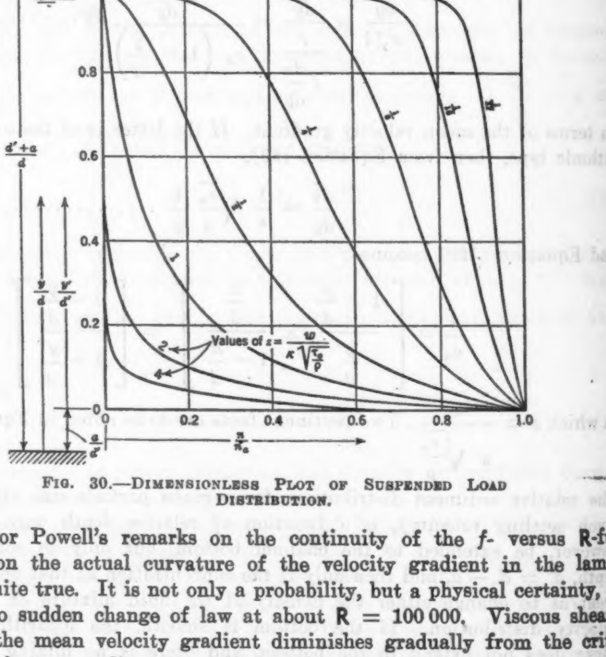

FIG. 30.—DIMENSIONLESS PLOT OF SUSPENDED LOAD DISTRIBUTION.

Professor Powell's remarks on the continuity of the f- versus R-function and on the actual curvature of the velocity gradient in the laminar film are quite true. It is not only a probability, but a physical certainty, that there is no sudden change of law at about $\mathsf{R} = 100\,000$. Viscous shear in terms of the mean velocity gradient diminishes gradually from the critical region on, but never disappears. It is a simple matter to construct a smooth curve through the measured points, somewhat less simple to express its variation in a brief empirical formula, and, to date, quite impossible to determine this function analytically. Neither is there any abrupt limit to the laminar film—despite the obvious convenience of designating an arbitrary point of juncture between turbulent and laminar regions. As Professor Powell will have noticed, Equation (36) was offered to give a preliminary, "rough idea"

[50] "Transportation of Sediment in Suspension", *Civil Engineering*, May, 1936.

of boundary layer thickness "when the Reynolds number is high." To paraphrase his remark, it is not necessary to think of the velocity in the boundary layer as varying non-uniformly in this region, since the departure from uniform variation is quite insignificant—particularly when compared with the obviously arbitrary magnitude of v_w. Equation (62) completely avoids this latter discrepancy, and still introduces no appreciable error. Obviously, however, it does not apply to the region chosen by Professor Powell for illustration (R = 3 000), for as yet no successful analysis has been made of the Reynolds number range from 2 000 to 100 000.

Were the mechanism of turbulence basically different in the various phenomena in which it plays a leading rôle, Professor Powell's criticism that the title of the paper is too broad would be more fully justified. The writer's endeavor was not to present a complete text upon the subject, but to make available to hydraulic engineers the essential features in compact and comprehensible form, with pipe flow the most pertinent kind of illustration possible. It is only to be regretted that hydraulicians have previously had to rely upon aeronautical literature for such material, for the objectives of the two professions are by no means identical. On the assumption that criticism of this nature indicates imperfect success on the writer's part, a further effort was made in the foregoing relation of sediment transportation to the turbulent mechanism. It still remains to point out more explicitly the significance of the boundary layer to turbulence in general, particularly as the latter really includes the phenomenon of flow in pipes. However, while pipe flow is ordinarily a case of established uniform motion, primary interest in the boundary layer has to do with its rate of growth in the direction of flow; that is, the basic problem is essentially one of non-uniform movement.

Consider a smooth, thin plate moved at a steady rate through a fluid originally at rest. Since the fluid in immediate contact with the plate will have the same velocity as the plate itself, the resulting shearing stresses must cause movement of the surrounding fluid at a rate decreasing with distance away from the plate and increasing with distance back from the leading edge. Although this movement, mathematically speaking, extends an infinite distance away from the plate, it is convenient to designate that region in which the motion is appreciable as the boundary layer; in this sense, the boundary layer begins with a zero thickness at the leading edge and increases gradually from section to section. It is possible, analytically[31], to compute the thickness at any section as a function of the relative velocity of plate and undisturbed fluid, the kinematic viscosity, and the distance from the leading edge, proceeding on the assumption that the velocity distribution curve is a similar function at all sections; this assumption has been vindicated experimentally except in the immediate vicinity of the leading edge. (It should be evident that the kinematic, rather than the absolute, viscosity must be used, since non-uniform flow is a case of mass acceleration even when the motion is laminar.) Such analysis as this has led to basic expressions for the shearing stress and the velocity at any point in the fluid near the moving plate.

[31] "Grenzschichten in Flüssigkeiten mit kleiner Reibung", von H. Blasius, *Zeitschrift für Mathematik und Physik*, Band 60, 1912.

Since the fluid was originally at rest and the surface of the plate very smooth, the resulting movement is necessarily a laminar one; but as the boundary layer becomes increasingly thicker the farther back it extends, some distance from the leading edge an unstable condition is reached (marked by a fairly definite critical Reynolds number, R_δ, composed of the boundary layer thickness, the relative velocity, and the kinematic viscosity) at which movement within the boundary layer abruptly becomes turbulent. From this point, there exists a turbulent boundary layer distinguished by a different type of velocity distribution and a more pronounced shearing stress; but since along the surface of the smooth plate the velocity of the fluid must be identical with that of the plate, there must still be a thin laminar region directly at the boundary, in which no turbulence exists; this region is called the laminar sub-layer. The flow pattern in the turbulent boundary layer may be determined as a function either of a Reynolds number composed of the relative velocity, the kinematic viscosity, and the distance from the leading edge, or of another Reynolds number in which the thickness of the boundary layer replaces the distance from the leading edge[10]. A simple proportionality always exists between these two Reynolds numbers in the turbulent region.

Had the leading edge of the plate, or the plate surface, been sufficiently rough, the boundary layer would have been a turbulent one from the outset. The result would be similar if the fluid were not originally at rest but slightly disturbed, since only a small degree of instability is sufficient to bring about fully developed turbulence at a very early stage of boundary layer growth.

The relation between this phase of boundary layer study and the case of flow in pipes should be quite evident. At the beginning of a pipe line, if the entrance is well rounded and the supply of fluid completely at rest, a laminar boundary layer will begin to form at the entrance around the entire inside of the pipe, growing in thickness with distance from the entrance. The limit of growth is attained when the effective thickness of the layer is equal to the pipe radius (that is, when the layer has penetrated to the center line of the flow), beyond which section the flow is fully established.

If the critical Reynolds number of the boundary layer is reached before the flow is thus established, this layer will become turbulent and then continue to grow as such until it reaches the central regions of the flow. Under these conditions the initial onset of turbulence will obviously not be in the central, undisturbed core of fluid. If, on the other hand, the supply of fluid is not in a state of rest, or if the pipe is rough or the entrance poor, the boundary layer will be turbulent from the outset, and its growth will soon bring it to the center line of flow. From these facts it will be clear that what is popularly called the boundary layer in pipe flow is actually the laminar sub-layer, whereas the true boundary layer extends to the very middle of the pipe.

Although the equations of boundary layer growth are at present primarily of value to aeronautical engineers and naval architects for use in determining skin resistance of air and water craft, of interest to the hydraulic engineer should be the fact that the equations for established flow in pipes have almost identical counterparts for boundary layer phenomena, since the fundamental

mechanism of flow is the same. The coefficient of resistance, f, has its parallel in the local coefficient of resistance for the boundary layer, c_f, which necessarily varies with τ_0 from section to section:

$$c_f = \frac{\tau_0}{\rho \frac{V^2}{2}} \qquad (124)$$

If τ_0 is integrated over the distance, x, from the leading edge to yield the total resisting force, F_x, up to that section, then a mean coefficient of resistance may be used, having the form,

$$C_f = \frac{F_x}{b\, x\, \rho \frac{V^2}{2}} \qquad (125)$$

In the range of the laminar boundary layer, Equations (124) and (125) were shown analytically by Prandtl and Blasius to equal,

$$c_f = \frac{0.664}{\left(\frac{V x}{\nu}\right)^{\frac{1}{2}}} \qquad (126a)$$

and,

$$C_f = 2\, c_f = \frac{1.328}{\left(\frac{V x}{\nu}\right)^{\frac{1}{2}}} \qquad (126b)$$

Over a limited range past the critical point, corresponding to the Blasius range for pipe flow, Prandtl and von Kármán have shown the functional relationship to be closely exponential, just as in the case of pipes:

$$c_f = \frac{0.059}{\left(\frac{V x}{\nu}\right)^{\frac{1}{5}}} \qquad (127a)$$

and,

$$C_f = \frac{0.074}{\left(\frac{V x}{\nu}\right)^{\frac{1}{5}}} \qquad (127b)$$

For larger Reynolds numbers, however, at which viscous action need no longer be considered in the mixing process, the universal relationship for smooth pipe resistance (refer to Equation (68)) has a close double in von Kármán's universal equation for the boundary layer:

$$\frac{1}{\sqrt{c_f}} = 1.7 + 4.15 \log_{10} (\mathsf{R}_x\, c_f) \qquad (128a)$$

and,

$$\frac{1}{\sqrt{C_f}} = 4.15 \log_{10} (\mathsf{R}_x\, C_f) \qquad (128b)$$

in which R_x is the Reynolds number based upon distance from the leading edge. The three regions are shown in the logarithmic plot of Fig. 31, bearing striking similarity to Figs. 6 and 7.

Boundary layer growth has not yet begun to claim the attention of hydraulic engineers, in part because their interests, as opposed to those of aeronautical and naval designers, are still focused on problems of uniform flow; but uniform flow is by no means the sole type with which hydraulicians must deal, and such instances as siphons, draft-tubes, turbines, spillways, and

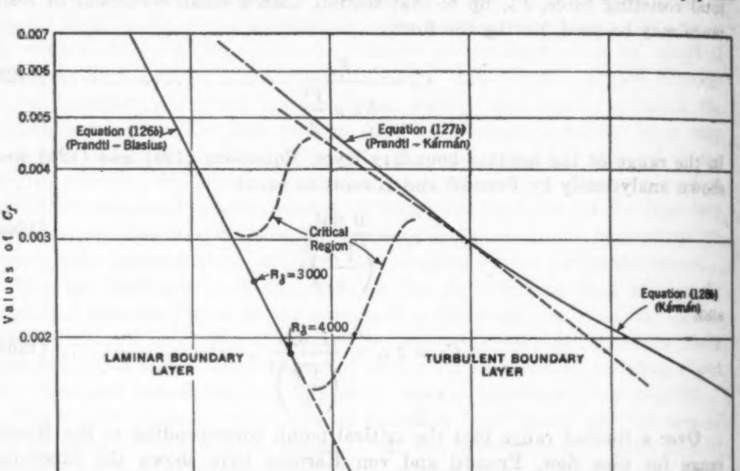

FIG. 31.—RESISTANCE CURVES FOR THE BOUNDARY LAYER.

even open channels, are only a few of the many cases in which occurrences within the boundary layer may have a decided influence upon the flow pattern. It has long been known that acceleration tends to make the velocity distribution more uniform, whereas deceleration (whether due to curvature or to local or general increase of flow section) not only hastens the spread of the boundary layer, but may even bring about a reversal of flow at the boundary surface. Under such conditions separation will occur, with a high rate of loss in the accompanying turbulent wake. Needless to say, unless the engineer remains content with rule-of-thumb empiricism, a clear understanding of boundary layer phenomena may soon become essential to healthy progress in hydraulic design.

Mr. Johnson has the writer's full appreciation for his excellent endeavor to extend the theories of universal velocity distribution to the difficult case of open channel flow—a very apt contribution at this time. Although, for many years, the velocity distribution has been held by certain engineers to be

logarithmic[53], complexities resulting from the existence of a free surface, non-uniformity of the flow section, secondary currents, variable shear over the boundary, and the presence of bed and suspended loads have continued to prove obstacles to a general rational analysis.

It is evident that at the free surface of a stream the mixing length cannot have its maximum value as in the case of pipe flow. In the latter instance, however, the discontinuity in the universal velocity distribution along the center line of the pipe, owing to lack of correlation in the fluctuations in this region, still does not introduce serious error in this relationship. It is possible that discontinuity at the free surface is no more serious, as indicated by Mr. Johnson's measurements. The question of secondary currents, however, cannot be ignored unless the channel width is extremely great. Prandtl has explained this secondary motion in closed conduits as the resultant action of the tangential components of fluctuation at points of maximum curvature of the isovels. Although further analysis may be necessary in applying this reasoning to the case of a free surface, one fact is clear: Since secondary currents depress the region of maximum velocity farther and farther below the surface as the width-depth ratio decreases, it is evident that such motion cannot be ignored in deriving a universal velocity relationship. Introduction of the hydraulic radius to average the different intensities of boundary shear (resulting, as do the secondary currents, from the shape and variable roughness of the cross-section) is still to be proved fully justifiable in a general expression; any given hydraulic radius may apply to a wide range of channel proportions, and surely the change in geometrical cross-section will influence the flow pattern. Mr. Johnson's empirical expression, $T = k\, v^2$, depends entirely upon judicious choice of k—which is at best a variable quantity Needless to state, movable-bed studies must continue to retain their empirical nature as long as uniform open channel flow itself has not been mastered.

Mr. Wilson will note that he has omitted an essential variable in Equation (92)—the slope, S, properly included by Lindquist[48]. However, it is questionable whether Equation (92) even then is complete (or exponential, as assumed), except for small, smooth-walled channels of approximately similar form. In the light of the foregoing discussion, uniform open channel flow with fixed bottom should be completely described by a relationship of the form,

$$\phi\left(\frac{V^2}{d_0\frac{\gamma}{\rho}}, \frac{V\,d_0}{\frac{\mu}{\rho}}, S, \frac{\epsilon}{d_0}, \beta\right) = 0 \quad \ldots\ldots\ldots\ldots\ldots (129)$$

in which the terms are, respectively, the Froude number, the Reynolds number (if $d_0 < b$), the relative roughness, and some dimensionless shape factor describing the proportions of the cross-section of flow.

[53] See, for instance, R. Jasmund, *Zeitschrift für Bauwesen*, 43, 1893; "Die Quergeschwindigkeitskurve bei turbulenter Strömung", von H. Krey, *Zeitschrift für angewandte Mathematik und Mechanik*, 7, 1927; and "Hydraulik", von P. Forchheimer, B. G. Teubner, Leipzig und Berlin, 1930, S. 179.

Either S or $\dfrac{V^2}{d_o \dfrac{\gamma}{\rho}}$ might be selected as the dependent variable, but it is evident that the resulting relationship, although physically correct, is too cumbersome to be practicable. However, by a development parallel to that leading to Equations (13) and (15), introduction of the mean wall shear, $(\tau_o)_m$, will lead to the expression,

$$(\tau_o)_m = \gamma R S = \frac{f}{4} \rho \frac{V^2}{2} \qquad (130)$$

or,

$$f = 4 \frac{\gamma R S}{\rho \dfrac{V^2}{2}} = 4 \frac{R S}{\dfrac{V^2}{2 g}} \qquad (131)$$

whence, in the Chezy form,

$$V = C_c \sqrt{R S} = \sqrt{\frac{8 g}{f}} \sqrt{R S} \qquad (132)$$

The Chezy coefficient, C_c, is different numerically and dimensionally from the C in Equation (92).

Assuming that the hydraulic radius, R, is a suitable length to be used in the Reynolds number and the term for relative roughness,

$$f = \phi'\left(\frac{V R}{\nu}, \frac{\epsilon}{R}, \beta\right) \qquad (133)$$

These three independent parameters will vary considerably in their relative influence on the resistance coefficient, f. The Reynolds number probably has marked significance only in small channels (such as are encountered in model studies) or those with very smooth boundaries, being subordinate to $\dfrac{\epsilon}{R}$ in appreciably rough channels, just as in the case of pipes. Of course, β becomes of no importance only as the width-depth ratio becomes great, unless the side slopes extend far into the central regions of flow. Some appropriate factor similar to the width-depth ratio, such as $\dfrac{d_o}{R}$, might conveniently replace β, as long as the channel remains of a given general form (that is, elliptical, trapezoidal, rectangular, etc.), but this evidently cannot define the relative proportions of all such forms at one and the same time.

Once non-uniform flow is considered, the problem becomes even more difficult. This phase has been approximately solved, as far as the immediate needs of practical design are concerned, by a combination of empirical data on resistance with rational analysis, through the use of certain simplifying

assumptions. The empirical data involve the magnitude of the Chezy C as a function of channel roughness, hydraulic radius, and mean velocity, and were largely determined for cases of uniform flow. It is generally realized that non-uniform flow—whether accelerative or decelerative—will result in a rate of energy loss (and, hence, boundary shear) differing from that in uniform flow at the same depth by more than a negligible amount.

The writer stresses these difficulties not from any sense of discouragement, but in order that full understanding of the obstacles to be surmounted may prevent investigators from plowing blindly into a field so demanding of careful cultivation. It is hoped, therefore, that the combination of the basic thesis as presented in the paper, the discussion, and the closure may prove a stimulus to further research in a subject that is most essential to hydraulic engineering. To Professor von Kármán the writer expresses his appreciation, not only for contributing to the discussion of the paper, but for critically examining the contents of this closure.

COMPARISON OF SLUICE-GATE DISCHARGE IN MODEL AND PROTOTYPE

BY FRED WILLIAM BLAISDELL[1], JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. RAYMOND BOUCHER, H. E. HURST, G. H. HICKOX, AND FRED WILLIAM BLAISDELL

SYNOPSIS

There is a need for experimental data to support hydraulic model theory because confidence in the use of models hinges upon this checking of model experimental results with prototype experiments. It is seldom possible to check model experiments with prototype experiments although this condition has shown considerable improvement in the last few years. In this paper the aim is to present the results of experiments on the prototype and the model of sluice-gates.

NOTATION

The symbols used in this paper are defined, as follows:

c = a coefficient; c_d = a coefficient of discharge;
g = acceleration due to gravity;
l = scale ratio of length = $\frac{L_n}{L_m}$;
m = a subscript denoting model;
n = an exponent in Equation (1); as a subscript, n denotes "in Nature" or "in prototype";
q = scale ratio of flow ($q = \frac{Q_n}{Q_m}$);
v = velocity;
A = area;
F = Froude's number;
H = head;
L = length;
Q = rate of flow; Q_n = rate of flow for prototype; Q_m = rate of flow for model.

NOTE.—Published in January, 1936, *Proceedings*.

Introduction

A thorough search of technical literature reveals that the United States Bureau of Reclamation has made several experiments on canal head-gates and that the Ministry of Public Works of Egypt has made very thorough prototype and model experiments on the Assuan Dam on the Nile River. The experiments[3] made by the U. S. Bureau of Reclamation were on the prototype only. The experiments on the Assuan Dam[4] were continued for a period of 20 yr and include experiments on sluices 2 m wide by 3.5 m high (6 ft 6¾ in. by 11 ft 5¾ in.) and 2 m wide by 7 m high (6 ft 6¾ in. by 22 ft 11½ in.) through the dam under heads (measured from the gate-sill) from 0.3 to 13.5 m (1.0 ft to 44.3 ft) for the smaller sluices, ten of which discharged into a large tank where the water was measured volumetrically. Six models were built of these smaller sluices and approximately 1 500 experiments were made. The comparison of model and prototype results for all experiments shows that the ratio of $\frac{Q_n}{Q_m}$ varies as $l^{2.5}$, or that Froude's model law will apply to discharge through sluices. The mean departure of $\frac{Q_n}{Q_m}$ from $l^{2.5}$ was found to range from − 4.6% to + 4.5%, with an average departure of + 0.4 per cent.

Prototype

Plans of the Tremont gates at Lowell, Mass., with copies of data on experiments performed on these gates in June, 1868, by the late James B. Francis, Past-President and Hon. M. Am. Soc. C. E., were made available by Arthur T. Safford, M. Am. Soc. C. E. These gates were set in a canal and were apparently calibrated by Mr. Francis in order that they might be used to measure the quantity of water passing them. There are two sluices, of ashlar masonry, 9 ft wide by 7.12 ft high, to the top of the arch (see Fig. 1). Each sluice is closed by wooden gates 10 in. thick; the floors are set above the bottom of the canal; and the openings are flared. When in operation both gates were opened the same amount and the head-water was maintained at about the level of the top of the sluice. The head-water elevation was measured in a well at the Tremont cotton house after being conveyed from the apron by a 1½-in. pipe through one of the sluices (see Fig. 1). The tail-water elevation was measured on a wooden gauge in the same well. The actual quantity of water passing the gates was measured with a rectangular weir and computed by means of the Francis weir formula. Correction for velocity of approach was made to the head measured at the weir, but such correction was not made to the head measured at the gates. This latter omission on the part of Mr. Francis was undoubtedly due to the fact that the gates were calibrated for practical purposes only. As this was the manner in which

CHANNEL

The channel in which the model of the gates was set, was constructed especially for this experiment. It consisted of four sections—a weir tank in which the water was measured; an entrance box in which the turbulence of the water due to passing over the weir was absorbed; the channel proper with plate-glass sides; and the exit box. The weir tank was 3 ft 6 in. square, 5 ft deep, and contained a sharp-edged weir 1 ft deep, with a 90° notch, which was calibrated by means of volumetric tanks immediately before being put into use on this experiment.

The water flowed horizontally, and with marked turbulence, from the weir tank into the entrance box. A vertical baffle placed near the exit of the weir box deflected the water downward and dissipated all the horizontal velocity. Another baffle set in the entrance box served to accelerate the water gradually so that it entered the channel with a minimum of turbulence.

The channel was 2 ft wide, and the bottom (a 4-in. non-reinforced concrete slab, 5 ft 3 in. long, supported on two 3-in. 5.7-lb I-beams) was set 3 ft 5 in. above the floor of the laboratory. It was designed so that there

would be practically no deflection under the heaviest possible loading. The sides consisted of $\frac{3}{4}$-in. plate-glass windows supported in structural steel frames. A head measuring gauge, reading to 0.01 cm, ran on adjustable rails, $1\frac{1}{16}$ in. in diameter, which were supported by $\frac{3}{8}$-in. bolts and double nuts spaced 9 in., center to center, from the steel framework for the glass channel sides. This gauge was movable in three directions so that measurements could be obtained in any part of the channel. No deflection was observed in the carriage rails when the gauge was in operation.

Water is collected in the outlet box, from which it is conveyed back to the main storage reservoir. It passes from the reservoir through a centrifugal pump and into a skimming tank in which a constant surface elevation is maintained under all conditions. Finally, it is distributed from this point to all parts of the laboratory under conditions insuring a constant rate of flow at all times.

Model

A scale ratio of 1 to 15 was determined upon as being the most satisfactory. The model was constructed in two parts which were grouted together after placing the model in the channel. A base section comprising that part of the model up to the floors of the sluices was constructed of sand-cement mortar. The top section containing the sluices and gates was constructed of cement and white pine sawdust. This use of sawdust resulted in a model approximately one-third as heavy as the sand-cement mixture, and no noticeable swelling or shrinking occurred after it had set. The model was smoothed (not polished) with an emery stone. The gates were of redwood, 0.66 in. thick; they were square-edged, and were held in place by wedges.

The elevation of the up-stream water surface was measured, as in the prototype (see Fig. 1), by means of a perforated pipe lying on the apron in front of the pier and leading to a glass well at the down-stream end of the sluices. The down-stream water-surface elevation was measured in a stilling-well, a vertical shutter arrangement controlling the tail-water elevation.

Experimental Procedure

In making an experimental test the gates were first set to the desired opening with the aid of the traveling gauge and were wedged in position. A predetermined rate of flow was allowed through the model, and the tail-water elevation was controlled by means of the shutters so that the head-water elevation would be at approximately the top of the sluices.

After conditions had become constant, readings were taken of water-surface elevations above and below the gates and at the measuring weir. Any unusual conditions of flow were noted. The water approached the model with little velocity and an absence of turbulence. After passing the gates there was considerable turbulence noticeable in the sluices accompanied by a horizontal surface roller near the gates. Under some conditions a hydraulic jump would form in the sluices and when this occurred the tail-water elevation was measured down stream from the jump.

Coefficient of Discharge

The experimental results are shown by broken lines in Fig. 2 and correspond to the solid curves for the prototype. For different gate-openings these curves are not parallel, as was the case with the curves for the prototype. This is also demonstrated by Table 1 in that n is not a constant for all gate-openings. The value of n in Equation (1), as obtained from the model experiments, is seen to vary from $+1.3\%$ to $+13.1\%$ of the values obtained from the prototype experiments with an average deviation of $+9.0$ per cent. The values of c_d obtained from the model experiments for use in Equation (1) can be seen to vary from -0.5% to $+4.1\%$ of the values obtained from the prototype experiments with an average deviation of $+1.3\%$, with the 0.2-ft gate-opening omitted. With $n = 0.5$ (which is the value commonly assigned to n) the values of c_d computed from the model experiments were found to vary from -4.7% to $+10.7\%$ of the values obtained from the prototype experiments with an average deviation of $+5.1$ per cent.

It will be noted that the results obtained for the 0.2-ft gate-opening were omitted from the averages. This was done because these experiments support the recommendation of Messrs. Hurst and Watt[3] that,

"Until further experiments on models of other structures define the limiting conditions more closely, it will be well to keep the product of velocity, in centimeters per second, and the smallest dimension of the orifice, in centimeters, above, say, 100 [cm^2 per sec = 0.11 ft per sec], and in general not to use orifices of less than 3 centimeters [$1\frac{1}{8}$ in.] in their smallest dimension."

The 0.2-ft gate-opening corresponds to a 0.41-cm ($\frac{5}{32}$-in.) model gate-opening and the velocity through the gates for a 5-ft head is 151 cm per sec (5 ft per sec) which gives 62 as the product of velocity and least dimension for the highest head. For the 0.6-ft gate-opening, the model gate-opening is 1.22 cm ($\frac{15}{32}$ in.) and the velocity is 31 cm per sec, or 1 ft per sec ($H = 0.5$ ft) which gives 38 as the product of velocity and smallest opening. In spite of the fact that the 0.6-ft gate-opening had values of gate-opening times velocity of considerably less than 100, the results were included in the averages because of the good agreement between model and prototype results.

The model gate-openings are not greater than 3 cm ($1\frac{1}{8}$ in.) until the 1.5-ft prototype gate-opening is reached, and the product of velocity, in centimeters per second, and the smallest dimension, in centimeters, for all heads is not greater than 100 until this same gate-opening is reached. Because of the fairly good agreement of the results obtained for model and prototype, it was felt that all results for gate-openings, of 0.6 ft, or larger, should be included in the averages. The average percentage deviation of values of c_d (see Fig. 3(a)), as obtained from model experiments, from values of c_d obtained from prototype experiments for different heads, was found to increase as the head increases. The reason for this increase is perhaps due to some peculiarity of the sluice which was not copied exactly or to the lessening effect of friction as the velocity increases.

The recommendations of Messrs. Hurst and Watt[3] were checked roughly. Good results were obtained for smaller values of least dimension and the product of velocity and least dimension. The lowest satisfactory values of

these items obtained in these experiments for all heads tested were 1.22 cm ($\frac{15}{32}$ in.) and 28 cm^2 per sec (0.03 ft^2 per sec), respectively. Upon the basis of these experiments it would seem that the recommendations of Messrs. Hurst and Watt are conservative.

Probable Errors

The measuring weir was carefully calibrated just before use in this model, and it is believed that the errors resulting from incorrect measurements of discharge are negligible.

There was some fluctuation of head and tail-water elevations in the glass tubes at the model in spite of all attempts to eliminate it. This, probably, caused some error in the experimental results. It is also probable that this error would be compensating.

Possibly there may have been some error in the gate-setting; but this was done with care and the error would be less than 0.02 cm, or $\frac{1}{128}$ in. (0.01 ft, full scale). In constructing the sluices there was some error in width, which ranged from -1.5% to -0.5%, with an average error of -1.0 per cent. This error in the width of the sluice will cause the same percentage error in the discharge.

During the experiment it was suggested to the writer that there might be an error in the zero reading of head that would cause part of the difference between model and prototype results. Accordingly, a series of curves with discharge raised to a power which would produce a straight line as ordinate and gate-opening as abscissa was made for the several heads tested (see Fig. 4). The points used in plotting these curves were obtained from the curves of Fig. 2.

The curves of Fig. 4 indicate that the zero of gate-opening was -0.265 ft for the model experiments and -0.135 ft for the prototype experiments. If the error had been equal for both model and prototype there would have been none in the experimental results. The error in the model, however, is 0.130 ft greater than that for the prototype. This will cause an average error of $+5.1\%$ in the results of the model experiments. Since this error is larger for the smaller gate-openings it would result in a general lowering of the curves of Fig. 3 which would be more pronounced for the smaller gate-openings.

In the experiments performed on models of sluices of the Assuan Dam[1] the models were made smooth to the touch (the prototype was of smooth-dressed stone and the values of l ranged from 33 to 67). Subsequently, coatings of fine sand and coarse sand were given one of the models in which l had a value of 33. These sand coatings had the effect of reducing the average discharge by 5% and 9%, respectively, for a fully opened sluice with maximum reductions in discharge of 6.5% and 11%, respectively, the effect increasing with the head. For the sluice four-sevenths open, the water did not touch the top of the sluice, and the average reduction in discharge was 2.4% and 3.1%, respectively, the percentage reduction being nearly constant for all heads. A reduction in discharge of the model will cause positive percentage

departures of $\frac{1}{l^{2.5}}\left(\frac{Q_n}{Q_m} - l^{2.5}\right)$, and negative percentage departures of $\frac{c_{dm} - c_{dn}}{c_{dn}}$.

Messrs. Hurst and Watt declare[3] that, "* * * if the frictional resistance is not exactly proportional to the square of the velocity, the relation, $Q = q\, n^{2.5}$ $[Q_n = Q_m\, l^{2.5}]$ is departed from. * * * The effect of frictional

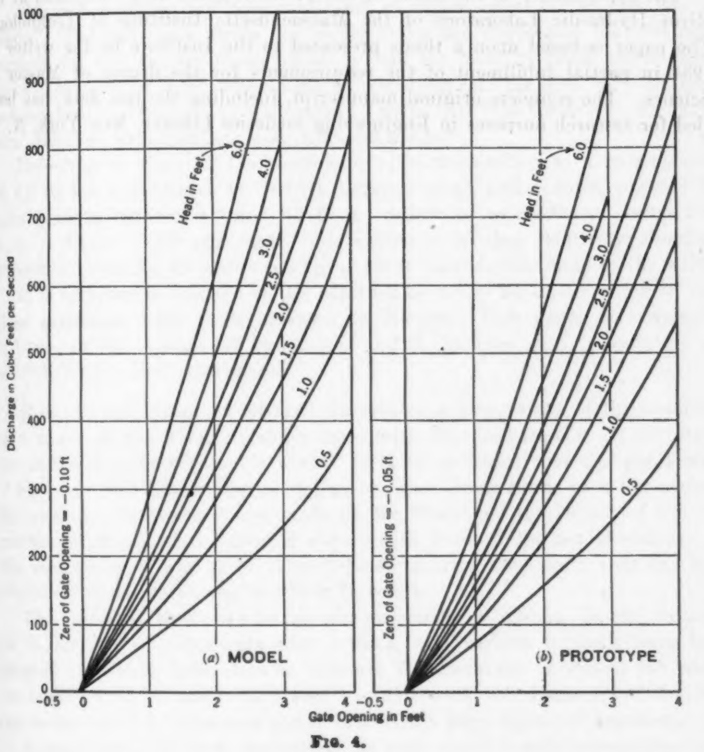

Fig. 4.

resistance becomes less as velocity and dimensions increase." All these factors are conducive to positive percentage departures from Froude's law. On the basis of the results obtained the writer assumes that the roughness of the model of the Tremont gates simulated the roughness of the prototype fairly well since the latter was fairly rough, the value of l was small, and the model had the roughness of about No. 0 sand paper.

Conclusions

In this paper the writer has attempted to show that: (1) Models of sluice-gates can be depended upon to predict the discharge of their prototypes with reasonable accuracy; (2) Froude's model law will apply to the discharge of

sluice-gates; (3) roughness of both model and prototype must be given consideration in the construction of the model; and (4) good results should not be expected for small gate-openings and low velocities.

Acknowledgments

The experiments on the model of the Tremont gates were conducted at the River Hydraulic Laboratory of the Massachusetts Institute of Technology. The paper is based upon a thesis presented to the Institute by the writer in 1934 in partial fulfillment of the requirements for the degree of Master of Science. The complete original manuscript, including the test data, has been filed for research purposes in Engineering Societies Library, New York, N. Y.

DISCUSSION

RAYMOND BOUCHER,[4] JUN. AM. SOC. C. E. (by letter).—More than ever the hydraulic engineer is in need of proofs that model experiments are trustworthy. Mr. Blaisdell's paper is an excellent contribution toward that end.

The author states that "the coefficient, c_d, is not equal for all openings or heads." The statement leaves the reader under the impression that the head depends on the gate-opening, which is not the case in these experiments because by varying the discharge the gate-opening and the head were adjusted independently. It would be preferable to write that "the coefficient, c_d, varies with different gate-openings and different heads."

Referring to Table 1, the coefficient, c_d, corresponding to a gate-opening of 4.0 ft, has a difference of + 4.1% between model and Nature, whereas for gate-openings between 1.0 and 3.0 ft the difference in coefficient varies only from − 0.5 to + 1.0 per cent. The existence of that relatively abnormal difference in c_d, for the gate-opening of 4.0 ft, is not quite clear to the writer.

It is remarkable that the values obtained by model experiments are in very close agreement with those obtained in Nature. This paper is a valuable addition to the science of hydraulics and is another step in proving the reliability of model experiments.

H. E. HURST,[5] ESQ. (by letter).—In making a comparison of the discharge of a model of the Tremont sluice-gates with the discharge of its prototype, the author has done valuable work. It is to be hoped that the publication of his paper will lead to the recording of other comparisons of a like nature. He mentions the comparisons, made by Mr. Watt and the writer, of the discharges of models of the Assuan sluices with those of the actual sluices. In this connection it will be of interest to summarize some work that has been published[6] since the papers to which he refers.

The full-scale sluice discharge measurements at Assuan depend initially on volumetric measurements with a tank, and various methods have been adopted to extend these data to measure the discharge of sluices for which the tank cannot be used. As a result of this work, the discharge of the Nile can be measured by means of the sluices with a high degree of precision.

A comparison of these measurements with simultaneous measurements of the discharge by means of current meters has shown that during the low stage of the river the difference between the sluice and the current meter measurements is negligible. During the flood period the discharge given by the current meters was about 5% greater than the discharge given by the sluices.

The Assuan model experiments to which Mr. Blaisdell refers were made on sluices high above the river bed and discharging freely into air. For these

Paper No. 24*, Ministry of Public Works, Egypt; also, "Further Experiments on the Discharge of Models of Sluices", by H. E. Hurst, *Physical Dept. Paper No. 25*, Ministry of Public Works, Egypt. (A copy of *Papers Nos. 24* and *25* are available for reference, at Engineering Societies Library, 33 West 39th St., New York, N. Y.)

experiments there was very good agreement between model and prototype. Since then experiments have been made on the type of sluice, 7 m (23.0 ft) high by 2 m (6.56 ft) wide, through which the river passes under a low head in flood time.

For these sluices the conditions are very different. They are not very high above the river bed and, therefore, are affected by differences on the river bed up stream of them. They are used when the velocity of approach is high and the direction of approach is different for different sluices. They are partly submerged down stream and the down-stream level is very difficult to measure in the turbulent condition of the water. It is also very different at different places owing to the large variation in the level of the bed down stream of the dam.

The mean discharge of six similar sluices is 6% less than the discharge inferred from the model. Two of these sluices are more similar in condition to the majority of the sluices than the other four, and for these two the mean discharge is only 1.7% less than that inferred from the model. The experiments on the model were very complete and covered a large range of up-stream and down-stream levels, and all measurements were made directly by means of a measuring tank.

As a result of these experiments three conditions of flow were found: (1) Free flow into the air; (2) submerged flow; and (3) intermediate types between Conditions (1) and (2).

(*1*).—Free flow into air persisted until the down-stream level was considerably above the sill of the sluice. In these conditions, the flow was represented by,

$$Q = c\,A\,\sqrt{2\,g\,(H - F)} \qquad (2)$$

in which Q is the discharge; A, the area of the gate-opening; H, the head above the sill of the sluice; and c and F are constants for any particular gate-opening.

(*2*).—The submerged condition begins when the down-stream level is well above the top of the sluice-opening, in which case the discharge is represented by,

$$Q = c\,A\,\sqrt{2\,g\,(H - h)} \qquad (3)$$

in which h is the head down stream above the sill.

(*3*).—The transition condition lies between the free and submerged conditions. The down-stream level affects the discharge, which, however, is not given by Equation (3). These conditions are best illustrated by reference to Fig. 5[7] in which a form of representation is adopted that is very useful in the study of the discharge of sluices or weirs.

In Equations (2) and (3), $\frac{Q^2}{A^2}$ is a linear function of H and, therefore, in Fig. 5, the two are plotted against each other. The result shows immediately the type of flow under any conditions of up-stream and down-stream

[7] *Physical Dept. Paper No. 25*, Ministry of Public Works, Egypt, Pl. 3.

level. The actual observation points are not shown, but they were numerous and fell very closely on the lines drawn in the diagram.

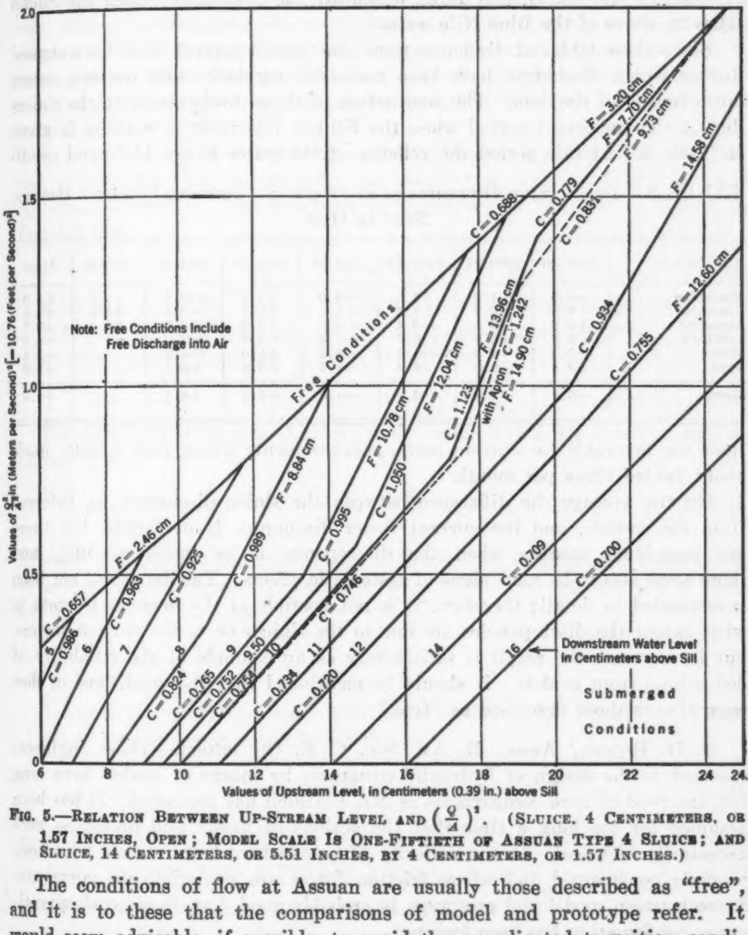

FIG. 5.—RELATION BETWEEN UP-STREAM LEVEL AND $\left(\frac{Q}{A}\right)^2$. (SLUICE, 4 CENTIMETERS, OR 1.57 INCHES, OPEN; MODEL SCALE IS ONE-FIFTIETH OF ASSUAN TYPE 4 SLUICE; AND SLUICE, 14 CENTIMETERS, OR 5.51 INCHES, BY 4 CENTIMETERS, OR 1.57 INCHES.)

The conditions of flow at Assuan are usually those described as "free", and it is to these that the comparisons of model and prototype refer. It would seem advisable, if possible, to avoid the complicated transition conditions in using a model sluice as a means of inferring the discharge of its prototype, as it may be that the discontinuities do not occur always at the same points on both. For example, one of the Assuan type of sluices showed a condition in which there were two separate values of the discharge for the same head where only one could be obtained on the model, although this condition was actually in the region of free discharge into air.

The results of the Assuan model experiments led to the use of models as a means of inferring the discharge through the sluices of the dam on the

Blue Nile, near Sennar. The results of this work are described in *Paper No. 25* previously mentioned, and from these results are constructed the tables of discharge for the Sennar Dam, which are the basis upon which the Sudan takes its share of the Blue Nile water.

Since these tables of discharge were constructed several years have elapsed during which discharges have been measured regularly with current meters down stream of the dam. The comparison of these discharges with the sluices during the important period when the Sennar Reservoir is working is given in Table 3. At this period the velocity of the water is not high, and conditions are favorable for current meter measurements which were usually made about twelve times per month.

TABLE 3.—PERCENTAGE DIFFERENCES BETWEEN SLUICES AND CURRENT METERS, SENNAR DAM

Month	1929–30	1930–31	1931–32	1932–33	1933–34	1934–35	1935–36	Mean
November	−0.6	+1.0	+4.3	+4.0	+5.9	+10.4	+9.8	+5.0
December	+4.3	+0.2	+1.4	+2.1	+6.1	+9.8	+4.4	+4.0
January	+3.3	−3.5	−3.4	−2.3	+3.8	+3.6	+3.6	+0.7
February	−6.2	+2.6	−8.6	−7.3	−1.6	−2.6	....	−4.0
March	−5.9	+4.5	−5.3	−3.5	+1.0	−4.9	....	−2.4
April	+2.4	+9.0	−6.2	+1.2	+3.6	+8.2	....	+3.0
Means	−0.4	+2.3	−3.0	−1.0	+3.1	+4.1	....	+1.0

On the average the difference between the sluice discharges, as inferred from the models, and the current meter discharges is negligible, but there are occasional months when the discrepancy is as much as 10%, and there seem also to be some signs of systematic effects. The data have not been investigated in detail; therefore, it is not possible at the moment to state to what extent the discrepancies are due to the sluices or to the current meters, but in any case the result is satisfactory as an example of the reliability of deductions from models. It should be mentioned that the conditions of flow were always those described as "free."

G. H. HICKOX,[8] ASSOC. M. AM. SOC. C. E. (by letter).—Those engineers engaged in the design of hydraulic structures by means of models have long felt the need of such comparisons as Mr. Blaisdell has presented. It has been assumed for too long a time that the actions of model and prototype were necessarily identical. In the majority of cases where large models have been properly constructed and where friction forces are negligible the correspondence between model and prototype is probably good, but, in general, quantitative confirmation has been lacking.

The author's test results show a gratifying correspondence with the observations on the prototype. Such differences as exist are not readily accounted for, but may be due partly to the fact that the model does not represent the prototype accurately. The model was placed in a straight flume and the water approached it directly, whereas in the prototype, the channel supplying water to the gate approached at right angles and immediately above it. The channel in the prototype is also somewhat wider above the gates than below

[8] Hydr. Engr., TVA Hydr. Laboratory, Norris, Tenn.

them, whereas in the model, both parts of the channel were represented by the same straight flume. Part of the differences found may be due to the consequent difference in the effect of the velocity of approach. It would seem difficult to reproduce the up-stream head with certainty in the straight channel used. The measurement of tail-water elevation may also be open to some question. Although it is by no means certain that they are the only causes of discrepancy, it seems very probable that at least they are contributing factors.

In models in which both gravity and friction forces are effective, the friction requirement may be satisfied by considering both Froude's law and Manning's equation. For similarity with respect to the gravity forces, by Froude's law,

$$v = \sqrt{l\,g} \quad \text{.........................} (4)$$

in which v, l, and g (in accord with the author's notation) are the scale ratios of velocities, lengths, and accelerations due to gravity, respectively. Since g is commonly unity, Equation (4) may be written,

$$v = \sqrt{l} \quad \text{...........................} (5)$$

For similarity with respect to friction forces, Manning's equation may be utilized thus:

$$v = \frac{l^{\frac{2}{3}}\, s^{\frac{1}{2}}}{n} \quad \text{..........................} (6)$$

in which s and n are the scale ratios of slopes and roughnesses, respectively. Where geometrical similarity exists between model and prototype, s = unity, and Equation (6) becomes:

$$v = \frac{l^{\frac{2}{3}}}{n} \quad \text{...........................} (7)$$

In order to satisfy the two conditions simultaneously, Equations (5) and (7) must give the same value for v; that is,

$$l^{\frac{1}{2}} = \frac{l^{\frac{2}{3}}}{n} \quad \text{..........................} (8)$$

from which $n = l^{\frac{1}{6}}$. In the case of the Tremont gates, the sluices were made of ashlar masonry with a probable value of n equal to 0.017. For correspondence, therefore, the n of the model should be: $\dfrac{0.017}{15^{\frac{1}{6}}} \doteq \dfrac{0.017}{1.57} = 0.0108$. This value of n can be obtained with smooth cement surfaces so that, in this case, it seems probable that the requirement for similarity was nearly satisfied.

FRED WILLIAM BLAISDELL,[9] JUN. AM. SOC. C. E. (by letter).—It has been suggested by Mr. Boucher that the statement, "the coefficient, c_d, is not equal for all openings or heads", be changed to "the coefficient, c_d, varies with different gate-openings and different heads." In Table 1 the coefficient, c_d, varies

[9] Junior Soil Conservationist, Hydr. Laboratory, National Bureau of Standards, Washington, D. C.

with different gate-openings but is constant for each gate-opening. In Table 2, where $n = 0.5$, the coefficient, c_d, varies with both gate-opening and head.

At present, the writer is unable to find a good reason for the erratic value of c_d in Table 1 when the gate-opening is 4.0 ft. It will be noticed in Fig. 2, however, that the experimental points obtained for the model gate-opening of 4.0 ft do not follow the curve as well as the points for other gate-openings.

The discussion by Mr. Hurst was of the type which the writer had hoped his paper would inspire. The accuracy of the results of tests made under the direction of Mr. Hurst indicates what can be expected from carefully constructed and carefully tested models. The fact that water is distributed in Egypt on the basis of model experiments indicates the confidence placed in these tests.

Equation (2), given by Mr. Hurst, applies only to free flow into air or to free-flow conditions. In this equation, F is usually assumed to be one-half the gate-opening, or $H - F$ is the head to the center of the gate-opening. In one of the publications mentioned by Mr. Hurst values of F are given for the sluices of the Assuan Dam[10]. These values of F range from 73 to 95% of the opening, which indicates that for the Assuan Dam the head should not be measured from the center of the gate-opening, but from some point above the center.

Mr. Hurst states[11] that:

"This 'Free Condition' with the down-stream level above the level of the sill of the sluice is always marked by the occurrence of a standing wave in the culvert downstream of the sluice-gate"; and, "Observation of the flow shows a well-marked standing wave when the flow is similar to free into air. As the upstream level is lowered to the point where free-flow conditions cease, the wave gradually works back along the culvert to the sluice-gate. While the standing wave exists the flow is steady. When the standing wave begins to disappear the flow is pulsating and the wave oscillates between the sluice-gate and a point a few centimeters down stream of it, appearing and disappearing."

In the model sluices of the Tremont gates, a hydraulic jump was noticed under some conditions. If the standing wave mentioned in the quotation can be called a hydraulic jump, then free-flow conditions, as defined by Mr. Hurst, undoubtedly existed at times in the Tremont gates model.

Equation (3) corresponds to the writer's Equation (1). Submerged flow is the type of flow that existed most of the time in the Tremont model, although it is possible that intermediate flow is present at times. An attempt was made to construct a plot for the Tremont gates experimental results similar to Fig. 5 but there were too few points to define the curves properly.

The derivation of a value for the roughness factor, n, for use in the Manning equation, by Mr. Hickox, is of interest. In this model of the Tremont gates the roughness factor does not assume major importance because of the relatively rough prototype, the large scale ratio, and the ease of building a model having a roughness factor of about 0.108 as computed by Mr. Hickox. In many models, however, the effect of roughness can not be disposed of so easily.

A DIRECT METHOD OF MOMENT DISTRIBUTION

By T. Y. Lin,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. L. E. Grinter, W. H. Huang, Felix H. Spitzer, Harold E. Wessman, Egor P. Popoff, L. T. Evans, G. S. Salter, Leon Blog, Austin H. Reeves, E. J. Bednarski, John T. Howell, I. Oesterblom, W. P. Li, A. A. Eremin, and T. Y. Lin.

Synopsis

The Cross method of distributing fixed-end moments in the analysis of continuous frames[2] has become recognized as such a convenient tool of structural design that it is unnecessary to state its importance, or its advantages over the older, classical methods. However, the necessity of going through a series of approximations is still disliked by many engineers.

The purpose of this paper is to present a direct method[3] of moment distribution, derived from the fundamental conceptions of the original method, but applied without the series of approximations. Designers of continuous frames will find that the method, being a direct corollary of the moment-distribution principle, is easy to learn. The time saved is considerable as compared with other methods, especially for frames subject to several conditions of loading, frames requiring the use of influence lines, frames with members of variable section, and frames in which convergence is slow by the original method and in which greater accuracy is desired. This method also affords a direct visualization of the "transfer" of moments in continuous frames, and thus throws new light on the economy of proportioning, the effect of fixation at the supports, of continuity, etc., which is true of the original method only indirectly.

Note.—Published in December, 1934, *Proceedings*.

[3] A more complete treatment is given in a thesis by T. Y. Lin, presented to the Univ. of California in partial fulfillment of the requirements for the degree of Master of Science in Civil Engineering.

Definitions and Notation

The following notation is used: K = stiffness of an end of a member; γ = carry-over factor of an end of a member; M' = fixed-end moment at an end of a member; and, M = actual moment at an end of a member.

The subscripts have the following significance: *ab* denotes End A of Member AB; *ba* denotes End B of Member AB; *b2* denotes End B of Member $B2$; *dc* denotes End D of Member CD, etc.; and *m* denotes a quantity "modified", due to the actual restraint of the support. For example, K_{ab} = stiffness of End A in Member AB; and γ_{3bm} = a modified carry-over

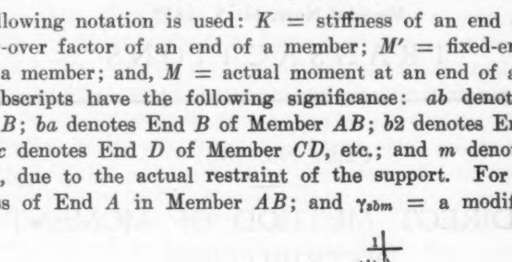

Fig. 1

factor of End 3 in Member $B3$, or the moment at End B due to a unit moment at End 3 with End B under the actual condition of restraint. Furthermore, (see Fig. 1), let,

$$R_{ba} = \frac{K_{ba} + K_{b1m} + K_{b2m} + K_{b3m} + \ldots}{K_{ba}} = \frac{K_{ba} + \Sigma K_{bnm}}{K_{ba}} \quad \ldots\ldots (1)$$

In Fig. 2, Member AB is simply supported at End A and fixed at Point B. Apply a moment at A to produce a unit rotation at that end of the Member AB.

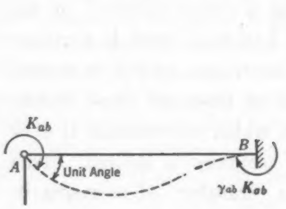

Fig. 2

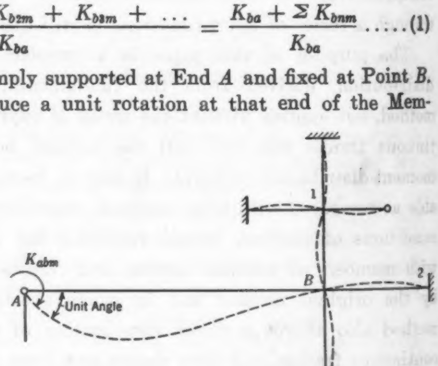

Fig. 3

Then, by definition, K_{ab} = the moment applied at End A = stiffness at End A of Member AB; $\gamma_{ab}\ K_{ab}$ = the moment induced at End B due to a moment K_{ab} at End A; and γ_{ab} = the carry-over factor, from End A to End B.

In Fig. 3, Member AB is simply supported at End A and is connected to several members at Joint B—$B1$, $B2$, $B3$, etc. Apply a moment at A to produce a unit rotation at that end of the member. Then, K_{abm} = the moment applied at A = the modified stiffness at End A of Member AB, with End B held by its restraining members; $\gamma_{abm}\,K_{abm}$ = the moment induced at End B in Member AB, due to the moment, K_{abm}, at End A; and γ_{abm} = the modified carry-over factor from End A to End B.

Sign Conventions

A moment at an end of a member is considered positive when the external moment acting at that end is clockwise. Therefore, a moment carried over does not change in sign; and the algebraic sum of all the end moments at any joint equals the external moment applied at that joint, which is usually zero. (See Fig. 4.)

Fig. 4

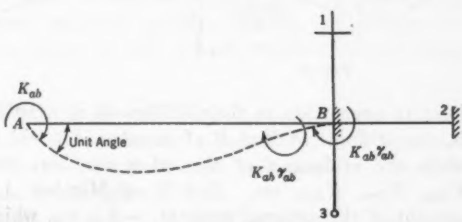

Fig. 5

Theory and Derivation of Equations

In the original method of moment distribution, the stiffness and the carry-over factor of an end of a member are calculated on the assumption that the other end is fixed. Hence, it is necessary to release one joint at a time, holding the joints at the other end of the connected members fixed, in order that the unbalanced moment at a joint may be distributed to the connected members in proportion to their stiffnesses and the distributed moments may be transferred by the carry-over factors. In the method herein presented, however, the modified values of the stiffness and carry-over factor of each end of each member are calculated in accordance with the actual condition of restraint at the other end. Hence, it is possible to release all the joints simultaneously and to distribute the unbalanced moments once only.

Only two formulas are necessary for the application of this method: One for the value of K_{abm}, the other for the value of γ_{abm}. These formulas will be derived from the fundamental concepts of the moment-distribution method as follows:

Given: The values, K_{ab}, K_{ba}, γ_{ab}, and γ_{ba}, of Member AB, and the values of K_{bnm} (see Equation (1)) for the members connected to AB at End B.

Required: The modified moment, K_{abm}, and the modified carry-over factor, γ_{abm}, for End A of Member AB.

Solution:

Step 1.—In Fig. 5, fix Joint B. Apply a moment at End A equal to K_{ab} to produce a unit rotation of that end. Since End B is fixed, a carry-over moment will be produced at End B of Member AB equal to $K_{ab}\ \gamma_{ab}$, which is held in equilibrium by the external moment, $K_{ab}\ \gamma_{ab}$.

Step 2.—Fix End A in this rotated position, as shown in Fig. 6. Release Joint B by applying an external moment of $-K_{ab}\ \gamma_{ab}$, which will rotate all the members meeting at that joint through an equal angle. Hence, this external moment will be distributed among the members meeting at the

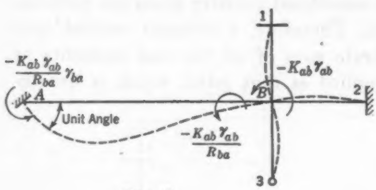

FIG. 6

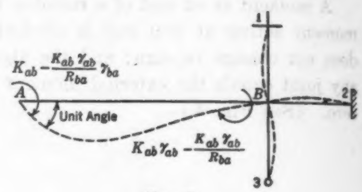

FIG. 7

joint in proportion to their stiffnesses as existing under this condition; that is, the stiffness at End B of Member AB will be K_{ba} (End A being fixed), while the stiffnesses of the other members will be their modified values, K_{b1m}, K_{b2m}, K_{b3m}, etc. End B of Member AB will take its proportional amount of the external moment, $-K_{ab}\ \gamma_{ab}$, which is,

$$-K_{ab}\ \gamma_{ab}\left(\frac{K_{ba}}{K_{ba}+K_{b1m}+K_{b2m}+K_{b3m}+\ldots}\right)$$

$$=-K_{ab}\ \gamma_{ab}\left(\frac{K_{ba}}{K_{ba}+\Sigma K_{bnm}}\right)$$

or,

$$M=\frac{-K_{ab}\ \gamma_{ab}}{R_{ba}}\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

Since End A is fixed, the distributed moment (Equation (2)), of End B will be carried over to End A by the carry-over factor, γ_{ba}. Hence, a moment will be produced at End A of Member AB equal to $\frac{-K_{ab}\ \gamma_{ab}}{R_{ba}}\gamma_{ba}$.

Step 3.—Next, examine the resulting elastic and static condition of Member AB at the end of Steps 1 and 2. (See Fig. 7.) End A of the member is rotated a unit angle and End B is connected to its adjoining members without any external restraint. The resulting moment at End A is the sum of the moments produced in the two steps; that is, $K_{ab}-\frac{K_{ab}\ \gamma_{ab}}{R_{ba}}\gamma_{ba}$. This is the moment at A necessary to produce a unit rotation at End A of Member AB, with End B under its actual condition of restraint. By definition, it is the modified stiffness at End A of Member AB. Therefore,

$$K_{abm} = K_{ab} - \frac{K_{ab}\ \gamma_{ab}}{R_{ba}}\ \gamma_{ba} = K_{ab}\left(1 - \frac{\gamma_{ab}\ \gamma_{ba}}{R_{ba}}\right) \quad \ldots\ldots\ldots (3)$$

The resulting moment at End B of Member AB, $K_{ab}\ \gamma_{ab} - \dfrac{K_{ab}\ \gamma_{ab}}{R_{ba}}$, is that produced at that end due to a unit rotation of End A, with End B under its actual condition of restraint. Its ratio to the resulting moment applied at A is, by definition, the modified carry-over factor at that end of the member, AB. Therefore,

$$\gamma_{abm} = \frac{K_{ab}\ \gamma_{ab} - \dfrac{K_{ab}\ \gamma_{ab}}{R_{ba}}}{K_{ab}\left(1 - \dfrac{\gamma_{ab}\ \gamma_{ba}}{R_{ba}}\right)} = \gamma_{ab}\ \frac{R_{ba} - 1}{R_{ba} - \gamma_{ab}\ \gamma_{ba}} \quad \ldots\ldots\ldots (4)$$

Equations (3) and (4) are the only ones necessary in this method. They may be simplified for special cases, as follows: (1) For a fixed end, R_{ba} equals infinity; (2) for a hinged end, R_{ba} equals unity; (3) for members of uniform moment of inertia, $\gamma_{ab}\ \gamma_{ba} = \frac{1}{4}$; and (4) for symmetrical members, $\gamma_{ab} = \gamma_{ba}$.

Application of Method

The general procedure consists of two distinct steps: First, to analyze the structure under no load; that is, to find the K_m and γ_m-values; and, second, to distribute the unbalanced fixed-end moments.

Step 1.—Find the values of K and γ of both ends of all members by the usual methods. When the R-value of one end of a member is known, the K_m and γ_m-values of the other end can be found from Equations (3) and (4), respectively. For a hinged end, R is unity; for a fixed end, R is infinity; and, for all other cases, R will have values between the two, and can be either calculated or estimated from the modified stiffnesses of the connected members.

Step 2.—Find the fixed-end moments of each loaded or deformed member by the usual methods. Distribute the unbalanced moments at each joint to all the members meeting at the joint in proportion to their modified stiffnesses. Carry over the distributed moment of each member to the other end by the corresponding modified carry-over factor. Distribute each carried-over moment among the connected members in proportion to their modified stiffnesses. Continue this process of carrying over and distributing to the supports of the structure. Add the fixed-end moment, the distributed moments, and the carried-over moments, to find the resulting moment at each end of each member.

Steps 1 and 2 explain the general procedure only. They can be modified easily to suit individual cases. Some of the important variations will be shown in the subsequent illustrations.

Limitation of the Method

Since the two fundamental equations (Equations (3) and (4)) are derived from the first principles of the moment-distribution method, this modified

method has the same limitations as the original. Problems such as sidesway,[4] that can be solved by the original method, can be solved similarly by the writer's method.

EXAMPLES

Example 1.—Consider the frame shown in Fig. 8. Ends G and F are hinged; Ends H and J are fixed; and Ends A and B are connected to members above the frame (not shown in the diagram), such that End A of Member AD has a value of $R_{ad} = 3.00$ and End B of Member BE has a value of $R_{be} = 6.00$.

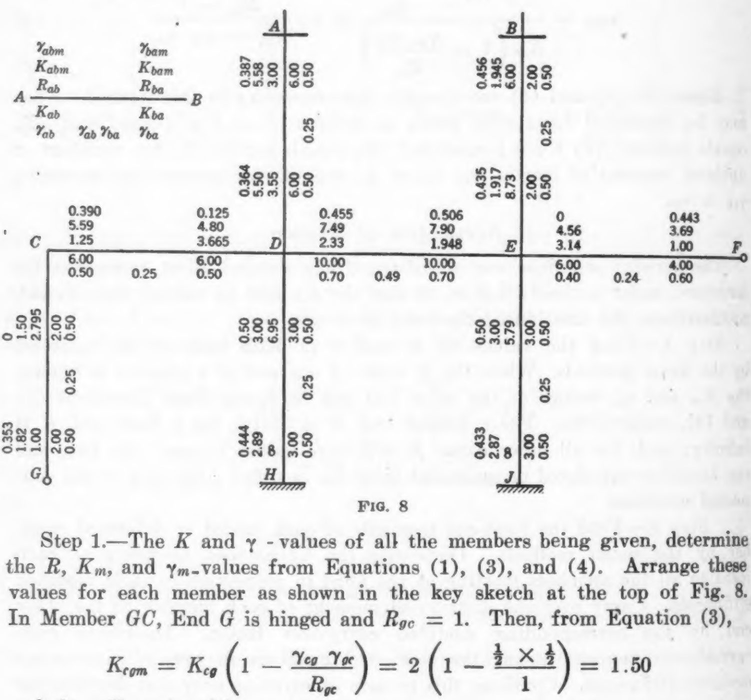

FIG. 8

Step 1.—The K and γ - values of all the members being given, determine the R, K_m, and γ_m-values from Equations (1), (3), and (4). Arrange these values for each member as shown in the key sketch at the top of Fig. 8. In Member GC, End G is hinged and $R_{gc} = 1$. Then, from Equation (3),

$$K_{cgm} = K_{cg}\left(1 - \frac{\gamma_{cg}\,\gamma_{gc}}{R_{gc}}\right) = 2\left(1 - \frac{\frac{1}{2} \times \frac{1}{2}}{1}\right) = 1.50$$

and, from Equation (4),

$$\gamma_{cgm} = \gamma_{cg}\,\frac{R_{gc} - 1}{R_{gc} - \gamma_{gc}\,\gamma_{cg}} = \frac{1}{2}\,\frac{1 - 1}{1 - \frac{1}{4}} = 0$$

Similarly, in Member CD, $R_{cd} = \dfrac{6 + 1.5}{6} = 1.25$; $K_{dcm} = 6\left(1 - \dfrac{0.25}{1.25}\right) = 4.80$; and, $\gamma_{dcm} = \dfrac{1}{2}\,\dfrac{0.25}{1.00} = 0.125$. In the case of Member HD, R_{hd} = infinity; $K_{dhm} = K_{dh} = 3$; and, $\gamma_{dhm} = \gamma_{dh} = \frac{1}{2}$. In Member

[4] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 9.

AD, $R_{ad} = 3$; $K_{dam} = 6\left(1 - \dfrac{0.25}{3}\right) = 5.50$; and $\gamma_{dam} = \dfrac{1}{2}\left(\dfrac{3-1}{3-0.25}\right)$ $= 0.364$. In Member DE, $R_{de} = \dfrac{10.0 + 5.5 + 4.8 + 3}{10.0} = 2.33$; K_{edm} $= 10\left(1 - \dfrac{0.7 \times 0.7}{2.33}\right) = 7.90$; and $\gamma_{edm} = 0.7\,\dfrac{1.33}{1.84} = 0.506$.

Consider Members BE, FE, and JE as a group. Determine the values of R_{ed}, K_{dem}, γ_{dem}, etc., and record all these values on the frame (Fig. 8). Evidently, many of these values of R, K_m, and γ_m are not needed.

Step 2.—Only some of the values calculated in Step 1 will be used in Step 2. Assuming an external moment of 100 at Joint D, distribute it among the members meeting at that joint in proportion to their K_{dm} - values (see Fig. 8), as follows:

$$\begin{aligned}
M_{dc} &= 4.80 \times \frac{100}{20.79} = 23.08\\
M_{da} &= 5.50 \times 4.810 = 26.45\\
M_{de} &= 7.49 \times 4.810 = 36.04\\
M_{dh} &= 3.00 \times 4.810 = 14.43\\
&\quad\overline{20.79} \qquad\quad \overline{100.00}
\end{aligned}$$

Carry over the distributed moments by the modified carry-over factors; thus:

$$\begin{aligned}
M_{cd} &= M_{dc} \times \gamma_{dcm} = 23.08 \times 0.125 = 2.88\\
M_{ad} &= 26.45 \times 0.364 = 9.62\\
M_{ed} &= 36.04 \times 0.455 = 16.40\\
M_{hd} &= 14.43 \times 0.500 = 7.21
\end{aligned}$$

Distribute each moment thus carried over among the connected members at the joint, in proportion to their modified stiffnesses: At Joint C, $M_{cg} = -M_{cd} = -2.88$; at Joints A and H, the frame ends, and no further distribution will be necessary; and at Joint E, the moment, $M_{ed} = 16.40$, will be distributed to the connected members, EB, EF, and EJ, thus:

$$\begin{aligned}
M_{eb} &= 1.917 \times \frac{-16.40}{1.917 + 4.56 + 3.0} = -3.31\\
M_{ef} &= 4.56 \times -1.73 = -7.90\\
M_{ej} &= 3.00 \times -1.73 = -5.19\\
&\qquad\qquad\qquad \overline{-16.40}
\end{aligned}$$

The foregoing distributed moments will again be carried to the far end of each member, thus, $M_{be} = M_{eb} \times \gamma_{ebm} = 3.31 \times 0.435 = 1.44$, etc. The resulting moments are shown in Fig. 9.

Example 2.—In Fig. 8, let the fixed-end moments in Member CD be $M'_{cd} = -1\,000$; and $M'_{dc} = 2\,000$ (see Fig. 10). The unbalanced moment at Joint C is then $-1\,000$; and at Joint D, it is $+2\,000$. Instead of distributing the unbalanced moments separately, a better procedure is as follows: (1) Release all the joints; (2) distribute the unbalanced moment of $-1\,000$ at Joint C to End C of Member CD, or, $1\,000 \times \dfrac{5.59}{5.59 + 1.50} = 788$;

(3) carry over 788 to End D of Member DC by the modified carry-over factor, γ_{cdm}, or, $788 \times 0.390 = 308$; (4) distribute the unbalanced moment of $+ 2\,000$ at Joint D to End D of Member, DC, or, $- 2\,000 \times \dfrac{4.80}{4.80 + 5.50 + 7.49 + 3.00} = - 462$; and, (5) carry over $- 462$ to End C by the modified carry-over factor, γ_{dcm}, or, $- 462 \times 0.125 = - 58$.

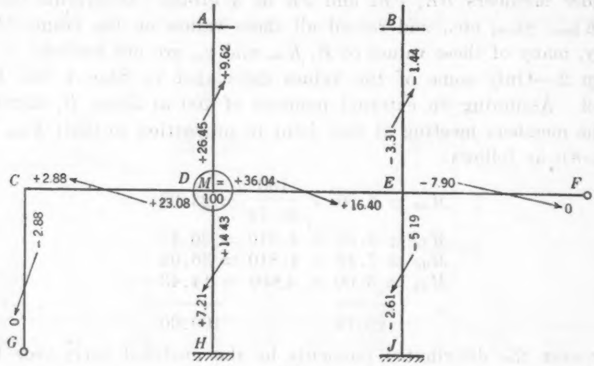

FIG. 9

The total moment at End C of Member CD will then be, $- 1\,000 + 788 - 58 = - 270$; and the total moment at End D of Member CD will be, $2\,000 - 462 + 308 = 1\,846$. These moments will be entirely resisted by their respective supporting or connected members. They are distributed and carried over to the ends of the frame, as shown in Fig. 10.

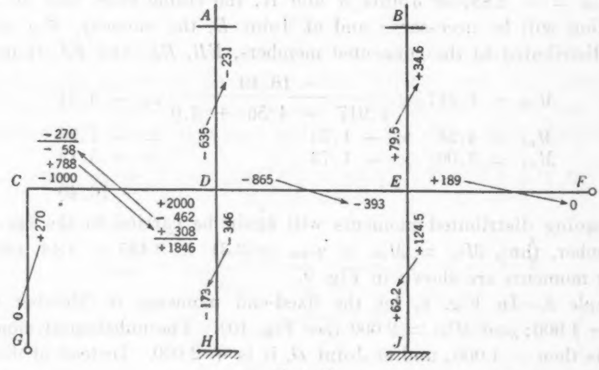

FIG. 10

Example 3.—Consider the frame in Example 1, with fixed-end moments on Girders CD, ED, and EF, as shown in Fig. 11 (identifying symbol, (f)). It is possible to distribute the unbalanced moments at the joints separately,

proceeding as in Example 1, or to find the end moments of each loaded member and proceed as in Example 2. A better method, however, is shown in Fig. 11: (1) Find the unbalanced moment at each joint and distribute it to **all the members meeting at that joint, identifying each distributed moment**

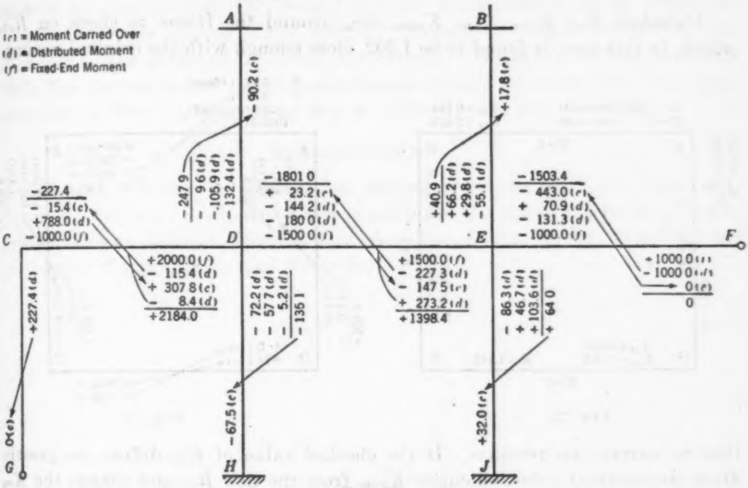

FIG. 11

by the symbol, (d); (2) after distributing the unbalanced moments at all joints, start from one end of the frame, such as Member *CD*, and carry over the value, $788(d)$, at End *C* to End *D*, producing a moment at End *D* equal to $307.8(c)$, identifying each moment carried over by the symbol, (c); (3) distribute this value, $307.8(c)$, among the supporting members, so that $M_{de} = -307.8 \times \dfrac{7.49}{7.49 + 5.5 + 3.0} = -144.2\ (d)$, etc.; and (4) combine the value, $-144.2(d)$, with the first distributed moment, $-180(d)$, at End *D* of Member *DE* and carry the sum over to End *E*, producing a carried-over moment at End *E* equal to $(-144.2 - 180.0)\ 0.455 = -147.5(c)$. Continue the foregoing steps until all the unbalanced moments are carried to the ends of the frame. Time is saved in this way by combining the moments carried over.

Example 4.—Consider the closed frame shown in Fig. 12. The fixed-end moments are $M'_{ab} = -1\,000$; and $M'_{ba} = 1\,000$. This box is made up of members of uniform moments of inertia and, therefore, only the *K*-values need be shown in Fig. 12.

Step 1.—Since the frame is closed, it is necessary, first, to assume the *R*-value of an end of some member. It can be seen by inspection that $R_{ab} = \dfrac{3 + 1(-)}{3} = 1.3$, approximately.

Then, from Equation (3), $K_{bam} = 3\left(1 - \dfrac{\frac{1}{4}}{1.3}\right) = 2.423$; $R_{bcm} = \dfrac{1 + 2.423}{1} = 3.423$; and, $K_{cbm} = 1\left(1 - \dfrac{\frac{1}{4}}{3.423}\right) = 0.927$.

Calculate R_{cd}, K_{dcm}, R_{da}, K_{adm}, etc., around the frame to check on R_{ab}, which, in this case, is found to be 1.302, close enough with the original assumption to warrant no revision. If the checked value of R_{ab} differs too greatly from the assumed value, calculate K_{bam} from the new R_{ab} and change the K_m and R-values as far as necessary. Then, calculate the γ_m-values from the values of R finally adopted.

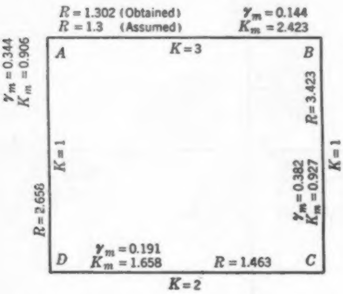

FIG. 12

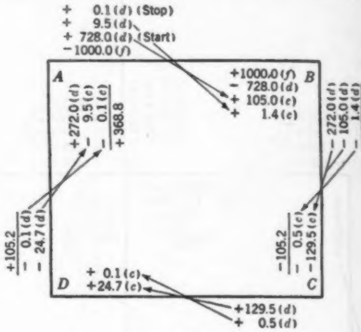

FIG. 13

Step 2.—Distribute the unbalanced moments at Joints A and B (see Fig. 13). Carry over the distributed moment, $728(d)$, at End A of Member AB to End B, producing $105(c)$, which is resisted by $-105(d)$ at End B of Member BC. The moment, $-105(d)$, is combined with the moment, $-272(d)$, at End B of Member BC, and carried over to End C of Member BC. Continue the cycle until the amount to be carried is negligible. For this case of a symmetrical frame and symmetrical loading, if the moment, $-728(d)$, at End B of Member AB is carried over to End A, and the cycle of distribution is performed in the other direction, the moments would evidently be the same, except with reversed signs. Hence, it can be seen that the resulting moments are, $M_{ad} = 272 - 9.5 - 0.1 + 105 + 1.4 = 368.8$; and, $M_{da} = -0.1 - 24.7 + 0.5 + 129.5 = 105.2$.

CONCLUSION

The greatest advantage of this method is its simplicity and directness. Only two formulas need be remembered in addition to the fundamental concepts of moment distribution. Equations (3) and (4) can be derived, and remembered, so easily that an experienced designer can estimate the modified beam factors, mentally, with sufficient accuracy. In these formulas, the effect of fixity of supports is shown by the value, R_{ba}, and the effect of haunching is shown by the value, $\gamma_{ab}\ \gamma_{ba}$.

It is considered best to limit this paper to a presentation of the method only. Its special adaptability, such as its application to continuous beams of varying sections, has not been discussed. The most interesting application is sometimes found in the approximate but sufficiently accurate estimate of moment by this method. However, it is not recommended as an invariable substitute for the original Cross method. Each has its own advantages, and it is left to the designer to choose for himself. Certainly, it will be worth while for engineers dealing with continuous frames to spend the little time necessary to learn it, so as to be able to utilize its obvious advantages.

Acknowledgments

The writer wishes to express his utmost gratitude to Bruce Jameyson, Assoc. M. Am. Soc. C. E., under whose guidance the study was made. Thanks are also due to John T. Howell, Jun. Am. Soc. C. E., for his valuable suggestions in the preparation of the paper.

DISCUSSION

L. E. GRINTER,[5] ASSOC. M. AM. SOC. C. E. (by letter).—In this paper the Engineering Profession is given a clear and concise statement of another method of analyzing continuous frames that is based upon the Cross method of balancing fixed-end joint moments. This method has been in use by associates of Professor Cross since about 1926, and a brief discussion of it has been published.[6] Several other papers have appeared, describing similar procedures. The writer has published two references to the method. The first will be found in his discussion of the paper[7] by Professor Cross where mention is made of an "approximate method of balancing moments where the carry-over moment is determined from the restraint at the far end of the member." The second occurs in a discussion on methods of checking rigid frame analysis.[8]

The foregoing references are mentioned, not with the idea of establishing prior authorship of the method (which obviously goes back to the original work of Professor Cross), but rather to establish the fact that the writer speaks from a background of experience when suggesting that the method described by Mr. Lin is of limited usefulness. It was introduced into the writer's graduate and undergraduate classes from 1929 to 1932. It has since been withdrawn from the undergraduate classes because experience has shown that its usefulness is limited and because it proved confusing to the student.

A study and comparison of Figs. 9, 10, and 11 of the paper, reveals a rapid increase in the volume of recorded calculations on successive illustrations. There are sixteen recorded results on Fig. 9, twenty-two on Fig. 10, and fifty on Fig. 11. The explanation is evidently found in the fact that the number of loaded spans has been increased from one to three. There would be a far smaller rate of increase in the number of recorded results by the original Cross method. The total number in the most complex case usually could be reduced to less than fifty, and still yield satisfactory accuracy. This fact is well illustrated by Fig. 14 which is the analysis of a frame similar to that of Fig. 11 by the procedure of balancing moments used by the writer. Incidentally, the five-place results recorded in Fig. 11 seem to be entirely unjustified and, in fact, their use is in conflict with the basic idea of the method which is most useful as an approximate method of moment distribution.

A comparison of the number of tabulated results as discussed in the previous paragraph is unfair to the original Cross method because the preliminary results recorded by Mr. Lin in Fig. 8 require repeated substitutions into formulas, whereas each result recorded by Professor Cross is obtained by a single setting of a slide-rule—or mentally by dividing a number in half.

[8] *Engineering News-Record*, August 23, 1934, p. 249.

Hence, in the majority of cases, the writer has found the standard method of balancing moments to be the simpler procedure, and invariably so when loads

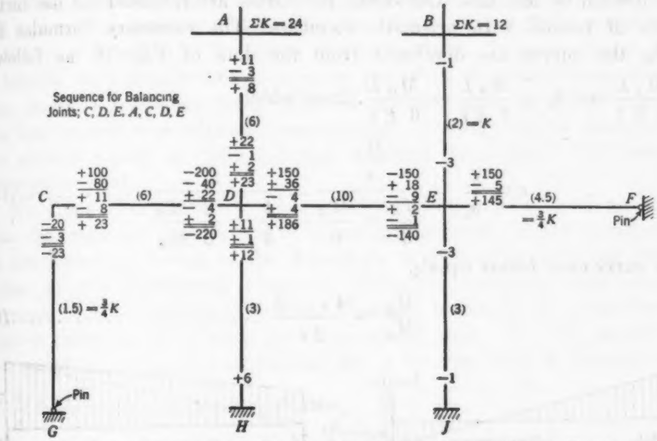

FIG. 14.—ANALYSIS OF A FRAME WITH THREE LOADED SPANS BALANCING FIXED-END MOMENTS.

occur on several spans. The method described by Mr. Lin is advantageous when one is "running out" moments into unloaded spans in the manner illustrated by Fig. 9.

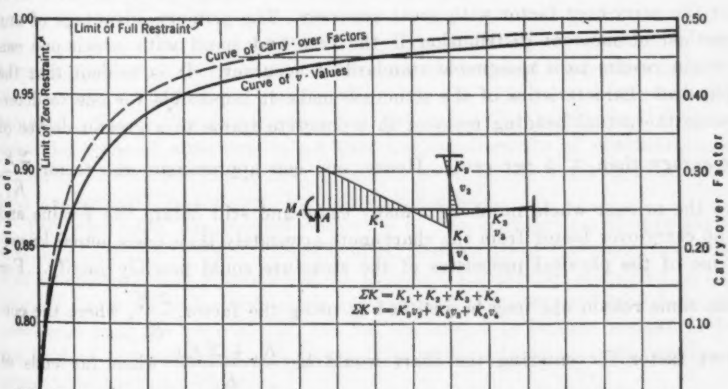

FIG. 15.—CARRY-OVER FACTORS AND v-VALUES FOR MOMENT DISTRIBUTION.

In order to make the paper as useful as possible, Fig. 15 is presented, which the writer developed several years ago for the use of his students. The nomenclature will be clear if it is understood that v is a factor

such that Kv represents the relative resistance of a member to end rotation taking into account its condition of restraint at the far end. Hence, Kv is K_m as defined by Mr. Lin. Obviously, the curves are intended for use in the analysis of frames with prismatic members. The necessary formulas for plotting the curves are developed from the data of Fig. 16, as follows: $\theta_1 = \frac{M_A L}{4 E I}$ and $\theta_2 = \frac{M_A L}{3 E I} - \frac{M_B L}{6 E I}$, from which,

$$v = \frac{\theta_1}{\theta_2} = \frac{\frac{M_A}{4}}{\frac{M_A}{3} - \frac{M_B}{6}} = \frac{1}{\frac{4}{3} - \frac{2}{3}\frac{M_B}{M_A}} \qquad \text{.............. (5)}$$

or, the carry-over factor equals,

$$\frac{M_B}{M_A} = \frac{4 v - 3}{2 v} \qquad \text{......................... (6)}$$

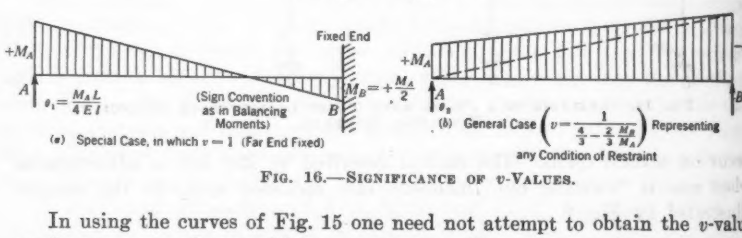

FIG. 16.—SIGNIFICANCE OF v-VALUES.

In using the curves of Fig. 15 one need not attempt to obtain the v-value or the carry-over factor with great accuracy. The primary advantage of any method of moment distribution is the ease and speed with which one can obtain results to a reasonable standard of accuracy. It is evident that the physical characteristics of the structure make it impossible for one to determine the actual bending moment in a concrete frame to a greater degree of accuracy than $\pm$ 5 per cent. Hence, one can approximate the factor, $\frac{\Sigma K}{K_1}$, to the nearest whole number in many cases and still obtain the v-value and the carry-over factor from the chart more accurately than one's actual knowledge of the physical properties of the structure could possibly justify. For the same reason one may be justified in using the factor, $\frac{\Sigma K}{K_1}$, where the correct factor for entering the chart would be $\frac{K_1 + \Sigma K v}{K_1}$ when far ends of restraining members are not fixed. The writer criticizes analytical precision that one can not hope to translate into sizes of members or amounts of reinforcing steel.

It is interesting to consider the effect of haunching of beams upon the moments in a continuous frame. It should be clear that the designer makes no effort to obtain better than a crude approximation of the Kv-value, or of

the carry-over factor, for a reinforced concrete beam as usually constructed monolithically with a slab in a rigid frame structure. Actually, the moment of inertia, I, varies widely for such a beam and is dependent on the amount and sign of the bending moment because of the change from a rectangular section to a T-section at the point of contraflexure. It seems almost absurd to involve one's calculations to care for the effect of a small haunch—which may change a carry-over factor from 0.5 to 0.47—when an equal irregularity has been passed over without consideration. A study of the discussions of the writer's paper[9] on "Wind Stress Analysis Simplified," will make this observation clear.

Mr. Lin's idea of direct moment distribution can be used as a check upon the original Cross method of balancing moments. Since moments must be distributed according to the Kv-values, it is possible to check the total values of the distributed moments (balancing moments plus carry-over moments, but not including original fixed-end moment) by comparing their relative values to the relative Kv-values at the joint. For this purpose, it is convenient to revise the expression for v by removing a constant factor of $\frac{4}{3}$ from the denominator to obtain:

$$v = \frac{1}{\frac{4}{3} - \frac{2}{3}\frac{M_B}{M_A}} = \frac{1}{\frac{4}{3}\left(1 - \frac{1}{2}\frac{M_B}{M_A}\right)} = \frac{3}{4}\ V \ldots\ldots\ldots(7)$$

in which, $V = \frac{1}{1 - \frac{1}{2}\frac{M_B}{M_A}}$. Hence, the distributed joint moments must also be in proportion to the KV-values. This is a complete check upon the balancing procedure, but is not a check upon the original fixed-end moments. Neither does it check the moments where there is a joint translation in the structure. The writer prefers to check his results by statics and then to draw the deflected structure to see that the requirements of continuity are satisfied. In one particular case a serious error in the analysis of a wind bent was located[10] by plotting the column deflections.

This discussion has pointed out some of the applications of this paper that may be found useful. The individual preferences of the reader may extend its application to a broader field. However, the extreme simplicity of the original Cross method recommends its use by those engineers who have an occasional need for such a tool, but do not intend to become specialists in the field of indeterminate structures. The writer places his undergraduate students in that classification.

W. H. HUANG,[11] ESQ. (by letter).—The fundamental equations for modified stiffnesses (which the writer has elsewhere[12] termed "conjugate" stiffnesses)

---

[12] *Journal*, The Chinese Inst. of Engrs., Vol. 9, No. 5.

and carry-over factors for members of constant moment of inertia may be given in the following forms:

$$R_{ab} = S_{ab}\left(1 - \frac{S_{ab}}{4\,(S_{ba} + R_{bc} + R_{bd} + R_{be})}\right) \dots\dots\dots (8)$$

and,

$$\gamma = \frac{1}{2 + 1.5\,\dfrac{S_{ab}}{R_b - R_{ba}}} \dots\dots\dots\dots\dots\dots\dots (9)$$

in which R_{ab} = the modified stiffness of Member AB at End A; $S_{ab} = S_{ba}$ = the stiffness of Member AB or BA; R_b = the summation of the modified stiffnesses of Members BA, BC, BD, and BE, at End B; and γ = the carry-over factor of Member AB at End A.

Instead of using the cumbersome Equation (8), or the author's Equation (3), which in certain cases can only be solved by successive approximations, the writer suggests[13] the use of the following approximate equation;

$$R_{ab} = S_{ab}\left(1 - \frac{S_{ab}}{4\,S_b}\right) \dots\dots\dots\dots\dots\dots\dots (10)$$

in which, $S_b = S_{ba} + S_{bc} + S_{bd} + S_{be}$. Equation (10) yields an error of less than 2.08 per cent. As the stiffness of a member usually cannot be determined within an accuracy of 2%, and as the effect of the errors on the final moment distribution is compensating, Equation (10) is recommended for general application.

The advantage of this method depends largely upon the ease with which the modified stiffnesses and the carry-over factors can be obtained. Therefore, a graphical method for solution is of value, and the writer uses nomographs in connection with Equations (9) and (10).

Felix H. Spitzer,[13] Assoc. M. Am. Soc. C. E. (by letter).—Justly, the author may claim for his presentation the advantage of superior convenience as a tool of structural design in comparison with the original Cross method; but he cannot maintain his claim when his method is compared with the modification of the Cross method introduced by L. E. Grinter, Assoc. M. Am. Soc. C. E.,[14] which has reduced labor to such an extent that frequently the calculation of stiffnesses of members and joints and other preliminary work common to all methods, becomes the major part of the work to be performed.

Due to the application of "modified" coefficients and of additional equations, although very simple, Mr. Lin's modification has lost much of the simplicity so characteristic of the Cross method. This desirable quality of a simple physical process easily visualized and remembered, is even more apparent in the Grinter modification, where the joints, which visual inspec-

[13] Structural Engr., Dept. of Public Works, San Francisco, Calif.

[14] Discussion of the paper by Hardy Cross, M. Am. Soc. C. E., entitled, "Analyses of Continuous Frames by Distributing Fixed-End Moments", *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 11.

tion finds to be most unbalanced, are successively released and balanced until an accuracy sufficient for the purpose is reached.

There is scarcely need to sacrifice simplicity to exactness when for all practical purposes the difference is small enough to be of no importance.

HAROLD E. WESSMAN,[15] ASSOC. M. AM. SOC. C. E. (by letter).—The so-called "direct" method of moment distribution is presented in this paper in a very satisfactory manner. Several engineers have previously indicated their preference for a single, direct distribution and have given general equations which evaluate actual end restraints and lead directly to the final moments.

Of the various forms, however, the writer prefers Mr. Lin's presentation of equations for correct stiffness and carry-over factors. His derivation proceeds quite logically in accordance with the basic sequence of operations so nicely outlined by Professor Cross in his fundamental method, a treatment which emphasized concepts in terms of simple words and numbers rather than of general algebraic equations.

A designer, analyzing a structural framework with a variety of members subject to a number of loading conditions, will find it worth while to become familiar with this direct method, or some other abbreviated procedure[16]; but in classroom practice, the writer feels that better results are obtained when moment distribution is taught with a minimum number of equations. That, of course, means teaching the basic method. The two equations proposed by the author, although simple, are not easily remembered unless one is using this tool of analysis constantly. Incidentally, Mr. Lin should have stated that it is necessary to remember three equations, rather than two. One must also keep Equation (1) for R_{ba} in mind.

In the "Synopsis" of his paper, the author might have qualified the term, "exact." The method is exact for any structure of the type in Fig. 17, which does not contain closed structural panels and in which the conditions of restraint of all external terminals, such as those at A, B, D, E, G, and H, are completely known. The method is not exact for any structure of the type in Fig. 18, which contains a closed structural panel, $CDGF$. One must

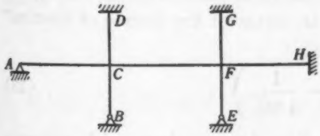

FIG. 17.

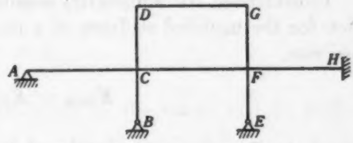

FIG. 18.

assume an initial value for R_{dc} or R_{gf}. The author notes a similar case in his Example 4. It is further illustrated by his assumption of values for R_{ad} and R_{be} in Example 1.

[15] Associate Prof. of Structural Eng. and Mechanics, Coll. of Eng., State Univ. of Iowa, Iowa City, Iowa.

[16] See methods proposed in "Continuous Frames of Reinforced Concrete," by Hardy Cross and N. D. Morgan, Members, Am. Soc. C. E.

Ordinarily, one can estimate these values closely enough so that the error involved in final moments is of no practical significance. It is also well to keep in mind that the error involved in moment distribution by terminating computations at the end of two cycles of distribution is ordinarily of no consequence in design.

EGOR P. POPOFF,[17] JUN. AM. SOC. C. E. (by letter).—The modification, presented by Mr. Lin, of the well-known Cross method of analysis contains material of considerable interest. It is timely to note that quite similar modifications have been proposed by a number of writers.

Mr. Lin uses the method of moment distribution, entirely, for the derivation of his equations for the modified stiffnesses of the members and for the "carry-over" factors. Other writers use the slope deflection method; but fundamentally the two methods are closely related.

Analyzing the work of three writers in this field,[18] it may be noted that a mere algebraic transformation is sufficient to put all the results into an identical form, if a common definition can be written for the "factor of restraint," R_{ba}. The expression used by Mr. Lin in Equation (1) is the restraining effect of the several members at a joint on the member under consideration. The factor of restraint is variously defined: Mr. Lin defines it by Equation (1), whereas others define it by $\sum \frac{K_{bnm}}{K_{ab}}$, and $\frac{\Sigma K_{bnm}}{K_{ab} + \Sigma K_{bnm}}$ (expressed in Mr. Lin's notation). Mr. E. B. Russell,[18] defines it as,

$$R'_{ba} = \sum \frac{K_{bnm}}{K_{ab}} \qquad (11)$$

whereas, L. T. Evans,[18] Jun. Am. Soc. C. E., and T. F. Hickerson,[18] M. Am. Soc. C. E., define it as,

$$f_{ba} = \frac{\Sigma K_{bnm}}{K_{ab} + \Sigma K_{bnm}} \qquad (12)$$

Of the foregoing definitions, perhaps Equation (12) is the most logical, because it has a value of 1 for the fixed condition and 0 for the hinged condition.

Considering, for simplicity, members of uniform cross-section, the expression for the modified stiffness of a member in terms of the degree of fixation[19] becomes,

$$K_{bnm} = K_{bn}\left(1 - \frac{1}{4\,R_{nb}}\right) \qquad (13)$$

which is Equation (3) developed by Mr. Lin for members with constant moment of inertia. The extension to a more general case is obvious.

[18] "Handbook of Rigid Frame Analysis", by L. T. Evans, Jun. Am. Soc. C. E., Edwards Brothers, 1934; "Structural Frameworks," by T. F. Hickerson, M. Am. Soc. C. E., Univ. of North Carolina Press, 1934; and "Analysis of Continuous Frames," by E. B. Russell, Ellison and Russell, 1934.

[19] "Handbook of Rigid Frame Analysis", by L. T. Evans, Jun. Am. Soc. C. E., Edwards Brothers, 1934 (In Equation (174), let $f = 1 - \frac{1}{R}$).

The idea of the modified stiffness of a member reveals a new concept. Thus, in addition to the dependence on the length and cross-section, the true stiffness is also dependent upon the degree of restraint at the far end of the beam.

For the special case of a member with a uniform cross-section, the following has been offered.[20]

$$\gamma_{abm} = \frac{1}{2}\,\frac{R_{ba} - 1}{R_{ba} - \frac{1}{4}} \qquad (14)$$

which is Equation (4) developed by Mr. Lin.

In the modifications cited for comparison herein, the equations developed are for the general cases, and many graphs and tables are prepared; but still other writers define some similar coefficients, such as R, differently, and thus the transformation into the form of equations as given by Mr. Lin is not quite as obvious as for the case shown, which is by far the most important one.

The method seems to be somewhat longer for the simpler problems than the usual Cross method. It appears to be especially inconvenient for closed frames as in Example 4 where several trials may be necessary to check the value of R originally assumed. However, this group of modifications is of practical significance for the cases in which there are several types of loading for the same structure. The method is also satisfactory for the simpler cases with the assistance of the extensive tables now available.[18]

L. T. Evans,[21] Assoc. M. Am. Soc. C. E. (by letter).—An interesting addition to engineering literature is contained in this paper, but it is to be regretted that Equations (1), (2), and (3) are incorrect. The first error is introduced in the assumption that a moment equal to $K_{ab} = \frac{I}{L}$ applied at End A will produce a unit angular deflection at A. Applying the modified slope-deflection[22] equations to End A:

$$M_{AB} = E\,K_c\,(C_1\,\theta_A + C_2\,\theta_B - [C_1 + C_2]\,R) - C_{AB} \qquad (15)$$

which, for the conditions of the problem, reduces to:

$$M_{AB} = C_1\,E\,K_c \qquad (16)$$

in which, K_c represents $\frac{I_c}{L}$ for a specified point of the beam, and C_1 is the beam coefficient, the value of which is determined by the variation of moment of inertia of the member. For a constant moment of inertia, $C_1 = 4$.

[20] "Structural Frameworks", by T. F. Hickerson, M. Am. Soc. C. E., Univ. of North Carolina Press, 1934, Equation (13), where, again, let $f = 1 - \frac{1}{R}$.

[21] Cons. Structural Engr., Long Beach, Calif.

[22] See "Modified Slope-Deflection Equations", by L. T. Evans *Journal*, Am. Concrete Inst., October, 1931, pp. 109–130.

Since an external moment applied to a joint will be resisted by the moments in the members which will be in direct ratio to the "modified stiffness" of each member, Equation (1) should be:

$$R_{ba} = \frac{C_1 K_{ba} + \Sigma K_{bnm}}{C_1 K_{ba}} \quad \text{.....................(17)}$$

The author has been inconsistent in using modified stiffness for Members $B1$, $B2$, and $B3$, but not for Member BA. In order to obtain the correct results for the problem as stated, the modified stiffness of Member BA must also be used. Under the assumed condition of full restraint[23] at End A in Step 2 the modified stiffness would be: $K_{ban} = C_1 K_{ab}$ and Equation (2) becomes:

$$M = -\frac{C_1 K_{ab} \gamma_{ab}}{R_{ba}} \quad \text{.......................(18)}$$

which changes Equation (3) to:

$$K_{abn} = C_1 K_{ab} \left(1 - \frac{\gamma_{ab} \gamma_{ba}}{R_{ba}}\right) \quad \text{..................(19)}$$

Expressed in terms of the degree of restraint at End B of Member AB (that is, f_{ba}) Equation (19) should read:

$$K_{abn} = K_{AB} \left[C_1 - (1 - f_{ba}) \frac{C_2^2}{C_1} \right] \quad \text{...............(20)}$$

which reduces to:

$$K_{abn} = K_{AB} (3 + f_{ba}) \quad \text{.......................(21)}$$

for constant moment of inertia, and Equation (4) for constant moment of inertia is:

$$\gamma_{abm} = \frac{2 f_{ba}}{3 + f_{ba}} \quad \text{..............................(22)}$$

It is to be noted also that the author's formulas, Equations (1), (2), and (3), apply only when the far end of Member AB is fixed, which introduces another error when applied to continuous structures. Equations (20) to (22) are general and apply for any degree of restraint at the far ends of the members.

The value, $R_{cd} = 1.25$, in the frame of Fig. 8 is equivalent to:

$$R = \frac{K_{CD} + \dfrac{K_{CG} (3 + f_{gc})}{C_1}}{K_{CD}} = \frac{6 + \dfrac{2 \times 3}{4}}{6} = 1.25$$

The correct value is:

$$R = \frac{6 (3 + f_{dc}) + 2 \times 3}{6 (3 + f_{dc})}$$

[23] For a complete development and application of the method of restraints, see "Handbook of Rigid Frame Analysis", by L. T. Evans.

which could yield $R = 1.25$ only for the special case of $f_{dc} = 1$. Members $DA, DE,$ and DH do not fix End D of CD; in other words, f_{dc} is less than unity and, therefore, the correct value of this R is greater than 1.25. The author does not give sufficient data concerning Member DE to allow the computation of f_{dc}.

The correct expression for R_{de} is:

$$R_{de} = \frac{C_1 K_c (0.51 + 0.49 f_{ed}) + 6 \times 3.2 + 3 \times 4 + 6 (3 + f_{ad})}{C_1 K_c (0.51 + 0.49 f_{ed})} \ldots (23)$$

Equation (23) takes into consideration both the beam coefficients and the actual degree of restraint at the far ends of the members.

Although one may begin with the fixed-end moments and make a correction, it seems more direct and logical to use a moment that takes into consideration the actual degree of restraint at both ends of the member. For example, consider the frame shown in Fig. 8. Let it be required to compute the moments, M_{AB} and M_{BA}, due to a concentrated load of 1 000 lb applied at the center of Span AB. The fixed-end moment is $\frac{P L}{8} = 3\,750$ ft-lb. The degree of restraint at End A of AB is $f_{ab} = \frac{3 \times 3.8}{3 \times 3.8 + 5 \times 4} = 0.363$, and, in a similar manner, $f_{ba} = 0.566$.

Now, let $D_4 = 3 + f_{ab} + f_{ba} - f_{ab} f_{ba} = 3.723$; and,

$$M_{AB} = - \frac{2 f_{ab} (3 - f_{ba})}{D_4} \times C_{AB} = - 1\,780 \text{ ft-lb}$$

and,

$$M_{BA} = + \frac{2 f_{ba} (3 - f_{ab})}{D_4} \times C_{BA} = + 3\,005 \text{ ft-lb}$$

These moments have the same values that would be obtained by the distribution methods after all joints have been "unlocked," all distributions completed, and the results totaled. It is seen that the "method of restraints" provides an easy, exact, and rapid solution and is especially adapted to problems of partial restraint, such as indicated at the bases on the columns of Fig. 8.

In the author's "Conclusion" it is stated that "the effect of fixity of supports is shown by the value, R_{ba}, and the effect of haunching is shown by the value, $\gamma_{ab}\ \gamma_{ba}$." This statement is in error because both the values, R_{ba} and $\gamma_{ab}\ \gamma_{ba}$, are influenced by both the degree of restraint at the ends of the members and by the moment of inertia variation.

Although the greater part of this discussion has been devoted to pointing out inconsistencies, the writer wishes to make it clear that this has been done to help Mr. Lin build up his work and not to destroy. The writer realizes from his own experience that the author has used considerable time

in the development of the material of the paper and deserves credit. Advancement of the profession can occur only through the hard work of the members.

G. S. SALTER,[24] M. AM. SOC. C. E. (by letter).—Several papers have been presented recently, on various modifications of the direct method of moment distribution. These variations are interesting if for no other reason than that they show that the profession is becoming increasingly conscious of the adaptability of the moment-distribution method of analysis as presented by Professor Cross, and as designers become better acquainted with the original they devise modifications which they find adapted to their particular use. Too often, most of these simplifications and "short cuts" are such only to the person who devises them and other analysts are slow to adopt even the best of the methods because they prefer to use those with which they are more familiar even though they may be more laborious.

For frames subjected to several conditions of loading or other complexities, time could probably be saved by the use of the author's or some similar method, but for the usual frame and loading conditions, successive balancing of the joints is as simple as could be desired and involves less chance of error. It may be, as Mr. Lin states, that the special value of his modification is its application to continuous beams of varying section; but if so, it would seem that the paper would have been of much greater value if this application had been demonstrated. This probably would necessitate the inclusion of several tables or diagrams before it would have been usable.

Mr. Lin's concept is similar to that offered by Professor Cross[25] in 1929. It is more complete in that Mr. Lin uses modified carry-over factors as well as the modified $\frac{I}{L}$ (K)-values; but Professor Cross secures the same results by using the regular carry-over values of $\frac{1}{2}$ and by distributing further at successive joints.

As one application of his method Mr. Lin presents the analysis of a symmetrical closed frame (Example 4). Such a frame (which is of common occurrence in the design of water and sewage treatment plants) can scarcely be included in the category of structures which are of sufficient complexity to warrant the use of the author's method because more time would be required in determining the frame constants than would be necessary to make the regular moment distribution. However, he could have simplified the analysis materially by utilizing a chart similar to Fig. 19 for the determination of necessary constants.

For example, in the regular moment distribution for a symmetrical frame it may readily be seen that, if the first balancing moments at the two ends of the side members are equal (and opposite in sign) the distribution is

[24] Structural Engr., San. Dist. of Chicago, Chicago, Ill.

[25] "Exact Method of Analysis", in his paper, entitled "Continuity as a Factor in Reinforced Concrete Design," presented before the Am. Concrete Inst.

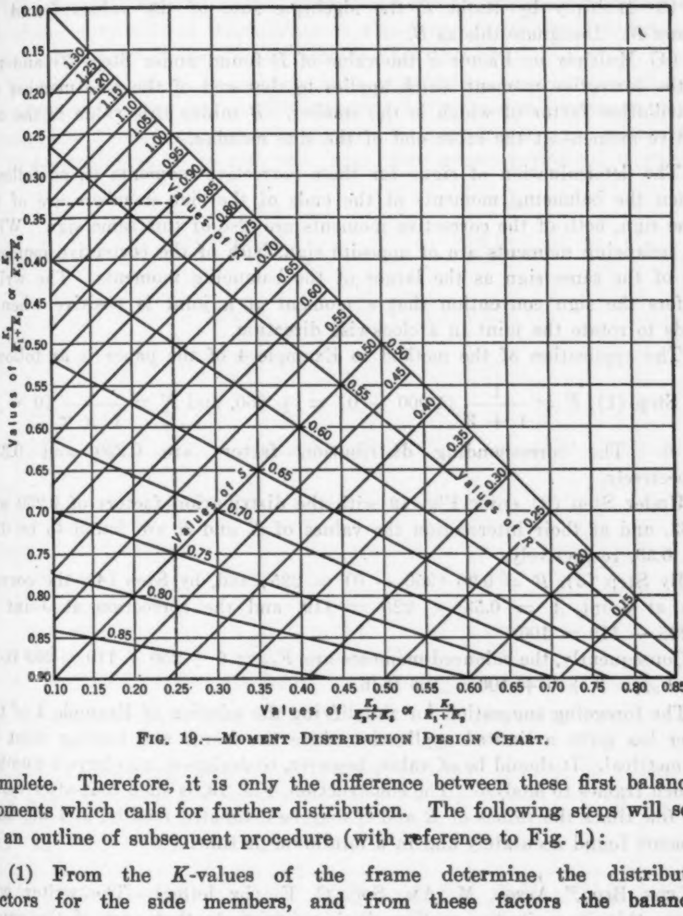

Fig. 19.—Moment Distribution Design Chart.

complete. Therefore, it is only the difference between these first balancing moments which calls for further distribution. The following steps will serve as an outline of subsequent procedure (with reference to Fig. 1):

(1) From the K-values of the frame determine the distribution factors for the side members, and from these factors the balancing moments at A and D. Designate these moments as $F = \frac{K_2}{K_1+K_2}(M_{ab} - M_{ad})$ and $N = \frac{K_2}{K_2+K_3}(M_{dc} - M_{da})$, respectively. This follows the regular moment distribution procedure. The variation is, as follows:

(2) With the distribution factors as found in Step (1) for the side member enter Fig. 19 using either factor as the abscissa and the other as the ordinate so that their intersection is within the diagram area. At their intersection find the value, S (a stiffness factor), and R, the ratio of stiffness factors.

(3) Multiply by Ratio R the algebraic sum of the values found for F and N. Designate this as B.

(4) Multiply by Factor S the value of B found under Step (3) and this is the corrective moment which applies to that end of the side member the distribution factor of which is the smaller. B minus this value is the corrective moment at the other end of the side member.

The determination of signs for these corrective moments is, as follows: When the balancing moments at the ends of the side members are of the same sign, both of the corrective moments are also of this same sign. When the balancing moments are of opposite sign, both of the corrective moments are of the same sign as the larger of the balancing moments. The writer prefers the sign convention that a moment at a joint is positive when it tends to rotate the joint in a clockwise direction.

The application of the method to Example 4 of the paper is as follows: By Step (1), $F = \dfrac{1}{1 + 3} (1\,000 - 0) = + 250$, and $N = \dfrac{1}{1 \times 2} (0 - 0) = 0$. The corresponding distribution factors are 0.250 and 0.333, respectively.

Under Step (2) enter Fig. 19 with the distribution factors of 0.250 and 0.333, and at their intersection the values of R and S are found to be 0.90 and 0.53, respectively.

By Step (3), $B = 0.90\ (250 - 0) = 225$; and, by Step (4), the correction at Joint $A = 0.53 \times 225 = 119$, and the correction at Joint $D = 225 - 119 = 106$.

Consequently, the balanced moments are, $F_{AD} = 0 + 250 + 119 = 369$ ft-lb, and $F_{DA} = 0 + 0 + 106 = 106$ ft-lb.

The foregoing suggestion for simplifying the solution of Example 4 of the paper has quite a limited application since the frame and loading must be symmetrical. It should be of value, however, to designers who have a number of such frames to analyze. The construction, Fig. 19, is such that after using it a few times the values of R and S may be estimated readily, and the final moments found accurately and in a minimum of time.

LEON BLOG,[26] ASSOC. M. AM. SOC. C. E. (by letter).—The writer will discuss this paper in two sections both referring to that part of the paper headed "Limitation of the Method."

Section I.—Limitation of the Lin Modification as Applied to Structures for Which Any of the Values of R as Defined by the Author Are Other Than 1 for a Hinged Condition and ∞ for a Completely Fixed-End Condition.—Hardy Cross, M. Am. Soc. C. E., demonstrated the basic method which the author proposes to modify by utilizing a structure that has its reaction ends of members either truly hinged, truly fixed, or truly cantilevered.[27] There were no approximations as to the degree of restraint in any of the members.

[26] Asst. Chf. Structural Engr., Div. of Bridges and Structures, City of Los Angeles, Los Angeles, Calif.

[27] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 5.

In his examples, Mr. Lin makes assumptions as to the degree of restraint of the second-story ends of the columns in Fig. 8 and for one end of the upper horizontal member of the closed frame of Figs. 12 and 13.

To check the effect of such restraint assumptions upon the accuracy of the solution for moments in the structure as well as the accuracy of the assumptions which must be made in order to begin the solution with values of R reasonably close to the true ones, the writer performed a parallel

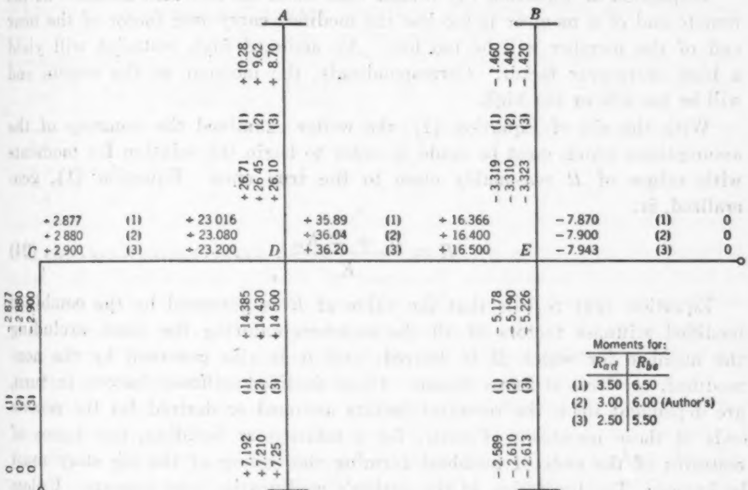

FIG. 20.—DISTRIBUTION OF AN EXTERNAL MOMENT OF 100 APPLIED AT D USING STEP 2 OF THE LIN PAPER.

TABLE 1.—RELATIVE VALUES OF CERTAIN MOMENTS OF FIG. 20 (EXPRESSED AS PERCENTAGES) BASED ON THE MOMENTS FOR R_{ad} = 3.00 AND R_{be} = 6.00

R_{ad}	R_{be}	M_{dc}	M_{dh}	M_{da}	M_{ad}	M_{de}	M_{ed}	γ_{dam}	K_{dam}
3.5	6.5	99.74	99.21	100.98	106.86	99.58	99.79	105.78	101.27
3.0	6.5	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00
2.5	5.5	100.91	100.48	98.68	90.43	100.46	100.41	91.48	98.18

distribution of a moment of 100 at D in Fig. 9 by giving R_{ad} and R_{be} simultaneous values of 3.5 and 6.5, and repeating the distribution with values of 2.5 and 5.5. The significant resultant moments are given in Fig. 20, and the relative values stated in percentages of the author's moments assumed as the true ones are given in Table 1, which also includes the modified carry-over and stiffness factors for End D, of Member DA, for reasons which follow.

From Table 1, observe that the greatest moment variations from the author's values occur for M_{ad}. For the case of restraint factors assumed as

0.50 more than those of the author, the surplus for M_{ad} is roughly 6% and for the case of 0.50 less than the author's, the deficit is about 9 per cent.

For the restraints assumed by the writer, the modified stiffness factor, K_{dam}, does not vary much from Mr. Lin's value so that K_{dam} cannot be the explanation for the large variations in M_{ad}; but the modified carry-over factor, γ_{dam}, varies almost as much as the moment, M_{ad}, and is almost directly responsible for the variations from the author's value of M_{ad}.

Inspection of Equation (4) reveals that when the restraint assumed at the remote end of a member is too low the modified carry-over factor of the near end of the member will be too low. An assumed high restraint will yield a high carry-over factor. Correspondingly, the moment at the remote end will be too low or too high.

With the aid of Equation (1), the writer examined the accuracy of the assumptions which must be made in order to begin the solution for moments with values of R reasonably close to the true ones. Equation (1), generalized, is:

$$R = \frac{K + \Sigma K_m}{K} \qquad (24)$$

Equation (24) reveals that the value of R is governed by the combined modified stiffness factors of all the members entering the joint, excluding the member for which R is desired; and it is also governed by the non-modified, or Cross stiffness factor. These modified stiffness factors, in turn, are dependent upon the restraint factors assumed or derived for the remote ends of those members. Finally, for a multi-story building, the degree of restraint of the ends of members forming the ceiling of the top story must be known. The limitation of the author's modification now appears. Unless at the outset of the analysis of such a structure, he can determine with certainty the degree of restraint that will prevail in the top-story members, the writer is unable to understand how Mr. Lin can claim that he has presented a rigid method having the same limitations as that presented by Professor Cross.

It is true that similar definiteness as to the degree of restraint or fixity for the ceiling members of the top story is requisite to the analysis of a multistoried structure by the pure Cross method; but Professor Cross did not find it necessary to introduce the concept of restraint factors intermediate in value between a hinged condition and complete fixity which the author evaluates, respectively, as $R = 1$ and $R = \alpha$. Having introduced the concept of partial restraint in connection with the Cross method, modified, Mr. Lin should give some indication as to the accuracy of estimating such restraint.

Table 2 shows how much error could be allowed in obtaining the combined modified stiffness factors of Equation (1) for the values of R which the writer assumed in his solution of Fig. 9, whereby he obtained the moment values of Table 1. Whether it is possible to stay within the limits of this error for a multi-storied structure, the writer is not prepared to state.

He has checked the closed structure of the author's Fig. 12 and Fig. 13 with the aid of a method presented[18] by L. T. Evans, Jun. Am. Soc. C. E. This is a method of determining the angular rotations produced in a structure when a unit moment is applied at one end of a member. However, it involves the idea of restraint at the end of the member opposite the one at which the unit moment is applied and is thus similar in that respect to the author's concept which is based on the amount of moment or stiffness which

TABLE 2.—Allowable Error in Obtaining Combined Modified Stiffness Factors of Equation (1)

R_{ed}	K_{ed}	K_m of adjoining members	Allowable error	R_{be}	K_{be}	K_m of adjoining members	Allowable error
2.5	6	9	....	5.5	2	9	....
			3				1
3.0	6	12		6.0	2	10	
			3				1
3.5	6	15	....	6.5	2	11	....

will produce a unit moment at the rotating end while the other end remains fixed. Mr. Evans gives a table by means of which such restraint may be estimated with reasonable precision. Were Mr. Lin to develop his modification so as to permit an estimate of the restraints which are considered the limitation of the method, the writer would use it for multi-storied structures for reasons which are enumerated in Section II of this discussion.

Section II.—Application of Lin Paper to Such Structures for Which the Reaction Ends of Members Are Definitely Either Hinged or Fixed-Ended and for Which, Therefore, the Values of R, According to the Author, Are Respectively, 1 and ∞.—Fig. 21 shows a part of Fig. 8, the upper story columns

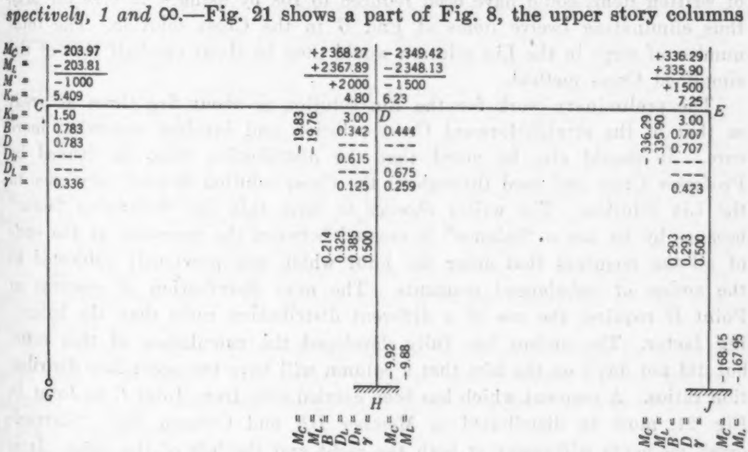

Fig. 21.—Comparison of Methods, Part of Fig. 8.

and Span EF having been deleted. The symbols, including those introduced by Mr. Lin, are defined as: M_C = moment by the Cross method, without

simplifications; M_L = moment by the Lin modification, according to Example 3; M' = fixed-end moment; K_m = stiffness factors; B = balancing factor applied to an unbalanced moment derived from the fixed-end moments, M'; D = distribution factor; D_R = value of D to be applied to an unbalanced moment which occurs to the right of Column DH; D_L = value of D to be applied to an unbalanced moment which occurs to the left of Column DH; and γ = modified carry-over factor. The members of this abbreviated structure have been given the same unmodified stiffness and carry-over factors, and the assumed fixed-end moments distributed are the same as those in Fig. 11. The restraints assumed for the reaction ends of the lower story columns are the same as those of Fig. 11. Since there is no upper story, the question of estimating the restraint of any member does not enter the solution of the problem. A comparison between the Cross method, without simplifications, and the author's modification can then be made. Fig. 21 shows how closely the two solutions check each other, utilizing an ordinary slide-rule.

TABLE 3.—COMPARATIVE WORK INVOLVED IN SOLUTION OF FIG. 21

Method	Preliminary distribution ratios and carry-over factor calculations	Items written in solution	Total steps	Balancing cycles
Cross.......	7	120	127	6
Lin.........	36	21	57	1

Table 3 shows the relative labor involved in these solutions. The number of written items could have been reduced to 108 by using $\gamma = 0.75$ for M_{cg}, thus eliminating twelve items at End G in the Cross solution. The total number of steps in the Lin solution would then be about one-half that of the simplified Cross method.

The preliminary work for the Lin solution is about five times as great as that of the straightforward Cross solution and involves somewhat more care. It should also be noted that the distribution ratio as defined by Professor Cross and used throughout the Cross solution is used only once in the Lin solution. The writer chooses to term this the "balancing factor" because by its use a "balance" is created between the moments at the ends of all the members that enter the joint which was previously subjected to the action of unbalanced moments. The next distribution of moment at Point D requires the use of a different distribution ratio than the balancing factor. The author has fully developed the calculation of this ratio, but did not dwell on the fact that a column will have two secondary distribution ratios. A moment which has been carried over from Joint C to Joint D, Fig. 21, must be distributed to Member DE and Column DH. "Carried-over" moments will occur at both the right and the left of the joint. It is easy to remember that the member which supplies the carried-over moment does not share in the distribution and that its modified stiffness factor is not used when evaluating the distribution factor. The writer has also found

it convenient to erase the balancing factor temporarily in order that it shall not be used after the first distribution.

To some readers who have noted that the calculations preliminary to actual distribution will be the most numerous for the Lin modification, the writer indicates the extreme rapidity of convergence of this technique. This quality results in a minimum of distributing and of carry-over items which are quickly added for a result. This part of the solution can be checked quickly. In the case of the pure Cross method, should the initial fixed-end moments be large or, should the convergence be slow, periodic summations of numerous moments must be made to determine when to cease distributing. Through an inadvertent interchange of distribution ratios between two members, joint moments may be erroneously balanced. This will not be discovered except through common-sense check when possible; but the writer prefers a technique which permits of speedy checking. He believes that the Lin procedure, when based on definitely determined restraint factors, affords such speed.

In conclusion, this modification of the Cross method is commended to the structural engineer for one-story structures with truly fixed or pin-ended reaction ends of members. If the author will develop a rapid method of estimating restraints for intermediate degrees of fixity, he will have made a valuable labor-saving contribution toward the solution of framed structures by the Hardy Cross method.

AUSTIN H. REEVES,[28] ASSOC. M. SOC. C. E. (by letter).—The "Conclusion" of this paper contains this sentence: "However, it is not recommended as an invariable substitute for the original Cross method."[1] It is neither advantageous nor advisable to substitute the author's method for the Cross method; the probable outcome of such substitution would be confusion.

When thoroughly understood, the Cross method is applied easily to any type of frame with the greatest simplicity, speed, and accuracy. The writer was much better able to utilize the Cross method because of a previous working knowledge of a few other methods, the most helpful of which was the conjugate point method.[29] This helpfulness was especially evident in the design of frames containing girders or columns with variable moments of inertia. A designer of rigid frames of all types is almost perfectly equipped if he has a thorough understanding of the application of the original Cross method, supplemented by an equally good working knowledge of the conjugate point method.

Mr. Lin could have explained his method much more easily by a statement that it is one of the special cases of the conjugate point method adjusted in a new and more complicated form to appear as a modification of the Cross method.

For example, to find the author's carry-over factors for any span, AB, by the conjugate point method, note where the U-line (Fig. 22) cuts the

[28] Newark, N. J.

[29] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 1.

span at Point U and where the V-line cuts the span at Point V. Now, $-\dfrac{AU}{UB} = \gamma_{ba}$ and $-\dfrac{VB}{VA} = \gamma_{ab}$. To find the author's "modified" carry-over factors for any span, AB, note where the J and K fixed points are located. Then, $-\dfrac{AJ}{JB} = \gamma_{bam}$ and $-\dfrac{KB}{KA} = \gamma_{abm}$. After obtaining γ_{abm} and γ_{bam} for all members, it is easy to find the author's K_{abm} and K_{bam} in each case. There would then be no necessity for calculating or tabulating R_{ab} and R_{ba} as the author has done.

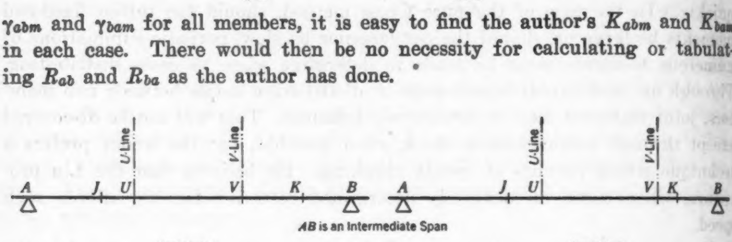

FIG. 22.

This leads up to what the writer considers the most unfortunate feature of the paper; namely, the signs. The carry-over factors should not be positive, but should have negative signs. To prove this statement, consider a horizontal continuous beam of three spans with simply supported ends. Twist the right-hand end with a moment, M, in a vertical plane through the longitudinal axis of the beam, there being no other loads on the continuous beam. The moment closing line will pass leftward from Point M, distance up or down on the R_4 line, and through J_3 until it intersects the reaction line, R_3; from this point on R_3 it will pass through J_2 in the middle span until it hits the reaction line, R_2; from which last named point it will pass through J_1, which is on the R_1-line. This demonstrates clearly that when a moment closing line passes through a point of inflection, the sign of the moment changes either from plus to minus or from minus to plus. Therefore, any carry-over factor should have a minus sign.

Furthermore, to finish a problem as in Fig. 11, Corner C, and have $+ 127.4$ on one side of the joint and $- 127.4$ on the other side, is at variance with both American and foreign texts, with customary practice (except in the slope deflection method),[30] and with common sense. It has been a source of deep regret to the writer that so many brilliant professors and engineers have seen fit to reverse Professor Cross on the matter of signs.

The writer agrees with Professor Cross as regards signs except in the following slight deviation in complicated frames; namely, the writer looks at all girders, truss chords, or arches from the bottom, at all outer columns from inside the structure, and at interior columns or web members of trusses from either direction. The moments are written on any member of a framework in such a manner that there can be no error as to which way the designer faced the member.

[30] *Bulletin No. 108*, Univ. of Illinois, Eng. Experiment Station, Urbana, Ill.

After solving numerous complicated problems of various types by the Cross method, the writer believes the Cross sign conventions eventually will be in general use, except for minor variations. In a paper entitled, "Sign Conventions for Bending Moments in Rigid Frames,"[31] Mr. Robins Fleming, of the American Bridge Company, states: "Notwithstanding the vigorous exceptions that have been taken, the writer has a preference for the convention used by Professor Cross * * *."

Some of the disadvantages of Mr. Lin's modification are:

1.—Considerable preliminary work is required before a beginning can be made on the actual determination of moments;

2.—Side-sway, when present due to (*a*) unsymmetrical loads; (*b*) an unsymmetrical frame; or (*c*) the more apparent overturning moments, would further increase the necessary preliminary work;

3.—More concentration of thought is required during the determination of moments, due to the necessity of handling two rigidities and two carry-over factors in each span instead of one;

4.—It is subject to erroneous interpretation by any one but an expert designer; and

5.—The work necessary to obtain the final moments increases rapidly with the number of members that are loaded.

It seems proper to conclude by using the fifth disadvantage to disprove one of the author's concluding statements: "The greatest advantage of this method is its simplicity and directness." Fig. 10 appears simple, but only one member was loaded and to the labor on this simple drawing must be added the work of preparing the data on Fig. 8. Fig. 11, with three members of this same frame loaded, certainly is much more complicated than Fig. 10 and, furthermore, the data on Fig. 8 are necessary for the preliminary analysis. Imagine how Fig. 11 would look if each of the eight members had been loaded. It would then be highly involved; but in addition it would have charged against it the time spent on Fig. 8 which contains a mass of data. More than one-half the data on Fig. 8 is unnecessary in the original Cross method, and it is this unnecessary majority which requires a large amount of work to produce. Besides being a highly involved method, lacking in simplicity, it is not a direct method. Imagine, in a speed contest, two designers given a complicated rigid-frame problem which neither had seen before with all necessary data to solve it by the original Cross method, but with no limitations on the method of solution. Assume that Designer No. 1 elects to stake all on the author's method whereas Designer No. 2 chooses to stake all on the original Cross method. At the expiration of 30 min of calculations, a halt is called and each contestant is then informed that there will now be available only 5 min in which to estimate on the basis of the work already done the final size and sign of all end moments. Designer No. 1 probably would be in no position to make this estimate as he would scarcely have finished with all the preliminary data such as those shown

[31] *Engineering News-Record*, February 14, 1935, p. 258.

on Fig. 8. On the other hand, Designer No. 2 probably would be about through with at least the second balancing and could make a fairly accurate forecast of the answer. This becomes important in design work where it may require two or more trials before the final moments of inertias of the members can be determined. Thus, which method would seem to be more simple and more direct?

E. J. BEDNARSKI,[33] ASSOC. M. AM. SOC. C. E. (by letter).—The classical universal method requires a solution of n simultaneous equations with n unknowns in each equation. When the value of n is fairly large—as, for example, 9—the work required is theoretically 60 480 times more than is necessary for the solution of one equation with one unknown. This gives an approximate idea of the work necessary in computing the stresses by the classical method in a multiple-story structure with several bays, such as the Empire State Building, in New York City.

Thus, the development of methods of analysis which save work is of great importance. The author solves the problem by developing original formulas which are simple and constitute the inherent properties of a given structure and which permit the distribution of any moment around any joint of the structure and the reaction to this moment by the other end of this member. Development of these relations is the most important and valuable result of the author's endeavor. Actually, the determination of the values of the factors, K_m and γ_m, constitutes the essence of the computation. (In certain structures the process of determination of K_m and γ_m will require one, or not more than two, repetitions of the computation for all practical purposes.) They are valid for any loading, in any structure that does not sway sidewise Unfortunately, in the analysis of ordinary structures, lateral forces and unsymmetrical loads that act on a structure which is not capable of resisting side-sway, are the most common cases encountered. The method is an excellent one, however, as long as its application is limited to symmetrical structures under symmetrical loading, continuous portals secured against sidesway, and continous beams. The writer checked a continuous portal given as an example by the late Professor A. Ostenfeld[32] and found the results identical with those given in the paper.

In a simple structure, such as Example 1, an application of other methods may prove just as efficient. The force polygon method introduced by J. D. Gedo, M. Am. Soc. C. E., for instance, has certain advantages in producing a direct exact answer to the problem by means of the solution of two simple simultaneous equations.[34] This corroborates the statement made by Professor Ostenfeld in his life work on statically undeterminate structures,[35] that each particular problem may be solved best by a certain particular method, although it may require a special study in itself.

[33] Structural Engr., Los Angeles, Calif.

[32] *Der Eisenbau,* November 8, 1921, p. 285.

[34] "Theory of Superstatic Structures," by J. D. Gedo, New York, 1935, Equations 117 and 118, p. 46.

[35] "Die Deformations Methode," by A. Ostenfeld, Berlin, 1926, Verlag Julius Springer.

The development of the "short cuts" in the analysis of statically indeterminate structures has recently gained a tremendous impetus. The writer wishes to express his hope that Mr. Lin may develop a solution of the problem that will include lateral and unsymmetrical forces acting on structures not secured against side-sway.

JOHN T. HOWELL,[36] JUN. AM. SOC. C. E. (by letter).—The method proposed by the author has proved to be of real practical value in the analysis of continuous frames. Engineers familiar with Professor Cross' method of moment distribution will be pleased with the manner in which the original concepts and definitions have been used to set up a direct method for determining moments. For those not yet familiar with this direct method a short general explanation will be given as the best way of comparing it with other modern methods.

The method offered is based entirely on Professor Cross' definitions of stiffness, carry-over factors, and fixed-end moments; and in a straightforward ingenious manner Mr. Lin develops simple relations for "modified" stiffness and carry-over factors.

The usual fixed-end moments are then distributed and "carried over" quite as one would visualize the restraining action of the actual frame. This "travel" of a moment to the ends of the frame is novel and interesting. Such a procedure is of importance to the designer as it affords valuable training in the art of estimating, accurately, the proportion and distribution of moment in any certain part of a structure, as controlled by the sizes and shapes of component members. This is true, since final moments are not determined by equations or formulas, or by repeated distributions, but are "written" on the frame in a regular routine manner by the use of simple arithmetic.

The method may be said to be of a type between the original method of moment distribution and various methods in which final moments are obtained directly by formulas. The analyst who prefers the simplicity of moment distribution and its easy application, but who wishes to avoid the numerous cycles of distribution necessary in many cases, will find great use for the direct method. After some practice one may estimate, with accuracy, the modified beam factors from the original stiffness and carry-over factors in particular cases. It is thus possible to "write in" the final moments in members of such indeterminate structures as multi-storied building frames with a degree of accuracy that is usually sufficient.

The most interesting feature of the method provides the greatest advantage or disadvantage, as the case may be, in comparing it with the method presented by Professor Cross. Since modified beam factors are determined before the fixed-end moments are distributed, and this preliminary calculation usually requires the major portion of the total time of analysis, it is important to consider the purpose and extent of any given analysis. In those cases where there is only one load, or a group of different loads taken together, it is quicker to use ordinary moment distribution. However, in cases

[36] Structural Engr., Structural Bureau, Portland Cement Assoc., Chicago, Ill.

where it is preferable to study the load effects separately, and in particular when influence lines are to be plotted, the direct method is much quicker and more satisfactory. This comparison shows that each method has its own field of use. The writer has found from experience that Professor Cross' method is quicker, and, of course, easier to apply in cases where one or two sets of joint moments are desired. The sign convention commonly attributed to L. E. Grinter, Assoc. M. Am. Soc. C. E.,[37] and also his "short-cut" in which large unbalanced moments are distributed and carried over before starting the regular distribution cycle, save some time.

In other types of detailed analysis previously mentioned Mr. Lin's modification is thought to be preferable. Considerable time will also be saved if the two fundamental equations for the modified beam factors, K_{abm} and C_{abm} (Equations (3) and (4)) are set up in the form of nomograms.

The writer has analyzed 8, 9, and 10-bbl siphon stiuctures by both methods, and has found that in the calculation of moments due to several load conditions where such effects are considered separately, and for the necessary analyses for shear correction coefficients, Mr. Lin's method is not longer than that of Professor Cross. A little practice in the determination of the "modified" beam factors for such frames will prove the procedure far easier than anticipated.

On the surface Mr. Lin's method and the alternate Cross method in which the "end-rotation constant"[38] is used, would seem somewhat similar. This is true in a superficial sense only, however, as the author's method is perfectly general whereas in the reference given "the end-rotation constant" method can only be used in those particular cases where the ratio of the changes in moment at the ends of the members are known.

During two years of practical use of the author's method the writer has noted a few points which might be mentioned. Under the heading "Definitions and Notation" the author has defined K as the stiffness of the end of a member. "Relative stiffness" values are most commonly used, the "absolute stiffness," that is, $K \propto \frac{E I}{L}$ being used where different materials make up the structure, or in the determination of fixed-end moments of haunched members subject to the lateral displacement of one end relative to the other, with no joint rotation.

Stiffness values in published tables or curves are usually in terms of $\frac{I}{L}$ or $\frac{4 I}{L}$. In general, any numerical value may be given to the K-values as long as they are consistent and proportionate to the respective $\frac{I}{L}$-values. The modified stiffnesses (Equation (3)) change by this same proportion, and the constants are cancelled in Equations (1) and (4).

[37] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 610.

[38] "Continuous Frames of Reinforced Concrete," by Hardy Cross and N. D. Morgan, Members, Am. Soc. C. E.

To clarify any possible slight confusion, it should be noted that in Mr. Lin's terminology the carry-over factor placed at an end of a member is that one which carries over distributed moments to the opposite end. In many methods the opposite is true.

The actual degree of restraint provided at the joints of a structure has been the object of much research in recent years. Riveted connections of various types have been shown to have different restraint ratios.[39] To obtain the most accurate analyses, correlated and consistent experimental data will be used to indicate the "degree of fixity" provided at the ends of critical members. For such analyses Mr. Lin's method is ideal. The R-term (Equation (1)) denotes the end restraint of a member, and may be assigned any value indicated by such research. The modified beam factors and, lastly, the joint moments are then found as before.

The fundamental formulas in the direct method may be further modified to make them correspond to formulas in other methods. The final moments at the ends of a member can be given by those altered formulas, but it is the opinion of those familiar with the author's method that one of its chief advantages lies in the fact that it retains some of the features of moment distribution.

The writer found the direct method easy to learn, and its application has afforded real pleasure. Mr. Lin has made a worthwhile contribution to structural engineering literature.

I. Oesterblom,[40] M. Am. Soc. C. E. (by letter).—This paper seems to have its principal value in demonstrating that a framework has elastic properties entirely apart from any system of loads which may be applied (in the same manner as a beam), and that these properties are definitely ascertainable by simple and elementary analysis.

This is not to say that Mr. Lin is the first to develop this idea. Presumably, it has been studied by many investigators, but no one has stressed the significance sufficiently to cause much quotation or comment. An exception might be Dr. Hermann Zimmermann, who long ago saw the significance of segregation and presented papers on the subject as early as 1907, before the Akademie der Wissenshaften,[41] in Berlin, Germany, and other scientific bodies. Unfortunately, Dr. Zimmermann did not realize that his many contributions assembled into one unit would serve as a powerful tool of analysis and design, until quite recently, and when his book on "Knickfestigkeit der Stabverbindungen" was published in 1925, it caused little or no comment.

To Mr. Lin, therefore, belongs the honor of bringing before thinking engineers an important fact, and, if anything, it merely adds to its value that the presentation has been made in terms of Professor Cross' brilliant moment distribution concept.

[39] "Elastic Properties of Riveted Connections," by J. Charles Rathbun, M. Am. Soc. C. E. *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 524.

[40] Civ. Engr., Chicago, Ill.

[41] *Sitzungsberichte*, 1907, 1909, 1921, 1923, 1924, and 1925.

It is to be regretted, however, that Mr. Lin did not confine himself to "elastic properties of a framework." That subject is so broad in itself as to provide material for many an academic thesis, and it needs emphasis because it has been so sadly neglected as a separate issue.

On the other hand, the writer is not convinced that Mr. Lin's procedure for finding the moments due to a system of loads will lead to results as quickly as Professor Cross' original procedure. For example, Equation (1) is most excellent for the analysis of important structures, where it is necessary to show graphically and clearly the elastic relations of the whole, but it should not be forgotten that in the usual framework four such equations must be solved for every nodal point. This means considerable work and is only a part of the total analytical task. The time required as compared to that allowable, for the usual run of designs, would automatically bar the method.

Professor Cross aimed at a series of progressive approximations leading ultimately to any degree of mathematical accuracy and all of a nature to be performable, even if not performed, by slide-rule. In ruling out the progressive approximations and bringing back a series of equations, it would seem that, on that point, Mr. Lin is taking a step backward. This criticism, however, is directed only toward over-enthusiasm in regard to the most vulgar applications and in no way lessens the writer's admiration for the fundamental idea of the paper.

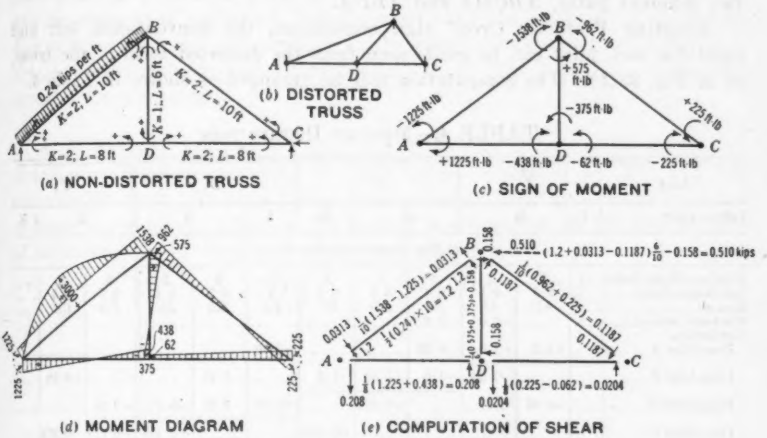
In view of its importance the paper is regrettably brief and for that reason is not fully convincing at all points. Unfortunately, most engineers would like to examine the mathematical demonstrations in full, and thus avoid spending extra time to provide "the missing pieces in the game." A few more pertinent details would have been helpful.

W. P. Li,[43] Jun. Am. Soc. C. E. (by letter).—The difference between the original Cross method of moment distribution and the Lin modification may be visualized readily by the following formularized method of procedure:

Assuming an end of a member as being $\dfrac{\text{in a natural condition of restraint}}{\text{fixed}}$, when the joint at that end is released, the unbalanced fixed-end moment is distributed among the members in proportion to the $\dfrac{\text{modified } (K_m)}{\text{direct } (K)}$ stiffness (that is, the $\dfrac{\text{inter-related}}{\text{separate, } \dfrac{I}{L}}$, stiffness). (Note that, in the modified method, for unbalanced "carried-over" moments the distribution is only among the connecting members.) The moment thus distributed, is carried over to the other ends of the members in accordance with $\dfrac{\text{a modified}}{\text{the Cross}}$ carry-over factor. For beams of uniform cross-section the carry-over factor in the Cross method is -0.5.

[43] Chf., Designing Dept., Kwangtung River Conservancy Bureau, Canton, China.

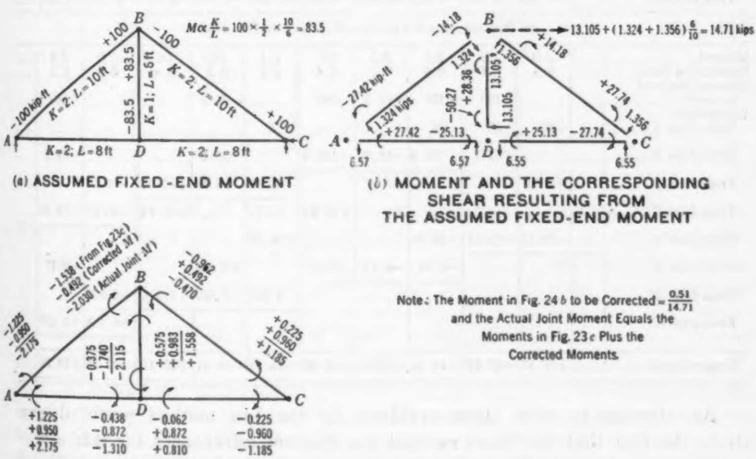
In the foregoing, compound rule, the inserts in the "numerator" refer to the modified method and those in the "denominator" to the Cross method. It is evident that the modified method is not entirely direct in its application since it requires two steps instead of one for the solution of the problem. The first step, that of computing the modified stiffness and the modified



(a) NON-DISTORTED TRUSS (b) DISTORTED TRUSS (c) SIGN OF MOMENT (d) MOMENT DIAGRAM (e) COMPUTATION OF SHEAR

FIG. 23

carry-over factor, is usually lengthy, especially when the R-value must be assumed at the beginning, as for the closed frames. Thus, it seems that the modified method is only a variant of the original method. One can



(a) ASSUMED FIXED-END MOMENT (b) MOMENT AND THE CORRESPONDING SHEAR RESULTING FROM THE ASSUMED FIXED-END MOMENT

Note: The Moment in Fig. 24 b to be Corrected = $\frac{0.51}{14.71}$ and the Actual Joint Moment Equals the Moments in Fig. 23 c Plus the Corrected Moments.

(c) ACTUAL JOINT MOMENTS

FIG. 24.

scarcely claim that the modified method is more direct than the original; ordinarily, the reverse is true. A closed frame such as that in Example 4 of the paper and in the truss in Fig. 23, and in Fig. 24, can be solved more easily and directly by the original method. It is difficult to assume a closed R-value for one of the truss members, say, AB (Fig. 23), and check it along two different paths, $ABCDA$ and $ABDA$.

Adopting Professor Cross' sign convention, the conventional left and right for each joint can be easily seen from the distorted form of the truss, as in Fig. 23(b). The computation may be arranged as shown in Table 4.

An attempt to solve these problems by the Lin method would demonstrate the fact that the Cross method has distinct advantages for this case.

Since the truss in Fig. 23(a) is unsymmetrically loaded with wind pressure, Joint B will undergo side-sway if subjected to wind pressure alone;

however, Joint D is held against side-sway by the horizontal member, ADC, which is twice as stiff as Member BD. The shear correction for the side-sway of Joint B can be computed as follows: (1) Find the horizontal force to be applied at Joint B in order to hold it against side-sway; (2) assume a system of convenient fixed-end moments and find the final moment and the corresponding horizontal shear at Joint B; (3) by proportioning the force and the shear thus computed, find the moments to be corrected at the joints due to side-sway; and (4), combine the corrected moments with the moments obtained by simple moment distribution (as in Fig. 23(c)) to obtain the actual joint moments.

A. A. Eremin,[44] Assoc. M. Am. Soc. C. E. (by letter).—The method of distributing bending moments in rigid frames described by Mr. Lin has considerable merit. It gives direct distribution of bending stresses from the moment at one joint. Likewise, the method is convenient for the construction of influence lines for bending stresses in rigid frames.

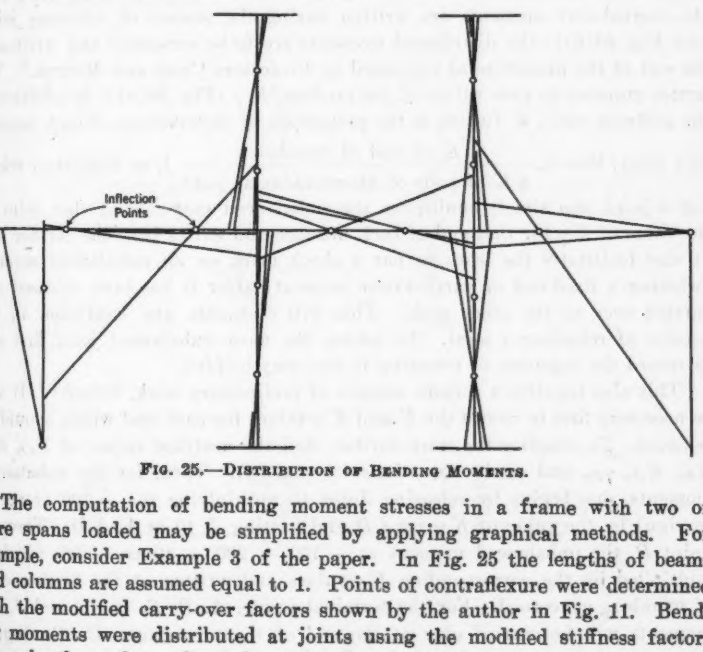

Fig. 25.—Distribution of Bending Moments.

The computation of bending moment stresses in a frame with two or more spans loaded may be simplified by applying graphical methods. For example, consider Example 3 of the paper. In Fig. 25 the lengths of beams and columns are assumed equal to 1. Points of contraflexure were determined with the modified carry-over factors shown by the author in Fig. 11. Bending moments were distributed at joints using the modified stiffness factors shown by the author. Carried-over bending moments were determined graphically by means of the points of contraflexure in Fig. 25. The resulting end bending moments in the members will be equal to the algebraic sum of moments scaled from Fig. 25 and fixed-end moments.

[44] Assoc. Bridge Designing Engr., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

Conventional rules for signs of moments in Fig. 25 are similar to those introduced in the paper. Positive bending moments at joints are considered clockwise and negative moments, counter-clockwise. The use of Fig 25 helps to avoid an error in the signs of bending moments. By graphical methods, the distribution of moments can be visualized readily. Furthermore, graphical construction reduces the work of distributing moments.

T. Y. LIN,[44] JUN. AM. SOC. C. E. (by letter).—Judging from the interesting discussions of this paper, many engineers have evidently found it valuable. Professor Grinter makes a thoughtful comparison with the original method; but he does not compare the two on the same basis. The members in Fig. 14 are all of uniform moment of inertia, whereas in Figs. 8 to 11, some are not. To make a fair comparison, the writer will solve Example 3 by a simplified Cross method which, he believes, requires the least amount of written work possible with that method. Instead of writing both the distributed and carried-over moments at the same time, as Professor Grinter does, only the carried-over moments are written during the process of releasing joints (see Fig. 26(b)); the distributed moments are to be computed and written at the end of the procedure as suggested by Professors Cross and Morgan.[45] The writer proposes to give values of the product, $K\gamma$ (Fig. 26(a)), in addition to the stiffness ratio, K (which is the proportion of distribution of each member at a joint; that is, $\dfrac{K \text{ of end of member}}{\Sigma K \text{ of ends of all members at joint}}$), so that when releasing a joint one simply multiplies the unbalanced moments at that joint by the value of $K\gamma$ for that end of each member and writes it at the farther end. It also facilitates the work to put a check mark on an unbalanced moment (whether a fixed-end or carried-over moment) after it has been released and carried over to the other ends. This will eliminate any confusion in the process of releasing a joint. To release the most unbalanced joint first and to record the sequence of releasing is also very helpful.

This also requires a certain amount of preliminary work, however. It will be necessary first to record the K and $K\gamma$-values for each end which should be released. To simplify the work further, find the modified values of K_{cg}, K_{ef}, K_{da}, K_{eb}, γ_{da}, and γ_{eb} by Equations (3) and (4). Then, for the unbalanced moments, one begins by releasing Joint C, multiplying the -100 (reversed in sign) by the value of $K\gamma$ for CD and writing $+40$ at End D. Then, at Joint D, the unbalanced moment $= -150 + 200 + 40 = +90$, which is multiplied by the corresponding $K\gamma$-values and written at the farther ends of members concerned. For the terminal joints, A, B, F, G, H, and J, the moments will be carried over at the end of the procedure. Continuing in the sequence shown, it is found that the values are converging rapidly, giving close results at the end of the ninth cycle. The unbalanced moment at each joint is then added and distributed to the ends of members meeting at

[44] Engr., Cheng-yil Ry., Chungking, Szechnan, China.

[45] "Continuous Frames of Reinforced Concrete", by Hardy Cross and C. E. Morgan, Members, Am. Soc. C. E., p. 104.

that joint in proportion to the K-values. Thus, at Joint D, the unbalanced moment is $245 - 135 = 110$, which gives -25 to Column DA, -45 to Girder DE, etc. The final moments are then as shown in Fig. 26(c). Moments

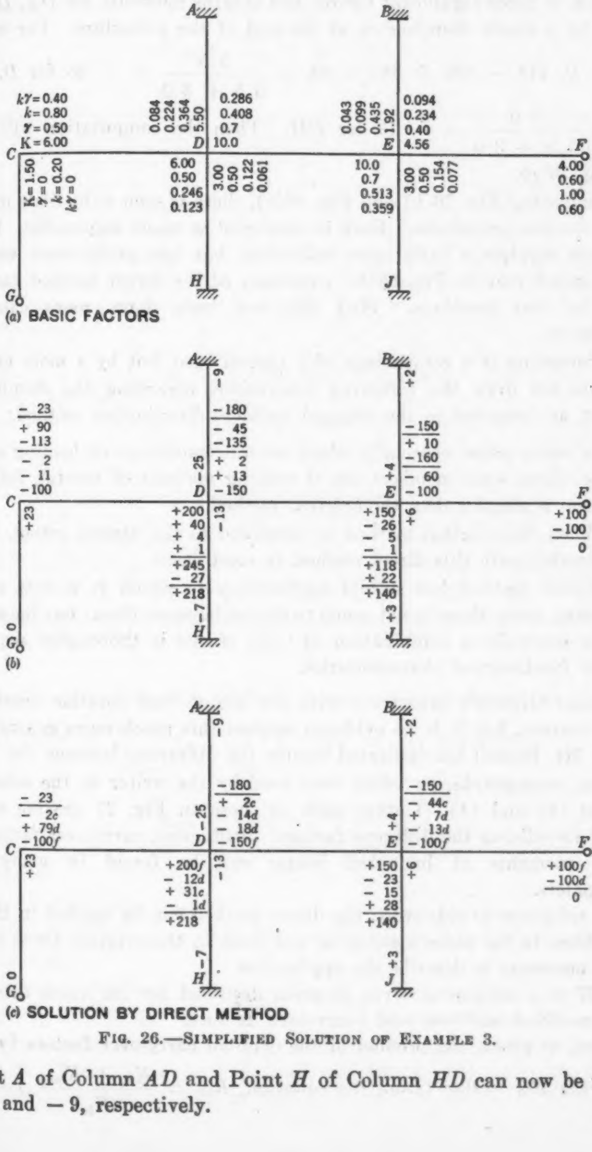

FIG. 26.—SIMPLIFIED SOLUTION OF EXAMPLE 3.

at Point A of Column AD and Point H of Column HD can now be found to be -7 and -9, respectively.

To do justice to the direct method, it should be noted that Fig. 11 has been made voluminous purposely in order to give the reader an unmistakable understanding of the procedure. It can easily be simplified if one carries the calculation to three significant figures and obtains moments for *DA*, *DH*, *EB*, and *EJ* by a single distribution at the end of the procedure. For example, at Joint *D*, $218 - 180 = 38$; $- 38 \times \dfrac{5.5}{5.5 + 3.0} = - 25$ for *DA*; and, $- 38 \times \dfrac{3.0}{5.5 + 3.0} = - 13$ for *DH*. Then the computation will appear as in Fig. 26(*c*).

By comparing Fig. 26(*b*) and Fig. 26(*c*), there is seen to be little to choose between the two procedures. Each is simplified as much as possible. Perhaps the former requires a little more balancing, but less preliminary work. It must be noted that in Fig. 26(*b*), equations of the direct method have been applied to four members. Had this not been done, more calculation would appear.

The foregoing is a comparison of a typical case, but by a more extensive study, one can draw the following conclusions regarding the simplicity of the direct, as compared to the original, moment-distribution method:

(1) In many cases, especially where several conditions of loading are considered or where some members are of varying moment of inertia, this direct modification is simpler than the original method.

(2) When the original method is simplified to the utmost extent, it compares favorably with this direct method in most cases.

(3) Either method has special applications to which it is best adapted, and, in many cases, there is not much to choose between them; but the simplest method is generally a combination of both, if one is thoroughly acquainted with their fundamental characteristics.

Professor Grinter's experience with the use of "end rotation constant" is probably correct; but it is no evidence against this much more general direct method. Mr. Howell has indicated clearly the difference between the two.

Curves, nomographs, or tables were used by the writer in the solution of Equations (3) and (4). Curves such as those in Fig. 27 provide a better means of visualizing the different factors. Stiffnesses, carry-over factors, and fixed-end moments of haunched beams can be found in many books and pamphlets.

With reference to side-sway, the direct method can be applied in the side-sway problem in the same manner as was done in the original Cross method. It is not necessary to describe the application.

Fig. 27 is a composite curve diagram designed for the quick determination of modified stiffness and carry-over factors.

Assume, as given, the product of the original carry-over factors ($\gamma_{ab}\ \gamma_{ba}$), and also the R_{ba} - value (from the equation, $R_{ab} = \dfrac{K_{ba} + K_{bnm}}{K_{ba}}$.) The in-

tersection of these values—using the solid R_{ba} curves—gives, at the bottom of the diagram the numerical value of $\left(1 - \frac{\gamma_{ab}\,\gamma_{ba}}{R_{ba}}\right)$ for use in the equation,

$$K_{abm} = K_{ab}\left(1 - \frac{\gamma_{ab}\,\gamma_{ba}}{R_{ba}}\right)$$

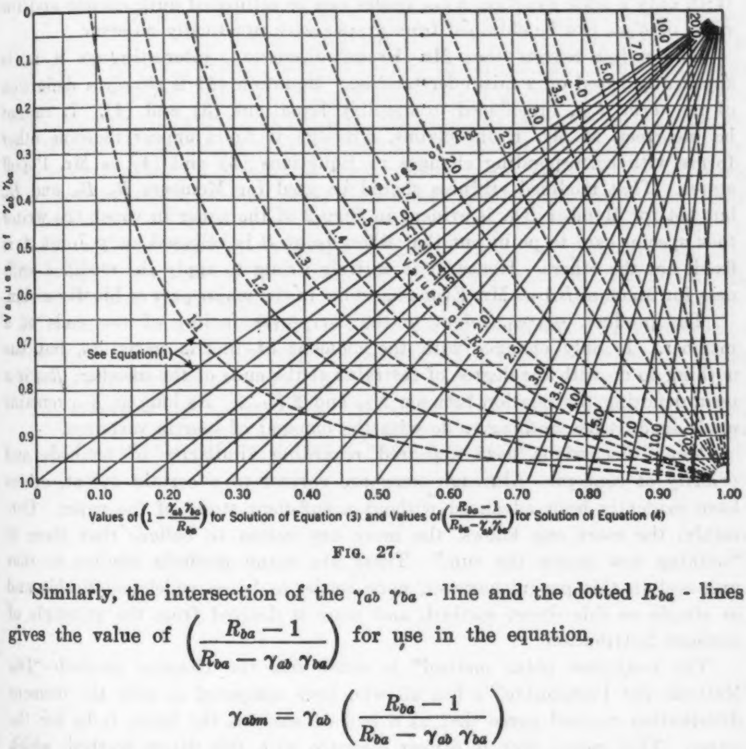

FIG. 27.

Similarly, the intersection of the $\gamma_{ab}\,\gamma_{ba}$ - line and the dotted R_{ba} - lines gives the value of $\left(\frac{R_{ba} - 1}{R_{ba} - \gamma_{ab}\,\gamma_{ba}}\right)$ for use in the equation,

$$\gamma_{abm} = \gamma_{ab}\left(\frac{R_{ba} - 1}{R_{ba} - \gamma_{ab}\,\gamma_{ba}}\right)$$

For example:

To find: K_{abm} and γ_{abm};

Given: $\gamma_{ab} = 0.50$; $\gamma_{ba} = 0.50$; $R_{ba} = 3.0$; $K_{ab} = 1.2$; and, $\gamma_{ab}\,\gamma_{ba} = 0.50 \times 0.50 = 0.25$.

In Fig. 27 follow the heavy line, $\gamma_{ab}\,\gamma_{ba} = 0.25$, to its intersection with $R_{ba} = 3.0$ on solid lines. Read at the bottom of the diagram the value 0.92. At the intersection with $R_{ba} = 3.0$, on dotted lines, read at the bottom the value, 0.73. Then, $K_{abm} = K_{ab}$ (0.92) $= 1.2 \times 0.92 = 1.10$; and $\gamma_{abm} = \gamma_{ab}$ (0.73) $= 0.50 \times 0.73 = 0.36$.

Professor Grinter and Mr. Huang both suggested the idea of using $\frac{K_{ba} + \Sigma K_{bn}}{K_{ba}}$ instead of $\frac{K_{ba} + \Sigma K_{bnm}}{K_{ba}}$. Mr. Huang has further found the resulting error in the value of K_{abm} to be less than 2.08 per cent. However, the writer finds that for haunched members the $\gamma_{ab}\,\gamma_{ba}$-value of which is greater than 0.25, the resulting error can be large, perhaps even more than 25 per cent. Hence, the writer prefers the use of estimated values of K_{bnm}. With only a little practice, K_{bnm}-values can be estimated quite closely and the value of K_{abm} can be obtained from graphs with practically no error.

The writer regrets that Mr. Evans' discussion, interesting as it is, is apparently based on a misunderstanding. Equation (1) is simply a definition of the term, R_{ba}, introduced to simplify Equations (3) and (4). It cannot be incorrect, as Mr. Evans claims, although it could appear in some other forms with corresponding changes in Equations (3) and (4) as Mr. Popoff states. That modified stiffness should be used for Members B_1, B_2, and B_3, but not for Member BA, is evident in Step 2 of the paper in which the writer took special care to point out that when Joint B is released, only Joint A is fixed, not the others. Hence, it is entirely wrong to apply the modified stiffness for Member BA as Mr. Evans has done in the major part of his discussion.

The product, $\gamma_{ab}\,\gamma_{ba}$, refers to the carry-over factors of two ends of a member. It only changes with the moment of inertia variation, but has nothing to do with the degree of restraint at the ends of the member; R_{ba} is a term denoting the relation between K_{ba} and $\Sigma\, K_{bnm}$. As long as K_{ba} remains unchanged, it has nothing to do with the moment of inertia variation.

Many discussions have appeared regarding similarity of methods and priority of concept. Although some are correct to a certain extent, others have evidently been advanced without a sufficient study of the paper. Certainly, the more one knows, the more one comes to believe that there is "nothing new under the sun." There are many methods similar to that proposed in this paper; however, none seems to be as widely applicable and as simple as this direct method, and none is derived from the principle of moment distribution.

The conjugate point method[39] is much like the German method—"Die Methode der Festpunkte"[46]; but all who have compared it with the moment distribution method agree that as a tool of analysis the latter is by far the better. This means that it cannot compare with this direct method, which can be much more easily learned and more widely applied.

It is to be regretted that the writer cannot obtain Dr. Zimmermann's book, mentioned by Mr. Oesterblom, and the thesis presented by Mr. A. Efsen to the University of Copenhagen in 1930 in fulfillment of the requirements for the degree of Doctor Technices, to which Theodore B. Host, Assoc. M. Am. Soc. C. E., has called the writer's attention by correspondence; but he infers from the opinions of the discussers that the methods are not derived in the same manner and probably cannot be as easily and generally applied.

[46] "Berechnung der Statisch-unbestimmte Systeme", von A. Strassner, Berlin, 1921.

Mr. Huang[19] has a paper published in Chinese that advances a similar method derived from slope-deflection equations. It is similar to other methods derived therefrom, but is more cumbersome. Probably the method presented by Mr. E. B. Russell[47] is most similar to that proposed by the writer. This method is developed from slope-deflection equations and introduces two rather complicated equations for finding the end moments. The same is true of the method[48] of T. F. Hickerson, M. Am. Soc. C. E., and that[49] proposed by H. M. Hadley, Assoc. M. Am. Soc. C. E.

In the original thesis,[3] there is a brief, but rather extensive, comparison of all methods of continuous frame analysis. It might prove interesting to one who is scholarly enough to make further investigations. After long study of, and experience with, the subject, the writer has come to the conclusion that although each particular problem may be solved best by a certain particular method, it suffices for all purposes to have learned the Cross method and this direct method. The latter is most valuable in the visualization and study of elastic properties of continuous frames and in the approximate but sufficiently accurate estimate of moments in them. Any one who has learned the fundamentals of this method should be able to "write in" moments to a sufficient degree of accuracy. He should be able to see mistakes in analysis. He should be able to visualize the effect of haunching; the effect of restraint; and to see a continuous frame as he sees a simple truss. He should know what approximation can be applied in analysis, and where changes in design can be made for economy.

BEHAVIOR OF STATIONARY WIRE ROPES IN TENSION AND BENDING

By Douglas M. Stewart[1], Jun. Am. Soc. C. E.

With Discussion by Messrs. C. D. Meals, G. P. Boomsliter, Ingvald E. Madsen, and Douglas M. Stewart.

Synopsis

This experimental investigation of the behavior of wire ropes in tension and bending was undertaken in order to determine their strengths and the stresses produced under load, and to compare these values with those given by the several formulas in common use. Altogether, nine tension and thirty-six bending specimens were tested over sheaves of four diameters. The ropes selected were 1 in. in diameter, with hemp centers, and the tests included studies of regular and Lang lay ropes, of 6 × 7 and 6 × 19 construction preformed and non-preformed types, and of two different grades of steel. Important results are contained in the curves for loss of strength in bending and for the variation in modulus of elasticity of the rope under pre-stressing, and a comparative summary is given of stresses and strengths as observed and as computed by several formulas.

Introduction

Since wire ropes were first produced in the early part of the Nineteenth Century, with a view to obtaining high strength combined with flexibility over sheaves, the question of the stresses set up by bending them has been a subject of sharp controversy. Literally dozens of formulas have been developed to evaluate this bending stress, most of them of an empirical nature, and each wire rope user, in the past, has given preference to one or another in

Note.—Published in February, 1936, *Proceedings*.

[1] Engr., Ingersoll-Rand Co., New York, N. Y., formerly Garrett Linderman Hoppes Research Fellow in Civ. Eng., Lehigh Univ., Bethlehem, Pa.

the light of his practical experience with ropes in service. In some cases, the formula was merely an expression of the results of a series of tests on specimens to determine the loss of strength over various sizes of sheaves, from which the bending stress could be evaluated in some measure. This has led recently to the expression of formulas for loss of strength in bending, which, in the end, is a more practical concept than that of the stresses to which this loss is due.

It was for the purpose of investigating the merits of these numerous bending formulas that this test program was originally conceived. Undoubtedly, there is a marked difference between the stress conditions in a stationary wire rope bent over a sheave and in one which is in rapid motion over the same sheave and possibly subjected to reverse bending as well. The scope of this investigation has been limited to a study of stationary ropes only, and while they hold admittedly a relatively minor place in wire-rope usage, the results may point the way to a clearer understanding of stress conditions in moving ropes as well as in stationary ones.

A program of tests of ropes over sheaves was planned accordingly, and a means devised for measuring the stress in any of the outer wires. For purposes of comparison a tension specimen of each type of rope was needed, and further stress observations were taken on these specimens. Because of the need in certain stress formulas for a value of the modulus of elasticity of the rope as a whole, numerous observations of this property were made, and this determination soon became one of the major branches of the investigation. Considerable data have been collected also on the untwisting effect in wire ropes under tension, on their shrinkage in diameter as their hemp centers are consolidated, and on the coefficient of friction between rope and sheave.

Notation.—The symbols used in this paper are summarized for reference in Appendix I.

The Problem

Review.—Probably the first and simplest formula that has been derived for the purpose of expressing the stress in a wire rope bent over a sheave was that of Reuleaux[3],

$$s = E \frac{d}{D} \qquad (1)$$

which was derived from the expression for bending stress in a slightly curved beam, by substituting instead of the diameter of the rod acting as a beam, the diameter of one wire (presumably in the outer layer) used in the rope. D is the diameter of the sheave and E, the modulus of elasticity of the wire, generally assumed to be about 28 500 000 lb per sq in. This formula is given by the late Robert Charles Strachan, M. Am. Soc. C. E. (4)[4], F. C. Carstarphen, M. Am. Soc. C. E. (1), and by numerous other writers.

[3] Given by Reuleaux in his book "The Constructor", 1893 Edition, and probably as early as 1876 in other writings.

[4] For reference to figures in parentheses, see "Bibliography", Appendix II.

It was soon found that Equation (1) gave values of the stress which were far too high to be practicable, in many cases even exceeding the ultimate strength of the wire for small sheave sizes. Accordingly, attempts were made to modify the formula by empirical and semi-empirical means. Shortridge Hardesty, M. Am. Soc. C. E. (2), has derived the formula (4):

$$s = E \frac{d}{D} \cos a \cos b \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

in which a is the angle between a helical wire and the axis of the strand and b is the angle between a strand and the axis of the rope.

Mr. R. W. Chapman (5) modified Equation (2) by expressing the formula as:

$$s = E \frac{d}{D} \cos^2 a \cos^2 b \ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

which gives values for the stress lower than those given by Equations (1) and (2).

B. R. Leffler, M. Am. Soc. C. E. (3) gives an empirical modification of this formula as adopted by the New York Central Railroad Company in 1928,

$$s = \frac{2\,Ed}{3\,D} \cos^2 a \cos^2 b \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Mr. Carstarphen (1) makes mention of an empirical formula of even simpler form,

$$s = 0.44\ \mathrm{E} \frac{d}{D} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

although it is not mentioned on what test results this formula is based.

All the preceding formulas have involved the use of the modulus of elasticity of the wire, and the tendency has been to reduce the abnormally high stress values by some coefficient. In 1918, Mr. James F. Howe (2) suggested that the proper value of E to use in a formula of the general type of Equations (1) to (5) was the modulus of elasticity of the rope as a whole, E_r; thus,

$$s = E_r \frac{d}{D} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

or, as it is often used,

$$s = \frac{E_r\, d}{D + d_r} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

This formula gave values considerably lower than those of Equation (2) or Equation (3), when using a value of 12 000 000 lb per sq in. as the modulus of elasticity of the rope.

In 1933, Mr. Carstarphen (1) approached the problem from an analytical standpoint, and on the basis of a wire rope consisting of a double set of open-coiled helical springs, in turn bent around a constant radius, arrived at an expression for the loss of strength of a wire due to such bending:

$$P = \frac{\pi\,(d)^4\ E\ G}{16\ R\ r_s\ [2\ G\ (1 + \sin^2 \alpha) + E \cos^2 \alpha]} \ldots\ldots\ldots (8)$$

in which P = loss of strength in a given wire; d = the diameter of a given wire; E = modulus of elasticity of a given wire; G = modulus of rigidity of a given wire, $\left[G = \frac{E}{2(1+\mu)}\right]$; μ = Poisson's ratio; R = radius of a sheave, $\left[R = \frac{1}{2}(D + d_r)\right]$; r_s = radius from the center of the strand to the center of the wire in question; and, α = the angle between the perpendicular to the axis of a rope and the tangent to the center line of the wire.

In Equation (8), when $r_s = 0$, substitute r_r which is defined as the radius from the center of a wire rope to the center wire of a strand.

The total loss of strength in a rope is equal to the value of P multiplied by the number of wires, or if the strand consists of a number of layers of different sized wires, a value of P must be computed for each layer and multiplied by the number of wires of that size in the layer. If a value of the bending stress were desired, this could presumably be obtained by dividing ΣP by the net area of steel in the rope. According to Mr. Carstarphen, Equation (8) "takes into account the diameter of the wires, the rope, the radius of curvature, the angle of lay, the modulus of elasticity in tension, and the modulus of rigidity." The test results reported in the same paper seemed to support this method of computing loss of strength.

Any of the preceding formulas, for bending stress, f, may be adopted to give loss of strength, or ultimate strength in bending, S, by inserting them in the general form of the equation:

$$S = A\,(t - s)\,\varepsilon \qquad \text{.......................(9)}$$

in which A is the net area of steel in a wire rope; t is the ultimate unit tensile strength of a wire; and ε is the efficiency of the rope in plain tension. Equation (8) is given by C. D. Meals, Assoc. M. Am. Soc. C. E. (1), and others, using Equation (7) to determine a value for f. Mr. Meals further developed an equation for the strength of a wire rope in tension, from which the efficiency, ε, might be computed:

$$S_t = n_s \cos b \left(\sum_{1}^{n} n_w S_i \cos^3 a_i\right) \qquad \text{..............(10)}$$

in which n_s is the number of strands in a rope; n_w is the number of wires of a given diameter in the ith layer; S_i is the tensile strength of a wire in the ith layer; a_i is the angle of pitch of the wires in the ith layer; and n_l is the number of layers of wires in a strand.

J. H. Griffith, M. Am. Soc. C. E., and Mr. J. E. Bragg (6) gave both Equation (9) and an empirical formula for tensile load based on the minimum results of tests, as:

$$T = C \times 75\,000\; d^2_r \qquad \text{.........................(11)}$$

in which, D is the diameter of the cable, in inches; and C is a constant for various constructions (see Table 1).

TABLE 1.—VALUES OF C FOR MEAN IN EQUATION (11)

Rope	Range From:	Range To:	Mean*
6×19 plow steel	0.9	1.1	1.0
8×19 plow steel	0.8	1.00	0.85
6×19 cast steel	0.8	1.00	0.85
6×42 tiller rope	0.3	0.45	0.35
6×7 guy rope	0.3	0.45	0.35

* Approximate.

On the assumption that slipping does not occur between the straight and curved wires, Mr. Carstarphen gave the following formula (1) for the tensile strength of a rope,

$$S = \cos\ (a + b)\ A\ S_w \qquad \text{(12)}$$

in which S_w is the ultimate strength of the wire.

The foregoing equations for stresses and strengths in bending and in tension are only a few of the many that can be found in engineering literature. They were chosen as representative of current usage, and the range in values given by them demonstrates clearly the uncertainty that still exists as to the ultimate effect of bending stresses on the strength of a wire rope. Each of these formulas has been applied to the wire ropes used in this investigation, and a table of the results is included herein, under the heading, "Summary".

The Present Investigation.—The most logical manner in which to determine the bending stresses and loss of strength in wire ropes, seemed to be a series of tests on ropes on which the stresses could be measured by some standard extensometer. Fortunately, such equipment was available in the form of four tensometers that could be mounted on individual outer wires at different points around the sheave. From these readings unit strains were recorded directly, by multiplying by the predetermined constant for each instrument. To convert these values to unit stresses, it was necessary to draw, from auxiliary samples of the wires used, stress-strain curves for each size of outer wires encountered. From these curves the observed strains could then be transformed readily to their corresponding stress values, thus giving values of the stress in the outer wires at any point along a sheave or on a straight tension specimen.

This same principle is made use of time and time again in laboratory work on mild steel specimens, where extensometer readings of strain below the elastic limit are multiplied by 29 000 000 lb per sq in. in order to give the stress at these points. The difference lies in the fact that steel, such as is used in wire-rope manufacture, does not have a sharp, well-defined elastic limit since it is heat-treated, with the result that the stress-strain curve shows a proportional limit of about 40% of the ultimate strength. Furthermore, in

the tests to destruction, strains were recorded on the ropes in most cases to about 90% of the ultimate load, the uniformity of the stress-strain curves of the wire even at these high loads permitting such readings to be made with considerable accuracy.

On the tension tests, a means was sought to determine the modulus of elasticity of the rope as a whole, in addition to the stresses in individual outer wires. One of the most satisfactory methods in use in the past has been described by G. P. Boomsliter, M. Am. Soc. C. E. (8). He utilized an 8-in. strain-gauge set in holes on brass rings soldered to the rope. Considerable difficulty was encountered due to the untwisting effect of the rope under load, which caused errors in his readings. In order to adapt this method to the present tests, and to minimize such errors, it was decided to use a 10-in. strain-gauge, with holes located on $\frac{1}{2}$-in. square brass lugs, curved to fit the rope and soldered to it. In this manner, the tendency of the rig to tear away as the rope shrinks under load was eliminated. To compensate for twist, two scales reading to hundredths of an inch were placed 10 in. apart on the rope, and read with the vertical hair of a surveyor's transit; the proper corrections to the measured gauge lengths were then computed after the completion of the test. The stress-strain curve of the rope could then be drawn readily and the modulus of elasticity obtained in the usual manner.

The tests reported by Professor Boomsliter showed quite definitely that the modulus of elasticity of a wire rope, especially one with a hemp center, is a decidedly variable quantity, and tends to increase as the number of loadings increases and as the stress to which the rope is loaded each time is raised. In view of these results, it was decided to investigate more fully this property of wire ropes with hemp centers and to load each tension specimen seven times to approximately 50% of its ultimate load, taking readings on the first, third, fifth, and seventh loadings. As the tests proceeded, it was found advisable to observe also the second loading. All bending specimens were similarly loaded seven times before finally fracturing them, both to insure conditions similar to those in their companion tension specimens and to work the individual wires so as to equalize the stress in them, as indicated by the tensometer readings.

Program of Tests

Because of the large number of variables involved in an investigation of this nature, it was decided to restrict as many of them as possible, and to confine the study to a determination of basic relationships. For this reason, the size of the rope to be tested was set at 1 in., since this was the minimum on which the outer wires extended along the surface far enough to admit attaching a tensometer on a $\frac{1}{2}$-in. gauge length. Similarly, a rope with a hemp center was selected as being more typical than one with an independent wire rope center, and less likely to be confusing in any analysis.

The variables to be investigated were: (1) Sheave diameter; (2) construction; (3) lay; (4) preforming; and (5) grade of steel.

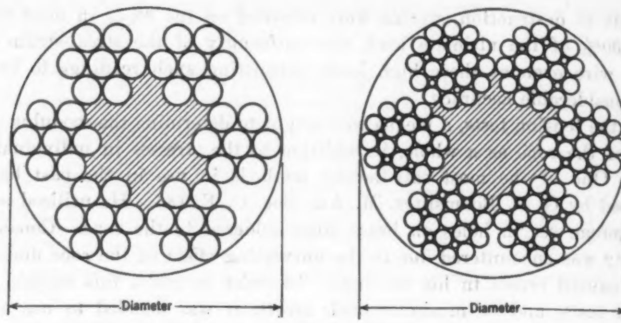

Fig. 1.—6 × 7 and 6 × 19 Wire-Rope Construction.

(*1*) *Sheave Diameter.*—Four values of D were selected: 18 in., 14 in., 10 in., and 7 in., each, measured at the root of the groove.

(*2*) *Construction.*—Ropes of both 6 × 7 and 6 × 19 construction were tested (see Fig. 1). The 6 × 19 ropes contained six filler wires of the same grade of steel as the main wires, added to give a smoother surface to the strand.

(*3*) *Lay.*—Both regular lay and Lang lay ropes were included (see Fig. 2). In regular lay ropes the angle of lay of the wire in the strand is equal and opposite to that of the strand in the rope, with the result that the outer wires lie parallel to the axis of the rope. In Lang lay construction, both wires and strands are twisted in the same direction. As the angle of lay was in all cases very close to $18\frac{1}{2}°$, the outer wires in a Lang lay rope were inclined at 37° to the axis of the rope.

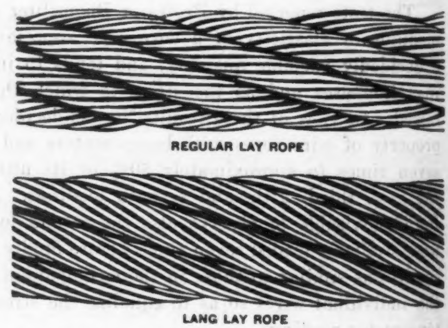

Fig. 2.—Regular Lay and Lang Lay Wire Rope.

(*4*) *Preforming.*—The process of manufacture by which both wires and strands are given an initial helical curvature as they are formed, is known as preforming. This process will be described in detail in succeeding paragraphs. Both preformed and non-preformed types were tested.

(*5*) *Grade of Steel.*—Most of the specimens tested were of cast steel, of the grade produced by almost all wire rope manufacturers, with a specified ultimate strength of 205 000 to 220 000 lb per sq in. A few tests were made for correlation on specimens of plow steel, with an ultimate strength of 235 000 to 250 000 lb per sq in.

Specimens.—Five specimens constituted a set. Of these, one was a tension specimen, 4 ft 6 in. long, and four were bending specimens, 7 ft long, for

the four sheave sizes. All the ropes were socketed by means of molten zinc in forged steel open sockets, and all the foregoing dimensions were taken from inside to inside of sockets. These sets were numbered as shown in Table 2.

TABLE 2.—PROPERTIES OF TEST SPECIMENS (HEMP CENTER; d_r = 1 INCH)

No. of set	Type	Lay	Forming
(a) 6×7 CONSTRUCTION			
1	Cast steel	Regular	Non-preformed
2	Cast steel	Regular	Preformed
3	Cast steel	Lang	Non-preformed
4	Cast steel	Lang	Preformed
(b) 6×19 CONSTRUCTION (SIX FILLER WIRES)			
9	Cast steel	Regular	Non-preformed
10	Cast steel	Regular	Preformed
11	Cast steel	Lang	Non-preformed
12	Cast steel	Lang	Preformed
13	Plow steel	Regular	Non-preformed

For determining the physical properties of the wires which made up these ropes, tensile tests were made on ten samples of each size of wire entering each construction, both of cast and plow steel. These sizes were as shown in Table 3.

TABLE 3.—SIZES OF WIRES

Construction	Number of wires in one round	Diameter, d, in inches
6×7	One core wire	0.115
	Six outer wires	0.105
6×19	One core wire	0.073
	Six intermediate wires	0.068
	Six filler wires	0.028
	Twelve outer wires	0.065

Observations were taken on these single wire specimens, of proportional limit, ultimate strength, modulus of elasticity, and location of fracture, and an average stress-strain curve was plotted for each size up to about 85% of the ultimate strength. Average values of these observations were used for determining the physical constants of the wire, and the probable error from this mean was noted.

MANUFACTURING PROCESSES

The various manufacturing processes and machines used in the production of wire and wire rope have been rather fully described elsewhere, notably by Messrs. Carstarphen (1) and Meals (1). The process is reduced essentially to three steps: First, the drawing and treating of the wire; second, the spinning of these wires into a strand of the desired size and construction; and, third, the closing of several strands around a hemp or wire rope center to form a wire rope. It is during this last step that the ropes are preformed, if so desired, so that the wires and strands are permanently deformed and lie in the finished rope with no tendency to unravel or kink.

Fig. 3 shows a large vertical closing machine at the point where six strands are drawn through a die over a lubricated hemp center to form a non-preformed, regular lay rope. The frame and die are held stationary, and the slotted cone and spools from which the strands are drawn rotate. In addition, the spools are given a planetary motion so that the strands are laid into the rope without any twist, and their lay is controlled by the speed with which the finished rope is withdrawn. For forming Lang lay rope, the frame is rotated in the reverse direction, and the spools given a back turn to minimize the untwisting effect

The contrast between this method and that used in making preformed ropes is illustrated in Fig. 4. The frame and die are the same, but, in this case, the smooth cone is replaced by one on which are mounted three small sheaves for each strand. These sheaves are placed as shown in Fig. 4 and the strands threaded around them so that a helical permanent set is imparted to them. This set is noticeable in the section of the strands just as they enter the closing die. The proper position of the small sheaves must be determined very exactly in order that the helix will be of the exact size required for forming the desired rope. In preforming Lang lay ropes, these small sheaves are replaced by spiral holes through which the strands are drawn, in order to minimize the twisting action to which this type is subject.

Testing Apparatus

All specimens both in tension and in bending were tested in a 300 000-lb testing machine, which was calibrated to 200 000 lb and found to be correct within 0.25 per cent. For the tension tests, the sockets were passed through the holes in the two heads of the machine and secured by steel plates, in which $1\frac{3}{4}$ - in. holes had been drilled to receive the socket pins. Brass gauge points for the gauge were cut from a section of 1-in. brass pipe, and when properly cleaned with emery paper were soldered to the rope. In all cases except the first test, where six gauge lengths were provided, two gauge lengths were used, directly opposite each other at about the center of the specimen. By exercising proper care in soldering, only one of all the brass gauge points broke away in the course of testing, and the fracture of the rope was never traceable to the heat treatment of wires in the vicinity of the soldering operations. For measuring the twist, two paper scales graduated to 0.02 in., were affixed to one side of the cable, just under each gauge point, by rubber bands, and these scales were read to 0.01 in. on the vertical hair of a surveyor's transit set up on a near-by table. The gauge holes in the brass plugs were also aligned vertically with this transit when drilled.

The operation of attaching the tensometers proved to be the most difficult part of the tension set-up, as the ropes contracted appreciably under load, causing the gauges to become loose. However, after some experimentation, it was found that for regular lay ropes a pair of tensometers could be mounted opposite each other on a standard gauge-holder, and could be held in place

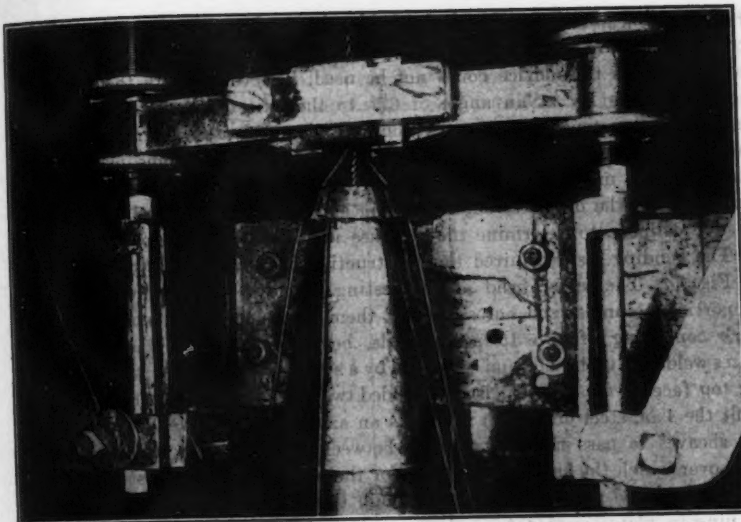

FIG. 3.—WIRE ROPE MACHINE FABRICATING A REGULAR LAY, NON-PREFORMED ROPE.

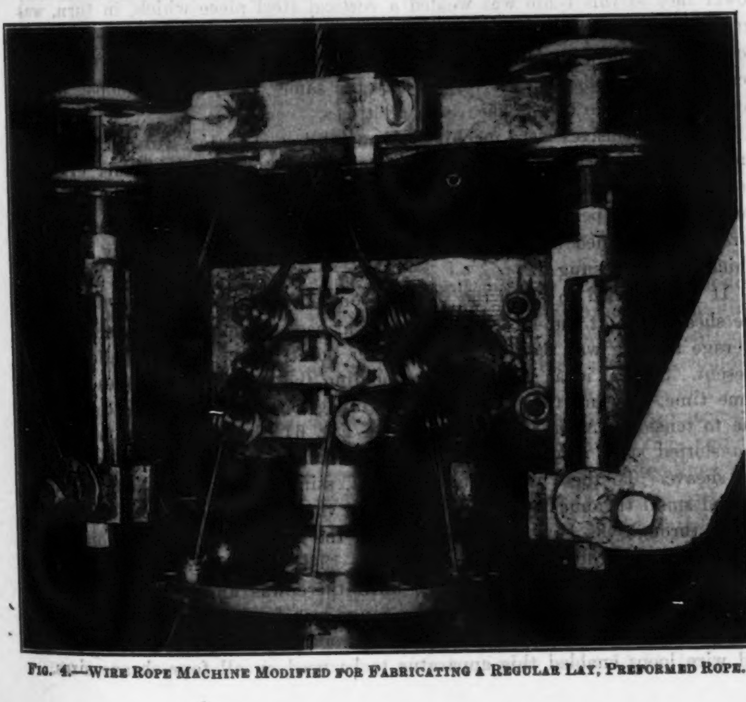

FIG. 4.—WIRE ROPE MACHINE MODIFIED FOR FABRICATING A REGULAR LAY, PREFORMED ROPE.

by connecting the far ends of the holder by a short strong spring. This arrangement gave consistently good readings even at very high loads. For Lang lay ropes this device could not be used, however, due to the fact that the outer wires lay at an angle of 37° to the axis of the cable. For this reason the two tensometers were mounted separately, on fittings especially built to hold the gauges at the required angle and allow some play as this angle changed under load. On many of the tension specimens measurements were taken of the diameter before loading and at nearly full load, with a pair of slide calipers, to determine the decrease in diameter under load.

The bending tests required the construction of a special testing rig shown in Fig. 5. The upper head of the testing machine was removed from its supporting columns, and across two of them was placed diagonally a framework consisting of two 15-in. channels, held vertically in place by $\frac{1}{2}$-in. plates welded to their ends and separated by a slot $2\frac{1}{2}$ in. wide. At the middle of the top face of these channels were welded two semi-circular bearing blocks, cut to fit the 4-in. steel pin which served as an axle for the sheaves. This allowed the sheaves to pass through the slot between the channels, leaving the top half, over which the cable passed, free for the mounting of gauges. The lower ends of the rope passed downward through the slot and the sockets were held by pins in plates welded to a short section of reinforced H-beam. To the lower face of this beam was welded a vertical steel piece which, in turn, was gripped by the jaws of the testing machine. The sheave at all times was free to rotate on its pin and the pin in its bearing-blocks; and from the gauge readings it is believed that very nearly the same stress was developed in the rope on each side of the sheave at all times.

The four sheaves were machined from solid steel plates, 2 in. in thickness, and in accordance with modern practice, as noted by Mr. Meals (7), the grooves were made $1\frac{1}{16}$ in. in diameter, and semi-circular to facilitate measurements on the ropes. A 4-in. hole was cut in the center of each sheave, and carefully machined so that the steel axle could be inserted easily by hand which insured a snug fit.

It was decided to place the four tensometers available, one at the top of the sheave, one at the 45° point, and one at each tangent point, since a good average reading was required at the latter point because of the high stresses present. Several ideas were tried for holding the gauges in place and, at the same time, meeting the problems of shrinkage and sliding along the sheave due to tension. As finally arranged (see Fig. 6), the apparatus consisted of two slotted steel rings which were slipped over the axle on either side of the sheave. To these were attached short, stiff springs, and these, in turn, carried small turnbuckles and wire loops of varying length. Small rods were passed through the holes in the gauges, in the case of regular lay ropes, and slipped through these wire loops (Fig. 6). The gauges were held firmly in place by tightening the turnbuckles until there was an appreciable tension in the springs on either side, and the gauge was free to move slightly along the sheave as the rope stretched. Various combinations of length of springs and wire loops enabled this apparatus to be used on all four sheave sizes.

For the Lang lay ropes the rig used was identical except that special holders of welded construction had to be devised for keeping the gauges fixed at an angle of 37 degrees. Although it was a rather delicate matter to set up the gauges for a test, this apparatus gave consistently good results. In some cases, the gauge could not be set directly at the tangent points, as no strand came to the surface there, and in this case they were set on the

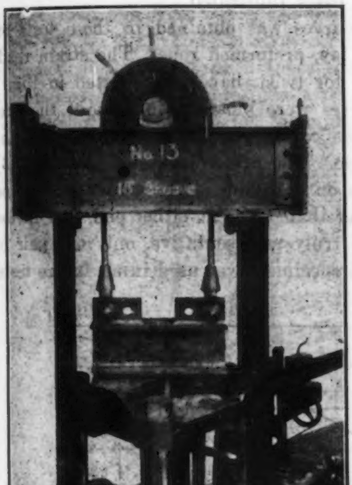

FIG. 5.—TESTING RIG FOR WIRE ROPE SPECIMEN OVER 18-INCH SHEAVE.

FIG. 6.—CLOSE-UP VIEW OF BENDING SPECIMEN, SHOWING MEANS OF ATTACHING TENSOMETERS.

next strand above the tangent point, the stretch causing them to pull down slightly during the test.

On all the regular lay ropes, an attempt was made to evaluate the bending stress by a plain bending test without tension. For this purpose an auxiliary rig was devised, consisting of a steel plate bolted fast in a horizontal position to a heavy table. In this plate were drilled holes into which steel pins could be inserted to simulate sheave diameters of 50, 25, 18, 14, 12, 10, 8½, and 7 in. A space was left clear in the center to allow placing a pair of tensometers on the rope, one on the compression side and one on the tension side, and the rope was bent over these diameters in succession by hand, while readings were taken of the strains that occurred. This apparatus was inherently awkward, and only by averaging a great number of results could any definite trends be established. The rig was not adapted for Lang lay ropes, as the attachments necessary for holding the gauges in place would not fit in the space allowed.

Single wire tests for determining the stress-strain curve were made on a 2 000-lb, hand-power testing machine, with specimens about 15 in. long.

Discussion of Test Data

The great mass of data taken during these tests does not permit the inclusion of all the test results. Accordingly, an attempt has been made to follow through the procedure in one particular typical instance, giving all the results and curves obtained, and to summarize the results in the form of curves for the remaining sets of ropes. Particular exceptions or variations from the typical results are noted and in some cases illustrated.

Tension Tests.—A typical set of curves was obtained in these tests on Set No. 2, a 1-in. 6 × 7 cast, regular lay, preformed rope. The strain readings on the rope as a whole, corrected for twist, have been plotted in Fig. 7 for the seventh loading. Similar curves were plotted for each of the preceding loadings in which the load was carried to only 35 000 lb, and the modulus of elasticity noted in each case. The first rope tested (Set No. 13) was arranged with three gauge lengths on each side. The center set showed values of the modulus about 3% greater than those at either end, and in the belief that this center value was more truly representative, only one pair of gauge lines, located at the center of the specimen, was used in all future tests.

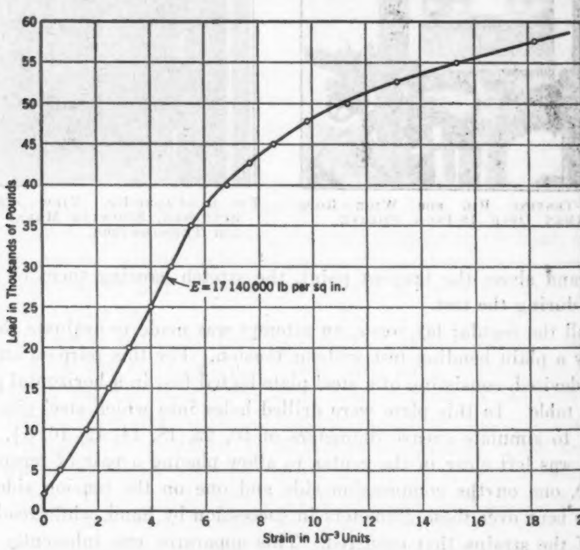

Fig. 7.—Set No. 2: Load Strain Curve of 1-Inch, 6 × 7, Cast-Steel Regular Lay, Preformed Wire Rope; Seventh Loading; Net Area = 0.374 Inch².

The reasons for the initial curvature of the load-strain curve, shown plainly in Fig. 7, are discussed by Messrs. Griffith and Bragg (6). Their conclusion is that at low loads the elongation under stress is not wholly elastic,

due to the presence of initial curvature in the strands and wires from the laying and a certain "slack" or curvature in the rope itself.

Fig. 8 presents curves showing the rise in modulus of elasticity with repeated loadings for all sets of ropes tested (see Table 2). The sharp initial rise in all these curves after the first loading is due to the large initial consolidation of the hemp center, and the compacting of the wires and strands. It will be noted that, in general, the 6 × 7 ropes (Sets Nos. 1 to 4) show values greater than the 6 × 19 construction. Furthermore, the Lang lay ropes (Sets Nos. 3, 4, 11, and 12) show a slightly higher modulus than the regular lay ropes, and the preformed ropes (Sets Nos. 2, 4, 10, and 12) seem to run higher than the non-preformed types. The one plow-steel specimen (Set No. 13) had a slightly higher modulus than its companion cast-steel rope.

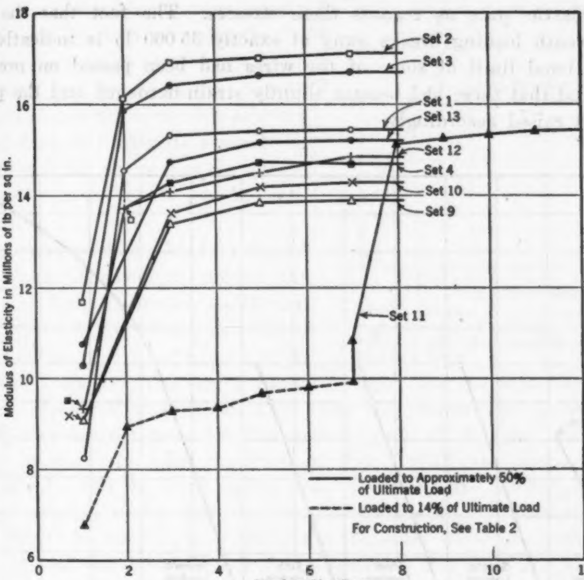

FIG. 8.—VARIATION IN MODULUS OF ELASTICITY OF WIRE ROPES WITH REPEATED LOADINGS.

The 1-in., 6 × 19 cast, Lang lay, non-preformed rope (Set No. 11) was tested for seven loadings to 10 000 lb (14% of the ultimate load), with a view to determining whether the same increase in modulus occurred at working loads as at relatively high loads. The seventh loading was then continued to 35 000 lb, or 49% of the ultimate, which was repeated until the eleventh loading, when the test was carried to destruction. Fig. 8 shows that at working loads a rise in modulus of elasticity does occur, but that the values are

much lower than when the load is increased to about the proportional limit. This is explained by the fact that at these low loads the stress-strain curve was still concave upward. The value selected as the modulus in such cases was the slope of the tangent to the curve at the maximum load. In every case, the slope was less than that found when the load was further increased, indicating quite definitely that the rope had not yet, at the low loads, reached a period of elastic behavior.

For the tension test of Set No. 2, Fig. 9 shows the load-strain curves for the average of two individual wires, as shown by the tensometers, for each loading. On the first loading, both gauges ran off the scale early in the test, but succeeding loadings show the wires to be taking stress in a very uniform manner. It is evident that the first loading tends to redistribute and equalize the stress in the several wires and further loadings bring the rope to an almost perfectly elastic state as regards these stresses. The fact that the curve for the seventh loading breaks away at exactly 35 000 lb is indicative that the proportional limit of some of the wires had been passed on preceding loadings, and that these had become slightly strain-hardened and the proportional limit raised accordingly.

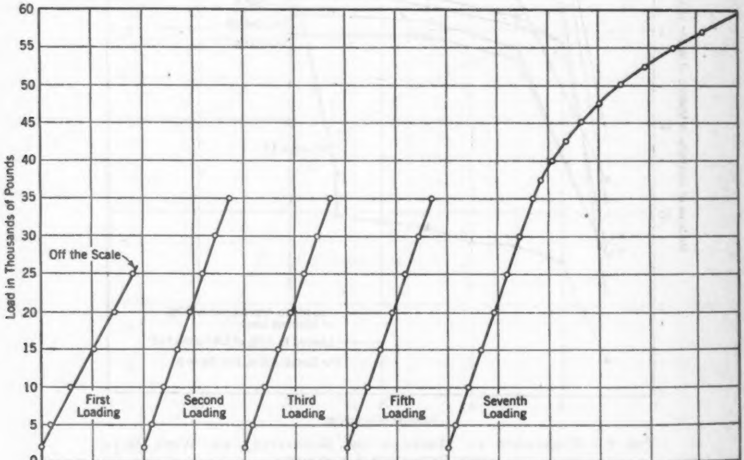

FIG. 9.—TENSION TEST, SET NO. 2; LOAD-STRAIN CURVES OF A SINGLE WIRE; 6 × 7 CAST-STEEL, REGULAR LAY PREFORMED WIRE ROPE.

The strains for the seventh loading (Fig. 9) were transformed into stresses as explained previously by use of a stress-strain curve for the single wire. Fig. 10 shows the stress-strain relations for this particular size of wire, 0.105 in. in diameter, cast steel.

The results of this transformation are expressed in the form of a load-stress curve, as shown in Fig. 11(*a*). It will be noted that up to the proportional limit the curve follows very closely the dotted line representing the load divided by the net area of steel, which is the curve for a homogeneous bar of the same area of cross-section. Beyond this point there is a reverse curve (although this is not present in every case). When extrapolated to a value of the load equal to the observed ultimate load on the rope, this reverse curve shows a stress value of 219 500 lb per sq in., which checks very closely the average single-wire strength for this grade, namely, 219 000 lb per sq in. As always, in extrapolating curves, there is a chance for error, but as every curve showed this ultimate stress to be close to 219 000 lb per sq in., these load-stress curves seem to be well established.

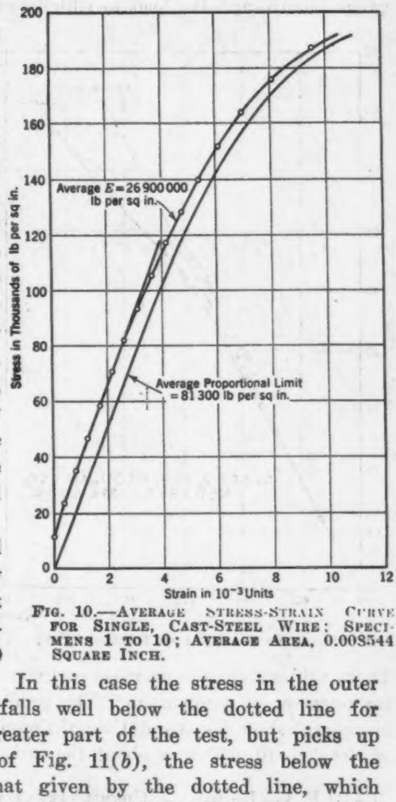

FIG. 10.—AVERAGE STRESS-STRAIN CURVE FOR SINGLE, CAST-STEEL WIRE; SPECIMENS 1 TO 10; AVERAGE AREA, 0.008544 SQUARE INCH.

The curve in Fig. 11(*a*) is typical of all those obtained on regular lay ropes. On Lang lay ropes, a different kind of curve was obtained, as is illustrated by Fig. 11(*b*), for 1-in., 6 × 19 cast-steel, Lang lay, preformed rope. In this case the stress in the outer wires is considerably lessened, and falls well below the dotted line for load divided by net area for the greater part of the test, but picks up rapidly at the end. In the case of Fig. 11(*b*), the stress below the proportional limit is 0.803 times that given by the dotted line, which may be assumed to be that for the regular lay rope. Theoretically, this factor should be cos 37°, or 0.799, since the outer wires are inclined at 37° to the axis of the rope. The average value of this ratio for all the Lang lay ropes tested was 0.783, and this agreement is within the limits of experimental error.

The difference in load-stress curves for the tension tests of preformed and non-preformed ropes is obscured by the incidental variations of each test. There seems to be no appreciable difference in the stress conditions for the two cases when loaded up to seven times, although some tendency for a quicker equalization of stress in the individual wires has been noted for the preformed type. The 6 × 7 ropes show a less steep load-stress curve than those of the 6 × 19 construction, indicating the presence of higher stresses, but this increase is in inverse proportion to the net area of section, and the foregoing facts are modified only in this proportion.

A summary of the untwisting effect observed for every rope is presented in Table 4. The values given are in inches of circumferential twist in a 10-in. gauge length, and the load to which each loading was taken is also recorded.

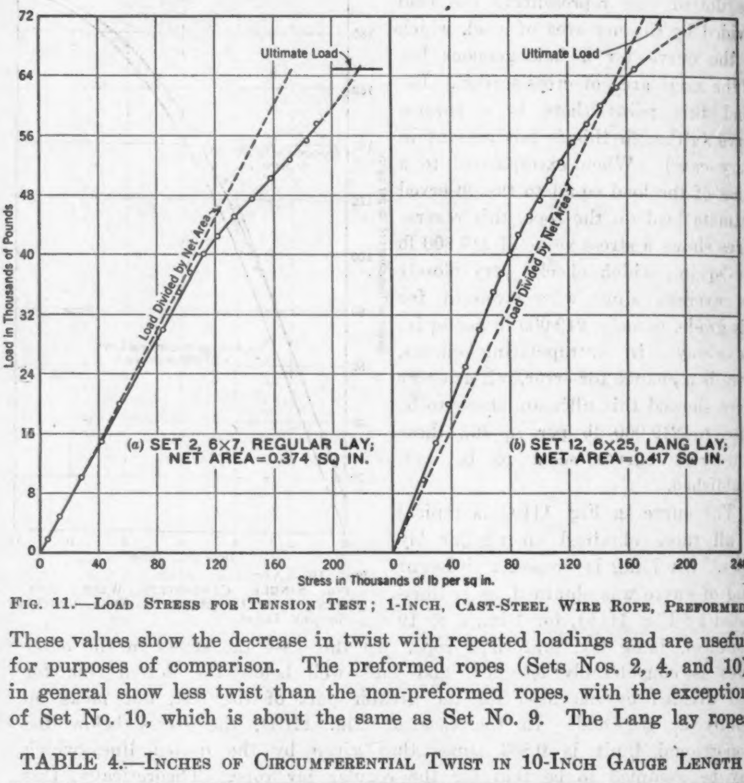

FIG. 11.—LOAD STRESS FOR TENSION TEST; 1-INCH, CAST-STEEL WIRE ROPE, PREFORMED.

These values show the decrease in twist with repeated loadings and are useful for purposes of comparison. The preformed ropes (Sets Nos. 2, 4, and 10) in general show less twist than the non-preformed ropes, with the exception of Set No. 10, which is about the same as Set No. 9. The Lang lay ropes

(Sets Nos. 3, 4, 11, and 12) do not show any greater untwisting than regular lay ropes; in fact, Set No. 12 shows much less twist than its companion specimen, Set. No. 10. It must be remembered, however, that the ends of these specimens were totally fixed against rotation under load, by the frictional forces acting on the heads of the testing machine. Ropes of 6 × 7 construction (Sets Nos. 1, 2, 3, and 4) seem to untwist about as much as those of the 6 × 19 construction.

Data on the shrinkage of wire ropes due to consolidation of the hemp center are available for most of the specimens tested. These data are assembled in Table 5, the diameters being recorded to the nearest 0.01 in., and show that a rope will acquire a permanent decrease in diameter of 1% to 2% when loaded to 50% of its ultimate load, and that the total decrease at fracture is about 5 to 6% of the original diameter.

TABLE 5.—DECREASE IN DIAMETER (INCHES) OF ROPES UNDER LOAD

Set No.	Average original	At beginning of final loading	During Final Loading	
			Load, in pounds	Diameter, in inches
1	1.01	....	60 000	0.96
2	1.02	....	57 500	0.97
3	1.00	0.98	62 500	0.95
4	1.00	0.98	60 000	0.95
9	1.02	....	68 000	0.99
11	1.02	1.01	65 000	0.98
12	1.04	1.02	65 000	0.99

The efficiency of a wire rope in tension is its ultimate load divided by the product of the net area by the ultimate strength of the wire, the denominator being the theoretical maximum load that a homogeneous rod could attain. Values of the efficiencies obtained in these tests are tabulated in the "Summary".

Bending Tests.—Set No. 1 (Table 2), has been selected as typical of the bending test results obtained. Observations were made of the strains at the top of the sheave for the first, third, and fifth loadings, and of the strains at the top, 45° point, and the two tangent points for the seventh loading to destruction. The load-strain curves for these loadings of the specimen bent over the 18-in. sheave, are shown in Fig. 12(*a*); very similar curves were obtained over the other three sheave sizes. The friction effect on stress at the top of the sheave is well illustrated by the curves for the first, third, and fifth loadings. As all the stresses are below the proportional limit, these are also load-stress curves to another scale. Upon release of the load, the stress at the top point remained constant until the friction load caused by stretching the cable decreased to zero, and built up until slipping occurred along the sheave in the reverse direction. Thus, this drop is a measure of twice the frictional force present. According to the foregoing reasoning, the values of strain at the tangent points should follow back the original curve as the load is removed, with no hysteresis, and this has been found to be the case. On practically every one of the Lang lay ropes, an initial compression was observed on the first loading, which is evidently due to poor initial stress distribution inherent in this type of construction.

The transfer of strain values to stresses as described for the tension test was made for the seventh loading of Fig. 12(*a*), giving the set of load-stress curves shown in Fig. 12(*b*). These curves show very definitely that the maxi-

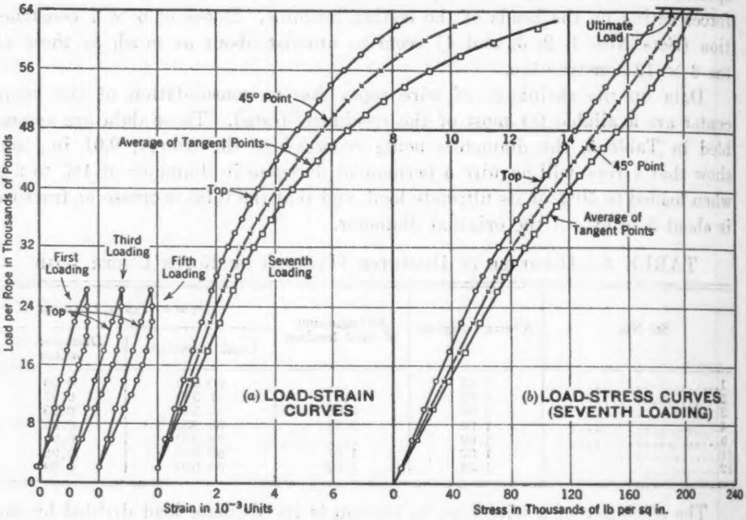

FIG. 12.—SET NO. 1; BENDING TEST OVER 18-INCH SHEAVE.

mum stress lies at the tangent point, where the rope meets the sheave, and that the stress decreases progressively up and around the sheave, due to the increasing frictional forces present, to a minimum value at the top. The coefficient of friction of rope on the sheave was determined in each instance by the formula[4]:

$$\frac{s_g}{s_p} = e^{0.5\pi f} \qquad \text{.......................... (13)}$$

Two values of the stress ratio for each sheave size were taken from the load-stress curves, one at the proportional limit and one near the ultimate load; in most cases these values were in reasonable agreement. The values of f for all four sheave sizes of each set were then averaged, with the results shown in Table 6. The average values for regular lay ropes is about 0.14, and for Lang lay ropes the value is raised to 0.38, due to the fact that the inclined wires on the surface offer much greater resistance to slippage than the wires of regular lay construction, which are parallel to the direction of motion.

In eleven cases out of the thirty-six bending tests, the load-stress curve for the 45° point at the lower loads fell to the left of the curve for the top point, indicating a lower stress to be present. It seems likely that the stresses at the top and at the 45° point for low loads are not very different, and that differences in the individual wires on which the gauges were set account

[4] "Applied Mechanics", by A. P. Poorman, M. Am. Soc. C. E., Second Edition (1932), p. 132.

for this seeming inconsistency. It might be noted that in every case where this occurred, the curves crossed and showed higher stress at the 45° point before the gauges were removed from the rope prior to failure.

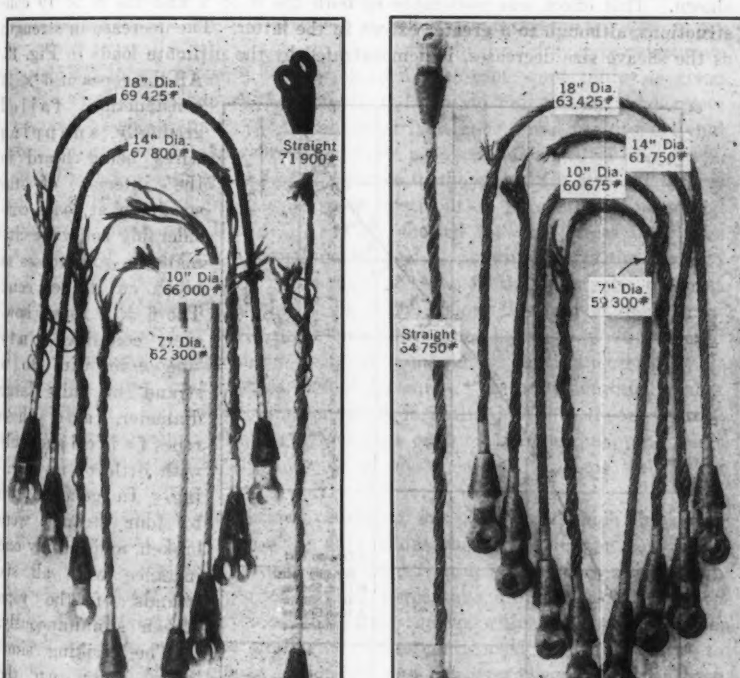
The Lang lay ropes showed load-strain and load-stress curves similar in form to the specimens of regular lay ropes. These curves, as in the tension test, lie to the left of the corresponding curves for regular lay rope, and show



(a) Non-Preformed. (b) Preformed.

Fig. 13.—Typical Failures of Tension and Bending Specimens.

on an average 80% of the stress values. Again, the difference between stress conditions in preformed and non-preformed ropes was not marked after seven loadings, and the 6 × 7 ropes showed stresses higher than the 6 × 19 ropes in inverse proportion to their net areas. The plow-steel specimens showed exactly similar effects, with loads and stresses raised in proportion to the ultimate strengths of the single wires.

The manner in which the bending specimens failed supports the observations drawn from the preceding curves that the greatest stress occurs at the tangent points. With a very few exceptions, all bending specimens failed at one of the tangent points. The only exceptions were those that failed at the socket, which failure occurred for only two specimens of Set No. 12. This fact is demonstrated clearly in Fig. 13, which also illustrates the difference in the type of failure of preformed and non-preformed ropes. Fig. 13(a) shows Set No. 9, non-preformed, while Fig. 13(b) shows Set No. 2, preformed, after fracture of each rope. The scattering of the wires in the non-preformed rope and the relatively little disintegration of the preformed type, are distinctly shown. This effect was noticeable in both the 6 × 7 and the 6 × 19 constructions, although to a greater extent in the latter. The decrease in strength as the sheave size decreases, is demonstrated by the ultimate loads in Fig. 13.

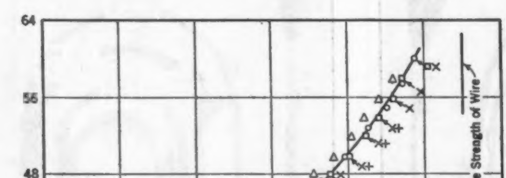


FIG. 14.—COMPOSITE LOAD STRESS CURVE FOR TENSION AND BENDING TESTS, SET NO. 1.

All the ropes of 6 × 19 construction failed gradually, snapping wires being heard in the interior of the specimen at loads considerably below the ultimate, in some cases as much as 10 per cent. The 6 × 7 ropes, however, contained only one core wire to a strand, of quite large diameter, and these ropes failed suddenly with little or no warning. In general, two to four strands were broken, and in only one instance were all six strands of the rope broken simultaneously.

The striking similarity between the curves for stress at the tangent point over all four sheave sizes and the corresponding

curve for the tension test, led to the plotting of these values for Set No. 1 on the same co-ordinates, as shown in Fig. 14. All the curves are seen to coincide within the range of experimental errors, and this was found to be the case for all the ropes tested, although the agreement was not so perfect for the Lang lay ropes. This demonstrates that the bending stress is not increased after the rope is initially bent over the sheave, but that thereafter the rope behaves exactly as in a tension test. Bending over a given sheave, therefore, is equivalent to shifting the curve of Fig. 14 to the right by a constant amount, thus causing the curves to intersect the vertical line representing their ultimate strength at successively lower values of the load as the bending stress increases. This fact served as a basis for a graphical determination of the bending stress, by extrapolating the load-stress curve to the breaking load and subtracting the stress there observed from the known ultimate strength of 219 000 lb per sq in. Although this method is admittedly crude, its accuracy in determining bending stress may be judged from the values recorded in the table on correlation of bending stress formulas, given in the "Summary".

The shape of the load-stress curve in all cases is essentially the same. One would normally expect this to be a straight line for a homogeneous material, but in a composite body, such as a wire rope, opportunity is given for some wires to yield more than others and thus to redistribute the stresses in a strand. An explanation of the observed fact that beyond the proportional limit the outer wires take more than their proportional share of the stress, as shown by the breaking away of the curves to the right of a straight line, is found in a theoretical analysis of stress distribution in a strand, presented by Messrs. Griffith and Bragg (6). They showed that the stress in a wire of a given ring is directly proportional to $\cos^2 a_n$, in which a_n is the angle of lay of the wires in the strand. The ratio of stress in the outer wire to stress in the core wire, therefore, should be 0.899, below the proportional limit. When the inner wire or wires reach this point, they begin to yield first, and this ratio will rise, approaching unity as a maximum, until theoretically at fracture the stress in all wires should be equal. Actually, certain weaker inner wires will fail before this condition is realized. This theory is supported by the experimental observations that on 6 × 19 ropes snapping wires were invariably heard in the interior of the specimen at loads well below the ultimate.

For illustration an exaggerated condition was chosen, in which the strain in the outer wire was assumed as 0.74 times the strain in the core wire. Proper values of the stress were then selected from a typical wire stress-strain diagram, and these were plotted against percentage of total load, as shown in Fig. 15, together with the average stress curve, which is a straight line, as would be expected. The similarity of the curve marked "Outer Wire" to the observed load-stress curves is notable, and for comparison there has been included on this plot the results of the tension test of the 1-in., 6 × 19 cast-steel, regular lay, preformed specimen. It is evident that the assumption that the outer wire takes 74% of the stress in the core wire, below the proportional limit, was none too extreme.

The results of the plain bending test without tension, in which the regular lay ropes were bent by hand over steel pins, are represented typically by Fig. 16, for 1-in., cast-steel, non-preformed ropes of 6 × 7 and 6 × 19 construction. Each point is the average of two readings on each of four ropes, a total of eight readings. These curves are interesting in that they show

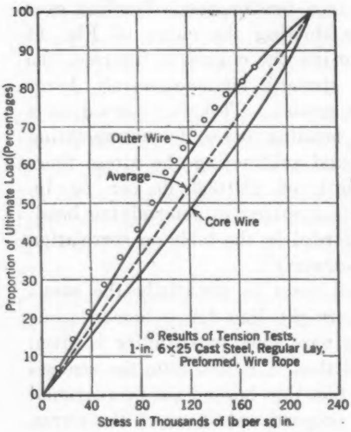

FIG. 15.—THEORETICAL STRESS DISTRIBUTION IN A STRAND (STRAIN IN OUTER WIRE = 0.74 STRAIN IN CORE WIRE.)

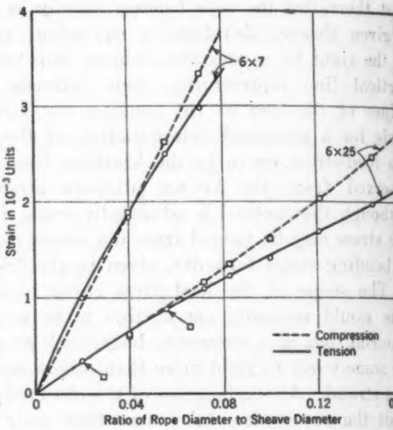

FIG. 16.—STRAIN SET UP BY PLAIN BENDING WITHOUT TENSION; 1-INCH CAST-STEEL REGULAR, NON-PREFORMED WIRE ROPE.

that the stress on both the tension and the compression sides of the rope increases nearly linearly with the ratio of rope diameter to sheave diameter at the root. Although in every case the compressive stress exceeds the tensile stress, this is of little importance, as the addition of direct stress in the form of a pull will decrease this stress and soon bring these wires into tension as well. When these strains are transformed into stresses, another value is obtained for the bending stress, and these results have also been listed in tabular form in the "Summary". The values for the 6 × 7 ropes were much higher than those for the 6 × 19 construction, and the method broke down completely for these values. However, the trend is notable, and, as will be shown subsequently, the loss of strength of a rope varies in exactly this manner with the ratio of rope diameter to sheave diameter.

A summary is presented in Fig. 17 of the loss in strength in bending plotted against the ratio of rope diameter to sheave diameter for every set of ropes tested. A curve presented by Mr. A. S. Rairden (1) for tests on $\frac{5}{8}$-in. 6 × 19 plow-steel, regular lay, non-preformed ropes, is also included with the reciprocal of his ordinate scale used in this case. It is believed that by inverting this ratio (thus converting a hyperbolic curve into a straight line), the curve may be fitted much more easily to a number of fairly erratic points, as the origin is fixed and only one degree of freedom is allowed in locating the curve. The curved relationship shown for some of the sets may very well

be due to an inaccurate value for the tension test, which affects all the points, and is equivalent to shifting the curve up or down. Such a shift has been made in the case of Set No. 11, where the tension specimen failed at the socket at a load of 71 650 lb, without developing its full strength. This load was so low as to indicate an actual increase in strength over the 18-in. and

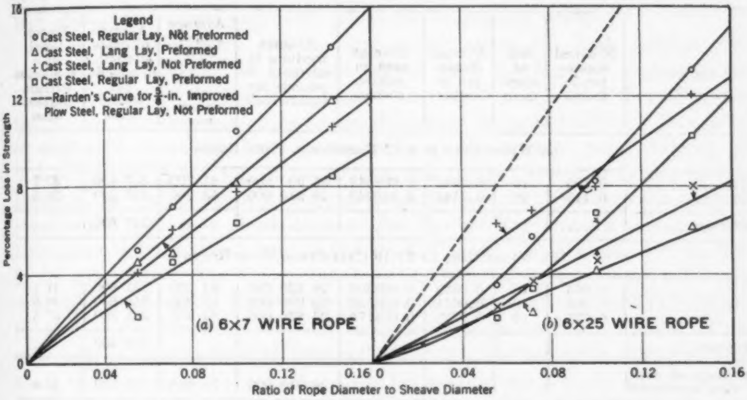

FIG. 17.—LOSS IN STRENGTH OF WIRE ROPES IN BENDING.

the 14-in. sheaves, and in view of the relationships amply demonstrated in the other ropes, the value has been raised to 75 000 lb by shifting the straight line to pass through the origin, and the loss in strength computed on this basis. The short arrows on this plot serve merely to identify each point with its proper curve, and do not indicate that the point itself has been moved.

It may readily be seen that the non-preformed ropes show a greater loss in strength in every case than the preformed types. Similarly, in all but one instance, the Lang lay ropes show less loss in strength than their corresponding specimens of regular lay, due to the lower bending stresses present. There seems to be very little difference between the results for the 6 × 7 and 6 × 19 constructions and for the cast and plow grades of steel, when the loss is considered on a percentage basis. Considerably more data are needed, however, before any definite conclusions can be reached on these points.

A third method used in determining the bending stress in the rope is to divide the loss in strength by the product of net area and efficiency in tension, the denominator being the effective net area resisting bending. The results are shown in the "Summary".

Single-Wire Test Data.—A summary of test data on the various specimens of single wire tested is given in Table 7. On the basis of these results, an average ultimate strength of cast steel used in these ropes was selected as 219 000 lb per sq in., and for plow steel as 246 500 lb per sq in. A modulus of elasticity of 26 500 000 lb per sq in. was selected as characteristic of both the cast-steel and plow-steel specimens. Fig. 10 is an example of the average stress-strain relation for the ten samples of cast-steel wire 0.105 in. in

diameter. As an example of the consistency of these data, for the plow-steel specimens, all had ultimate strengths within 3.2% of the average value, whereas 95% had values of modulus of elasticity within 7% of the average. The cast steel showed similar consistency with minor exceptions, notably the

modulus values for the specimens 0.115 in. in diameter. Although the diameters of all test specimens were measured to 0.0001 in., the nominal diameters were used in computing net areas in all further calculations, on the basis that they represented an average condition of manufacture.

SIGNIFICANCE OF RESULTS

The most significant results of the tension tests on the various wire ropes studied are contained in the plots for increase in the modulus of elasticity of the rope as a whole with repeated loadings. In the past a value of 12 000 000 lb per sq in. has often been considered the maximum modulus that a wire rope would attain, and this value has frequently been termed conservative when used in bending stress formulas. From the data presented herein it may be noted that one excessive loading up to about 50% of the ultimate load will raise the modulus frequently greater than 14 000 000 lb per sq in., and even with working loads as low as 14% of the ultimate, a definite increase in modulus occurs, although it is probable that the value would never reach as high a figure as when overloaded once. For running ropes, it is considered

desirable to have a fairly low modulus, so that the rope can "give" and absorb some of the shocks of sudden starting, whereas for stationary installations the reverse is true. In the case of suspender cables and guy-work for which accurate lengths are needed, the value of several pre-stressings to a fairly high load may be seen very plainly. This procedure has been followed in the past, and values for the modulus greater than 19 000 000 lb per sq in. have been obtained on large suspender cables for suspension bridges.

Of equal significance are the load-stress curves for both tension and bending over sheaves. It has been shown that the bending stress is not increased after the rope is once bent over a sheave. and that thereafter the rope at the tangent point behaves as if it were in pure tension. The point of maximum stress has been shown to be at the tangent point, falling off to a minimum at the top of the sheave due to the frictional forces acting. Probably the true point of maximum stress is just slightly above the tangent point, since it takes a short distance for the bending stresses to come into action and the frictional loss is low at this point. The stress distribution in the strand itself has been pointed out, and indications are that the inner wires take considerably higher stresses than the outer wires at ordinary working loads. The beneficial effect of Lang lay rope in reducing stresses in the wires both in tension and in bending is notable, the reduction being proportional to the cosine of the angle which the surface wires make with the axis of the rope, in this case, 37 degrees. A disadvantage of this type of cable, however, lies in its greater tendency to kink and untwist, and the ends should always be rigidly fixed against rotation.

None of the formulas dealing with wire ropes takes preforming into account. It is significant that for the ropes tested the summary of ultimate loads which follows shows that the preformed ropes are about 4% to 5% weaker in straight tension due to the process of manufacture. However, they are shown to develop less loss of strength due to bending, in some instances by quite appreciable amounts. The initial stress distribution among the individual wires of a preformed rope does not seem to be greatly improved over a non-preformed rope, but there is some tendency for re-adjustment and equalization of stress to occur more quickly in a preformed specimen. The modulus of elasticity of the preformed ropes seems to run slightly higher than that of the non-preformed types. The chief advantages to the use of preformed ropes seems to be the case in handling, cutting, and splicing them, the elimination of kinking to a large extent, and the manner in which they tend to remain closed when several wires are broken rather than bristling with jagged ends.

The curves for loss of strength over sheaves are of primary importance, and a new and simpler method of plotting these curves has been shown. The various features of these curves have been discussed previously, but it is worth noting here that Mr. Rairden's (1) curve based on tests of $\frac{5}{8}$-in. wire ropes does not agree with the results herein obtained, although a ratio of the diameters has been used. This leads to the speculation that possibly the ratio of rope to sheave diameter may not be the proper one to use in such a

plot, and indicates the need of further experimentation on ropes of different diameters to discover whether results on one diameter can be transformed to another diameter by a simple ratio.

Summary

Three tables are presented to summarize the wire-rope test results and the formulas with which they were compared. The first, Table 8, presents seven bending-stress formulas, and observed values obtained in most cases by three

different methods, as explained previously. Values that are underlined exceed the ultimate strength of the wire, even with no tensile load applied. The second, Table 9, summarizes the observed values of ultimate load and efficiency in tension as well as those predicted by the three formulas. The third, Table 10, presents similar predicted values of the ultimate load in bending over each of the four sheave sizes by two formulas, and the observed values for comparison.

* Using $C = 0.85$ for 6×19 cast-steel ropes.

† Values should be 75 000 lb and 82.1% efficient as explained in test.

Which of the three observed values of bending stress is the most nearly correct is a doubtful question. From the foregoing discussion, the limitations of the plain bending test without tension and the method of extrapolating the load-stress curve to the breaking point are apparent, and the most logical method seems to be the first one presented in Table 8 Column (9)—that of

TABLE 10.—SUMMARY OF PREDICTED AND OBSERVED VALUES OF ULTIMATE LOAD IN BENDING OVER SHEAVES

* In which $s = \dfrac{E_r\, d}{D + d_r}$.   † Fractured at socket.

dividing the loss of strength by the product of net area and efficiency in tension. Either on this basis or by striking an average of all three methods. one must exclude all the formulas except Equation (8) as giving values too conservative for use on stationary ropes. Although Equation (8) frequently does not come very close to the observed values, in view of the doubt as to

the accuracy of these latter values, the discrepancy is not nearly as large as for any of the other formulas, and Equation (8), although unwieldy, gives results most comparable with the test data.

For the tension test predictions (Table 9), Equation (11) is admittedly based on minimum values, which are low. Equation (10) gives values that are in most cases slightly too high, whereas Equation (12) fits the test data very well on the average. According to this latter formula, all the ropes tested should show efficiencies of 79.9%, whereas the average for the seven ropes was 80.6 per cent. One factor, however, which the equation does not take into account is the slight loss of strength due to preforming.

Ultimate loads in bending could be predicted for any of the formulas listed in Table 8, but the last two only have been selected as giving possibly reasonable values. Mr. Meals states (1) that for his formula (a modification of Mr. Leffler's formula), the error is a maximum for the lower ratios of $\frac{D}{d_r}$. This statement is fully confirmed and values of ultimate load over the 7-in. sheave are far too low, in two cases even being a minus quantity. For large-sized sheaves as recommended in modern practice, Equation (10) tends to approach the observed values, but is consistently conservative. Equation (12), from which the expression for bending stress was derived, might be expected to give equally good predictions for strength, and observation will disclose that predictions based on this formula vary from the observed values in no case by more than 14%, in this case on the safe side. The average error on the unsafe side in only 2.5% and on the safe side, 4.5 per cent.

It should be remarked that all the formulas that have been found herein to vary from the observed data, have varied on the safe side, and that those which best fit the data vary sometimes on the safe side, but almost as often on the unsafe side, although the percentage error is very small in comparison with all the other formulas. Undoubtedly, velocity and reverse bending affect the ultimate load and the bending stress adversely, and until more tests are made of wire rope in motion under load, it is preferable on such installations to err on the safe side in stress computations.

Conclusions

From a study of the data obtained in this investigation, the following conclusions have been drawn, applying to stationary wire ropes with hemp centers in tension and in bending over sheaves:

(1) The modulus of elasticity of a rope as a whole was increased about 50% by one loading to 50% of the ultimate load, and continued to rise slowly upon further repetitions of the load. Even for ordinary working loads such a rise took place, but the values for modulus were only from 60 to 70% of the values when overloaded by pre-stressing.

(2) For tension tests of regular lay ropes below the proportional limit of the wires, the stress in the outer wires coincided very closely with that obtained by dividing the load by the net area of cross-section.

(3) The variation in stress with load for ropes bent over sheaves was exactly the same as for the same ropes in tension, except that a definite

bending stress, the magnitude of which depended on the sheave size, was added at the time of bending, and this did not vary as the load increased.

(4) The maximum stress in a wire rope bent over a sheave occurred at or immediately above the point of tangency to the sheave, and the rope might be expected to fracture at this point. The minimum stress in the rope occurred at the top of the sheave.

(5) Initial fracture in ropes of 6 × 19 construction, and probably also in the case of those of 6 × 7 construction occurred in the interior wires of the strands, the stress in the core wire being always greater than that in the outer wires up to the point of initial fracture.

(6) The percentage loss of strength of a rope bent over a sheave varied linearly with the ratio of rope diameter to sheave diameter at the root.

(7) The coefficient of friction of a regular lay rope on a steel sheave was roughly 0.14, and of a Lang lay rope, roughly, 0.38.

(8) The stresses in the outer wires of a Lang lay rope were reduced in proportion to the cosine of the angle of inclination with the axis of the rope, a reduction of very nearly 20% for ordinary construction.

(9) A preformed rope showed less loss of strength in bending over sheaves, but also about 5% lower tensile strength and efficiency than a non-preformed rope.

(10) The most satisfactory formulas found for the prediction of bending stress, tensile strength, and loss of strength due to bending, were those presented by Mr. Carstarphen (1).

Acknowledgments

The testing program was conducted as a co-operative investigation with the Wickwire Spencer Steel Company, which Company furnished all the wire ropes tested and fitted the sockets. The tests were made in the Fritz Engineering Laboratory of Lehigh University, at Bethlehem, Pa., between November 1934, and May, 1935. The writer is indebted to Messrs. A. S. Rairden and Carl King, of the Wickwire Spencer Steel Company, for their valuable aid and suggestions, and to Inge Lyse, M. Am. Soc. C. E., Research Associate Professor of Engineering Materials, for his aid in supervising the tests and interpreting the results. Acknowledgment is also made to the members of the Laboratory Research Staff who have assisted materially in the conducting of these tests. A number of the illustrations used have been loaned by Mr. Rairden.

APPENDIX I

Notation

The symbols used in this paper are defined as follows:

a = angle that a helical wire makes with the axis of the strand; a_i = Angle a of the wires in the ith layer; a_n = angle of lay of Wire No. n;

b = angle that a strand makes with the axis of the rope;
d = diameter of a wire in a rope; d_r = diameter of a wire rope;
e = base of Naperian logarithms;
f = coefficient of friction;
g = a subscript denoting "at the point of tangency";
i = a subscript denoting the ith layer of strands in a rope;
l = a subscript denoting "layers";
n = number; n_s = number of strands in a rope; n_w = number of wires in a given diameter in the ith layer; n_l = number of layers of wires in a strand; as a subscript, n denotes "number";
p = a subscript denoting "at the top";
r = radius of a wire in a rope; r_s = radius from the center of the strand to the center of the wire in question; r_r = radius from the center of a wire rope to the center wire of a strand; as a subscript, r denotes "rope";
s = unit bending stress; as a subscript, s denotes "strand";
t = ultimate unit tensile strength of a wire; as a subscript, t denotes "tension";
w = a subscript denoting "wire";
A = area of a wire rope;
C = a constant representing a relation between the total tension on a wire rope, and its diameter, for various constructions;
D = diameter of sheave;
E = modulus of elasticity of a wire in a rope; E_r = modulus of elasticity of a wire rope;
G = modulus of rigidity in a rope $= \frac{E}{2}(1 + \mu)$;
P = loss of strength in a wire due to bending;
R = radius of a sheave $= \frac{1}{2}(D + d_r)$;
S = ultimate strength of a wire rope in bending; S_i = strength of a wire in the ith layer; S_t = strength of a wire rope in tension; S_w = ultimate strength of a wire;
α = angle between the perpendicular to the axis of a rope and the tangent to the center line of a wire;
ϵ = efficiency of a rope in plain tension;
μ = Poisson's ratio.

DISCUSSION

C. D. MEALS,[5] ASSOC. M. AM. SOC. C. E. (by letter).—Another "link in the chain" has been wrought by Mr. Stewart in his splendid paper pertaining to the strength of stationary wire ropes looped over sheaves. Of the bending stress formulas, Equations (1) to (7) inclusive, it may be noted that Chapman's (5)[3] formula antedated Hardesty's (2)[3] formula; the former was published in 1908 and the latter in 1918; consequently, it should not be implied that Chapman modified Equation (3).

Equation (5) was developed by Josef Hrabak[6] and published in 1902. Hrabak's writings on the subject are frequently ignored, and yet he presented the first logical theory on the subject as compared to the Reuleaux formula in vogue in 1902. Howe's formula, Equation (6), was first published in 1907, although credit is generally given to his 1918 paper (2)[3]. The years 1902 to 1918 saw the publication of many formulas for the calculation of bending stresses in operating wire ropes, and there may have been some justification for the consideration given the subject, as ropes did break before being worn appreciably, which was considered as indicative of abnormal bending stresses.

With the present knowledge of designing wire ropes, it is appreciated that improper proportioning of the wires lead to their premature breaking. If less time had been spent on bending stress theories and more time devoted to the engineering design of the rope, the troubles experienced would have been greatly eliminated.

In discussing bending stresses in wire rope, the author of an article[7] published in 1930, noted that "the intensity of stress due to bending varies inversely as the radius of curvature; consideration of this fundamental fact leads to the conclusion that the wires in contact with the sheave or drum, *i. e.*, those bent to the least radius of curvature, are subjected to the greatest bending stress." An extensive experience in testing moving wire ropes, under load, over one sheave and under another sheave, subjecting the rope to a reverse bending, has verified the foregoing statement.

In a discussion of Leffler's paper (3)[3], the writer noted that "the maximum bending stress [in an operating wire rope] is not necessarily in the outer wires of the strand farthermost from the axis of the rope." With some types of wire ropes and under certain conditions of loading and operation, however, the outer wires of the strand break next to the manila center of the rope where they are not susceptible to inspection.

For the determination of the strength of a wire rope bent over a sheave and subject to a static load, in a recent paper[8], the writer modified Equa-

tion (9) as follows,

$$S = k_1 A \epsilon \left\{ t - \frac{E_r D}{D + d_r} \right\} \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

in which k_1 is a correction factor with the following values:

$\frac{D}{d_r}$	k_1	$\frac{D}{d_r}$	k_1
3	1.150	8	1.080
4	1.135	10	1.055
5	1.120	12	1.03
6	1.105	14	1.00
7	1.095		

and E_r is the modulus of elasticity of the rope as manufactured and as determined by the first run loading on it, the load not to exceed 30% of the strength of the rope.

The use of Equation (14) will increase the values given in Table 10, under the heading, "Equation (9)", and using the first-run modulus values given in Fig. 8. The changes in tabular values are given separately in

TABLE 11.—STRENGTHS OF ROPES BENT OVER SHEAVES

Set No.	Equation (14)			
	Sheave Diameters, in Inches			
	18	14	10	7
1	53 600	49 800	45 600	37 200
2	47 600	42 200	34 800	21 700
3	50 200	45 500	39 450	28 450
4	51 700	47 400	42 200	32 300
9	66 600	63 700	61 900	56 400
10	66 600	63 700	61 900	56 400
11	65 700	62 500	60 100	53 800
12	66 300	63 300	61 200	55 500
13	74 400	70 800	68 400	61 700

Table 11. These values show an appreciable advance compared with the data given in Table 10 for Equation (9); if the loadings on the ropes had not been so abnormally high, lower first-run moduli would have resulted, with a corresponding increase in the values of Table 11.

It should be appreciated that Equation (14) is only an approximation, and yet it gives values quite closely in accord with the results of Skillman's (9)[3] and Rairden's (1)[3] series of tests and also with the test results of many 6 × 19 and 6 × 37, steel-center, suspender ropes as used on recent suspension bridges; although, as indicated previously, it is not in as close agreement with Mr. Stewart's test results.

For 6 × 19 ropes with manila centers, the efficiencies of the ropes reported by Mr. Stewart are higher than those of Skillman's (9)[3] tests for 6 × 19 Warrington plow-steel ropes and of Rairden's (1)[3] tests of 6 × 19 filler-wire improved plow-steel ropes, and it appears from a comparison of these three series of tests that the efficiencies may vary for the different types and grades of 6 × 19 ropes and even for ropes of the same type as made by the different

manufacturers; consequently, too much reliance must not be placed on any particular formula until more tests are conducted to verify their accuracy, although no brief is being held for Equation (14) as the writer appreciates its limitations.

Equation (10) has been used for a number of years to determine the strengths of special wire ropes and has found to be more accurate than is indicated in Table 9. To verify this statement, tests were made of $\frac{7}{8}$-in. and 1-in. ropes with manila centers, the data pertaining to the ropes being noted in Table 12, and the results of these tests in Table 13.

TABLE 12.—Description of $\frac{7}{8}$-Inch and 1-Inch Wire Ropes

Set No.	Description of ropes	Metallic area, in square inches	Angles: a	Angles: a_s	Angles: b
14	$\frac{7}{8}$-in., 6 × 7 Lang lay plow-steel, non-preformed	0.31975	14° 15′	12° 13′	15° 13′
15	1-in., 6 × 9 filler-wire regular lay cast-steel, non-preformed	0.41268	17° 28′	14° 4′	18° 50′
16	1-in., 6 × 19 filler-wire regular lay plow-steel, non-preformed	0.41268	17° 28′	14° 4′	18° 50′
17	1-in., 6 × 19 filler-wire regular lay plow-steel, preformed	0.41268	16° 44′	13° 28′	19° 10′

The ropes were tested by the Ontario Department of Mines, in Toronto, Ont., Canada, and the individual wires of the ropes were check-tested by the Steel Company of Canada, Limited, at Hamilton, Ont. It will be seen from Table 13 that Equation (10) does agree quite closely with test values, and it is difficult to reconcile these efficiencies with those noted by Mr. Stewart in Table 9.

TABLE 13.—Actual and Calculated Breaking Strengths and Efficiencies of Wire Ropes

Set No.	Actual Tests: Load, in pounds	Actual Tests: Efficiency (percentage)	Equation (10): Load, in pounds	Equation (10): Efficiency (percentage)	Equation (12): Load, in pounds	Equation (12): Efficiency (percentage)	Equation (16): Load, in pounds	Equation (16): Efficiency (percentage)
14	66 050	90.2	65 300	89.1	63 750	87.1	65 000	88.8
15	67 285	85.6	67 500	86.0	63 300	80.6	66 000	84.0
16	83 425	85.4	83 700	85.7	78 800	80.6	82 000	84.0
17	81 225	85.9	81 900	86.6	76 600	81.0	79 600	84.2

One criticism of Equation (12) is that it does not take into consideration the difference in the angles of lay of the various wires in a strand. For example, it will give the same efficiency for a 6 × 19 two-operation strand, a strand having 12 wires laid over 7, as for a 6 × 19 one-operation strand rope as a filler-wire construction; and yet it must be obvious that the efficiency of the latter is greater than that of the former construction. Equation (10) makes this differentiation, whereas Equation (12) does not; also, the latter part of Equation (10) will give the breaking strength of the individual strands of the rope quite accurately.

Equation (12) may be modified to take into consideration the varying lays of wires in the strand by taking a as the average angle of lay of all the wires in the strand, or $a_a = \sum \frac{na}{n}$, which, for a 19-filler wire strand, becomes,

$$a_a = \frac{6\,a_1 + 6\,a_2 + 12\,a_3}{25} \qquad \text{(15)}$$

and, accordingly, Equation (12) may be written:

$$S = A\,S_w \cos\,(a_a + b) \qquad \text{(16)}$$

Values in accordance with Equation (16) are noted in Table 13.

It is regrettable that certain pitfalls were not avoided in Mr. Stewart's tests inasmuch as they detract somewhat from the value of the paper. Among others, four may be noted, as follows: (*a*) Loadings at 49% of the rope strength for the determination of the modulus of elasticity values; (*b*) a decidedly short gauge length of 10 in. for the measurement of the stretch of the rope under load; (*c*) the use of fixed clamps on the rope; and (*d*) the adoption of ropes with manila centers.

(a).—Loadings at 49% of the Rope Strength for the Determination of the Modulus of Elasticity Values.—Most certainly this is an abnormally high loading and not representative of any engineering or commercial practice pertaining to wire rope; lower loadings are more in keeping with actual practice and would result in lower modulus values. Such abnormally high loads result in a permanent breaking down of the structure of the manila center, nicking of strand against strand, and a high modulus value that is unreal in so far as standard practice is concerned.

(b).—A Decidedly Short Gauge Length of 10 Inches for the Measurement of the Stretch of the Rope Under Load.—It has been general practice in modulus tests of wire ropes, to use a gauge length as long as possible; Skillman (9)[8] used a gauge length of 50 in., and for most of the suspender ropes as used on the large suspension bridges built in recent years, the gauge length has been 80 in. The merit of the longer gauge length is that any irregularities or errors in measurements or in the behavior of the rope are not proportionately of much consequence as they must be in the shorter gauge lengths; those experienced in such testing will appreciate this point.

(c).—The Use of Fixed Clamps on the Rope.—Special swivel clamps have been used that are free to swivel or rotate, and, consequently, to eliminate any twisting of the measuring apparatus due to the untwisting of the rope.

(d).—The Adoption of Ropes with Manila Centers.—That such ropes are used to avoid confusion in the mathematical analyses is appreciated, but they are not as typical as those with an independent wire-rope center (IWRC); particularly for the consideration of the loss in strength due to bending, as this applies to suspender ropes for suspension bridges and such ropes are always made with an independent wire rope center.

It is a fact fairly well known to wire-rope engineers, that the tensile strengths of preformed wire ropes are from 3 to 5% lower than the strengths

of non-preformed ropes, but sales policies have conveniently "glossed over" this fact. For the preforming of Lang lay wire ropes, the use of quills as described by Mr. Stewart is not necessary, as the roller head shown in Fig. 4 may be used; in fact, roller heads only are used in the making of all types and diameters of preformed Lang lay wire ropes by the writer's Company.

Relative to the coefficients of friction given in Table 6, it is presumed that these are for ropes that were dry—that is, devoid of any heavy lubricant. Mr. William Hewitt published data[9] pertaining to this subject in 1905, and it may be interesting to compare his values with those of the author.

That the bending stress in a Lang lay rope is approximately 20% less than that in a regular lay rope verifies a statement that the writer[10] made in 1928 regarding such ropes.

Mr. Stewart shows the same confusion as did Carstarphen and Rairden in the paper cited (1)[8] in considering that the loss of strength of a stationary wire rope looped over a sheave is the same as the bending stress in a moving wire rope operating over a sheave; the former is more susceptible of mathematical analyses than the latter. Reasons and examples were cited by the writer in his discussion of Carstarphen's paper (1)[8] to indicate that the latter was not susceptible to such an analysis and surely not to the extent that a "prediction of the bending stress" could be satisfactorily assured, as noted in Conclusion (10) of the paper. It would be a boon to the wire-rope users as well as to the manufacturers if such a prediction was possible.

G. P. Boomsliter,[11] M. Am. Soc. C. E. (by letter).—In calling attention to the increase in the modulus of elasticity of a wire rope under successive applications of load, Mr. Stewart has rendered a valuable service. A value of E of 18 000 000 lb per sq in. is not too great. As the author has shown, this value is perhaps high for repetitions of load under the proportional limit but, at some time or other during their period of use, most hoisting ropes are stressed beyond the calculated load. The writer is reminded of two such cases in his brief experience with wire ropes.

In one case a mine cage was customarily left all night at the bottom of a 250-ft shaft down which came the fresh air draft to a mine. One cold night the cage froze fast to the floor. It was finally pulled loose by stressing the hoisting rope, but the rope was 8 ft longer after pulling it loose than it was before. In another case, the circuit breaker on a hoist went out as a load of coal was being lifted in a shaft. A telemeter attached to the hoisting rope immediately above the cage showed that the action of the safety devices in stopping the cage caused stresses which were 2.29 times the dead load stresses. Many other conditions result in occasional applications of high stress to a rope so that after a short period of service its modulus of elasticity has been increased beyond that of a new rope. Indeed, calculations made in the telemeter test referred to, indicated a modulus of elasticity for the rope there tested of between 19 000 000 and 20 000 000 lb per sq in.

[11] Prof. of Mechanics, West Virginia Univ., Morgantown, W. Va.

Mr. Stewart deserves congratulations for his clever method of attaching the tensometers to his wire rope when it was bent about a sheave. He has pointed the way for further investigations of bending stress in wire rope. However, the results of bending tests such as those of this paper are likely to be misleading. Undoubtedly, they determine the stresses due to bending a wire rope about a thimble, or in a stationary rope bent over a sheave while in an unstressed condition, since there is no constraint as the wires adjust themselves to the curved position about the sheave, but a heavily loaded rope running over a sheave will have other stresses which the author has not considered. These stresses are due to the frictional resistance to sliding of the wires upon each other when the loaded straight rope bends about the sheave. To illustrate, consider an axial load of 30 000 lb on one of Mr. Stewart's 1-in. ropes of regular lay as it passes over a sheave. Each strand of 19 wires will be assumed to take one-sixth of the load, or 5 000 lb.

The lay length of the strand will be taken as 93 d and d as $\frac{d_r}{15}$, in which d_r = the diameter of the rope; and d the diameter of the individual wires. The lay length will then be $\frac{93}{15}$, or 6.2 in. and the length of half a lay will be 3.1 in. The lay angle is 18° 39′. The component of stress in a strand normal to the axis is 5 000 tan 18° 39′ = 1 688 lb.

Let Fig. 18(b) represent a half lay length of the strand. Fig. 18(a) shows the components of the stresses at the two ends of the length which are normal to the strand length. These components are held in equilibrium by pressures of the other strands, assumed normal to the strand in question. By analogy with the pressures and tensions in a cylindrical vessel, the total lateral pressure in a length of a half lay will be 2 × 1 688 = 3 375 lb. Now, assume that the lower end of this length is in contact with the sheave. The upper end will be at the outside of the rope. The part in contact with the sheave will shorten and the part at the outside of the rope will lengthen. This is

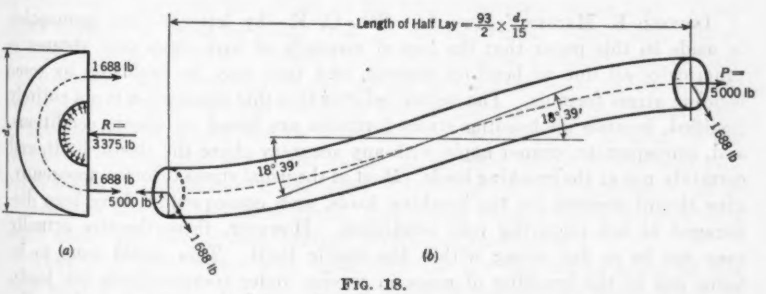

FIG. 18.

done by the slipping of the strand on its neighbors, but this slipping will be done against a friction. Assuming a coefficient of friction of 0.15, the frictional force set up to oppose this motion in a half lay length will be 506 lb. This force will be a measure of the difference between the stress in this

strand at contact with the sheave and at the outside of the rope. Note that this is 10.3% of the axial stress in the strand.

If the normal length of the rope is maintained at its line of contact with the sheave, all this frictional restraint (506 lb), will measure the increase in strand tension at the outside of the rope. If there is slip on the sheave the normal length of the rope is maintained along a line somewhere between the sheave and the outside of the rope. Assuming that this line coincides with the rope center, the stress at the inside is decreased and that at the outside increased, each by one-half the frictional restraint, or 253 lb. The area of the wire in one strand, as taken from Table 3 of the paper, would be 0.0694 sq in. The unit stress due to direct load would be 72 000 lb per sq in., and the frictional bending stress according to the first assumption would be 7 490 lb per sq in., and 3 745 lb per sq in., according to the second. These stresses, of course, are in addition to the stresses due to flexural bending. They would be independent of the ratio of the sheave diameter to the rope diameter. The formula expressing this stress would be:

$$s_f = 2\ s_R \tan \alpha\ f \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(17)$$

in which s_R is the axial unit stress in the rope; α is the angle of lay; and f is the coefficient of friction between strands. Since the same condition exists between the wires in a strand, Equation (17) is decidedly approximate and is given simply to indicate the effect of frictional resistance on sliding. The coefficient of friction is also assumed. Only further tests will indicate what it actually is, but the writer is firmly of the opinion that tests such as those presented by Mr. Stewart are likely to be misleading if assumed for a heavily stressed rope passing over a sheave. If a rope were rusted so that it could not slip, it would bend as a unit, of course, and Equation (7) would be a proper formula for bending stress. If it were so well lubricated that the friction was that of an oil layer on oil, this stress could be neglected. It is very doubtful whether this last condition would exist in a rope under heavy service. It is more likely that neglect would make f more than 0.15.

INGVALD E. MADSEN,[12] JUN. AM. SOC. C. E. (by letter).—The assumption is made in this paper that the loss of strength of wire ropes over sheaves is practically all due to bending stresses, and thus may be evaluated by some bending stress formula. The writer believes that this assumption is not entirely justified, because all bending stress formulas are based on elastic conditions, and, consequently, cannot apply with any accuracy above the elastic limit, and certainly not at the breaking loads. Most of the usual stress theories, apparently, give absurd stresses for the breaking loads, and, consequently, have been disparaged as not picturing true conditions. However, these theories actually may not be so far wrong within the elastic limit. This would seem to be borne out by the breaking of ropes in service under comparatively low loads, because the bending of the rope over sheaves causes stresses far above the fatigue limit, and it takes a relatively small number of repetitions of load to cause some of the wires to break.

[12] Apprentice Engr., M. of W., P. R. R., Pittsburgh, Pa.

The same conditions are present in the usual structural research problems. In order to determine the stresses in a structure, experimentally, the strains are measured and multiplied by the modulus of elasticity of the material (usually 30 000 000 lb per sq in. for steel). However, if the material has exceeded its yield point, large strains are present, and if the method is then applied, calculated stresses result which are far greater than the breaking stress for the material. Analogously, the same thing occurs when the stress theories for bending in wire rope, are extrapolated to the breaking loads.

Actually, when a wire is bent over a sheave, large bending stresses occur at first; but as soon as the yield point of the wire is reached the wire yields, resulting in a re-adjustment of stress. Since practically all the wires used in cables have no definite yield point, this is a gradual process.

There are several other causes that will weaken a rope when tested over a sheave. One of the most important is the nicking effect which occurs between the outside wires of the strands. As the strands are wrapped around the center core, the outside wires of the strands bear on each other, and since these individual wires cross each other at a fairly sharp angle on the inside

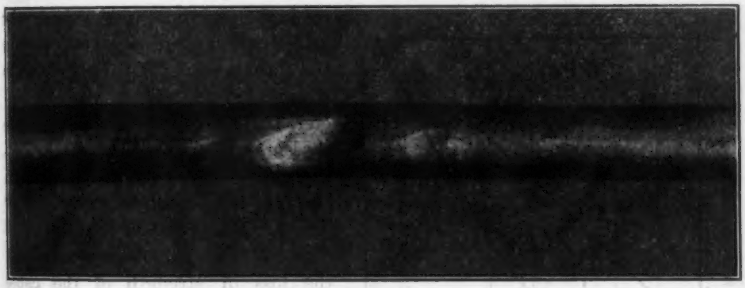

FIG. 19.—VIEW SHOWING NICKS IN WIRE ROPE.

of the strand, they nick each other as the rope compresses under load. These nicks reduce the cross-sectional area of the individual wires, and, consequently, weaken the wire. When a rope is bent over a sheave, the nicking effect is more pronounced, since the bottom of the rope bears on the sheave, and the normal force between the wires will be augmented by the radial force of the rope on the sheave and its reaction. This radial force[18] is equal to the tension in the rope divided by the radius, or, in other words, is inversely proportional to the diameter of the rope. No nicks of any magnitude occur between the wires of the same strand, since these wires cross each other at a small angle, and have a long bearing surface on each other.

Thus, the wires which will break first are not the inside wires as has been usually assumed, but the outside wires of the strands which break at the nicks formed by the crossing wires. These breaks are not visible to the eye, and were determined only by unraveling several cables which had broken over a sheave at one of the tangent points. When this was done, it was

[18] "Applied Mechanics", by C. E. Fuller and W. A. Johnston, Vol. 1, p. 268.

discovered that a large number of the outside wires of the strands, and only these, were already broken at the other tangent point, showing that these wires were the first to break.

The writer continued Mr. Stewart's work, and tested 1-in., 6 × 21, 1-in. 6 × 19 Seale, and 1-in. 6 × 19 Warrington, regular lay, non-preformed cables, with just about the same results obtained by the author. However, it was felt that if the wires were nicked by testing them over sheaves, these wires, of course, would be weakened permanently, which would be revealed in a simple tension test. After the several cables had been tested in tension, and over the 18, 14, 10, and 7-in. sheaves, they were unraveled, and ten individual wires of each size in the rope were taken from the part of the rope which lay over the sheave. These wires were carefully straightened by hand. Nicks were noticeable in all the outside wires, and a view of a typical nick is shown in Fig. 19. The reduction in cross-section is clearly shown. On the inside wires, there were no appreciable nicks and only a very small decrease in strength was revealed in the tension tests.

The nicks in the outer wires were larger in the specimens broken over the smaller sheaves, as would be expected, and, consequently, these wires were weaker than those taken from the cables which had been tested over the larger sheaves. This loss in strength of individual wires (diameter, 0.0795 in.) is shown by Curve *A*, Fig. 20. A graph of the loss in strength of the cables (cast-steel, regular lay, non-preformed) over the various sheaves is shown by Curve *B*, Fig. 20, and it is seen that the loss of strength of the cable over the various sheaves, and the loss of strength due to nicking are quite similar. The results shown, are for the 1-in. 6 × 19 Seale, and the results for the other cables were essentially the same. These results show that a large proportion of the loss of strength in cables is due to the nicking effect.

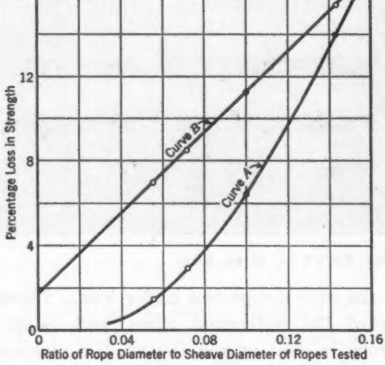

FIG. 20.

The occurrence of these nicks is an added explanation of the failure of cables running over sheaves at fairly low loads. Under the repetition of loads, the wires chafe on each other, enlarging the nicks and reducing the strength until the wire breaks, and this effect is much more pronounced when reverse bends are present.

Stress-strain curves were also drawn of the wires from the broken cables. For some reason, which is most likely the change in cross-section of the individual wires due to abrasion and squeezing in the cable, the stress-strain relationship of the wire seems to change during the testing of the rope. In

Fig. 21 are shown the stress-strain curves for a single wire in the rope. The dotted line is obtained from the wires which went into the rope. The full line is obtained from individual wires taken from a broken rope, and this is the curve that should be used in transposing strain data to stress data. If this is done, the load stress curves in the author's Fig. 11, will approach the load-divided-by-net-area line. Similar curves demonstrating this fact for the 1-in., 6 × 19 Seale are shown in Fig. 22. Curve *E* is obtained by using the dotted line in Fig. 21. This curve is seen to be similar to the 1-in. 6 × 7 regular lay, shown in Fig. 11. Curve *C*, in Fig. 22, is obtained by using the solid line in Fig. 21, and, at the breaking load, the stress in the wires is about equal to the average stress. This is what one would expect, since the plastic flow of the wires above the yield point, re-adjusts the stress throughout the various wires so that they are nearly equally stressed, and at the breaking load they have the same stress.

This condition is contrary to the author's theoretical stress distribution shown in Fig. 15. The writer believes that this distribution is in error for

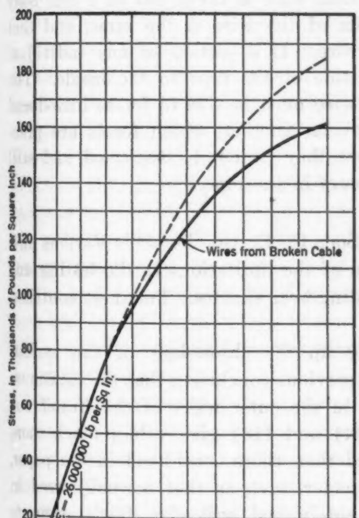

FIG. 21.—AVERAGE STRESS-STRAIN CURVE FOR SINGLE WIRE; 0.0795 INCH IN DIAMETER, CAST-STEEL SPECIMENS 1 to 10.

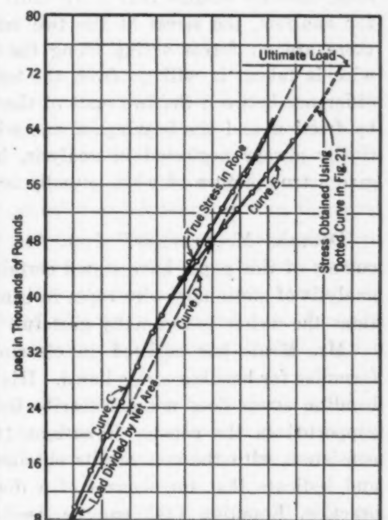

FIG. 22.—LOAD STRESS CURVE FOR TENSION TEST, 1-INCH, 6 x 19 SEALE, CAST STEEL, REGULAR, NON-PREFORMED.

several reasons: First, the wrong stress-strain diagram for the single wires was used; second, the instruments used to measure strain, measured it along the chord of the curved wire, and not the actual strain; and, third, the stress

in the outer wire is balanced against the assumed stress in the core wire, whereas actually there are enough more outside wires than core wires so that the average stress in the cable is not far from the stress in the outer wires. If these factors were taken into account, the stress in all the wires would be seen to be equal to the average stress as shown in Fig. 22.

A few more remarks on the general behavior of wire ropes may be appropriate. A wire rope may be considered as a single solid bar, or an assembly of individual wires, each acting separately. If thought of as a bar, the usual theories for curved beams would apply. Actually, the behavior of a wire rope is somewhere between these two conditions, the exact degree depending on the relative friction between the wires, the lubrication of the rope, the resistance of the individual wires to abrasion, and similar factors. The indeterminacy and the variation in these factors would tend to remove wire ropes from the fields of mathematical analysis. All bending stress theories are based on the assumption that the stress of a rope over a sheave varies from a maximum at the outside of the rope to a lesser stress on the sheave; and yet these theories assume that if an individual wire is taken out as a free body for analysis, the stress at the two ends of the wire is the same, and that there are no forces acting along the wire. If a section of any individual wire is taken, it will go from the outside of the rope to the inside. The difference between the two ends of the wire must be due to forces introduced by friction and the bearing of one wire on another, which forces are practically always neglected in analysis, but they cannot be neglected and still give a true picture of what actually occurs in the rope.

Douglas M. Stewart,[14] Jun. Am. Soc. C. E. (by letter).—Various discussers of this paper have stated certain of the limitations in the testing and analysis of stationary wire ropes in bending over sheaves. For these contributions the writer is especially grateful.

Mr. Meals has assisted in clearing up the chronology of the various formulas for bending stress listed. His previous conclusion that the maximum bending stress does not necessarily lie in the outer wires of the strand was supported in the paper. Equations (14) and (16) give values much more consistent with the test results obtained than those considered in the paper, and indicate that for sheaves of a diameter, such as that normally used in practice, Equation (14) can be used safely and will give fairly accurate predictions of strength.

Loadings of the tensile specimens too close to 50% of the ultimate strength, in determining the modulus of elasticity, were admittedly abnormally high when considered in the light of conventional factors of safety; and yet, as pointed out by Professor Boomsliter, overloads of this amount are frequently experienced in ordinary hoisting ropes, and when pre-stressing suspender cables for bridges to raise the modulus, such loads are commonly used. As shown by Set No. 11, in the ordinary range of working loads, a value of

[14] Engr., Ingersoll-Rand Co., New York, N. Y.

$E_r = 10\,000\,000$ lb per sq in. may be expected after a few loadings, and it is a matter for further investigation to determine whether such a rope in normal service will attain modulus values comparable with those tested.

The general consistency of test results for each specimen, and the agreement between measurements made on opposite sides of the specimen, indicate that a 10-in. gage length was adequate, although a greater length is undoubtedly to be preferred when physical limitations permit. On the specimens on which six 10-in gage lengths were used, a difference of only 3% in modulus between those nearest the sockets and those at the center shows this consistency, and the writer believed that accuracy of this order was within the experimental limits of such testing. Special swivel clamps would no doubt have been of assistance in eliminating twisting of the measuring apparatus, but corrections for twist using the transit and scale were of very small magnitude except for loads near the breaking point. The use of ropes with hemp centers for these tests was dictated by practical considerations, and the question of whether this type, or that with an independent wire-rope center, is the more typical seems debatable. An extended research into the properties of such ropes would clarify many questionable points in the analysis.

Professor Boomsliter has stated clearly one of the chief causes of variation in any mathematical analysis of stresses in a wire rope. There can be no question that forces of the nature described actually exist in a rope, but since so many assumptions must be made in considering them, such frictional stresses are usually neglected. That these forces may have an appreciable effect on the strength of a rope, in certain cases, is shown in the numerical example considered. Variation in the quantity of lubricant used in the ropes was not attempted; all tests were made on new commercial ropes and represent current practice in this respect. Mr. Madsen makes mention of such stresses in the last paragraph of his discussion, but the very fact that strengths in both bending and tension may be predicted with fair accuracy by the formulas given, whether empirical or otherwise, indicates that too careful consideration is not justified.

Mr. Madsen has had the opportunity of carrying on the writer's work on various other types of wire rope specimens, and his conclusions merit careful consideration. It is to be regretted that complete results of his tests were not available for his discussion.

Specifically referring to Mr. Madsen's discussion, it is stated that the usual stress theories, as represnted by Equations (1) to (7), inclusive, may not be far from wrong below the elastic limit. These formulas actually indicate that the elastic limit (if a wire rope may be said to possess such a property) is reached long before the point shown by actual tests. Furthermore, breaking of stationary ropes in service under low loads almost never occurs, although no one will deny that fatigue will cause breakage in moving ropes at values of load far less than that given by any of these formulas. Since the bending stress is constant regardless of the load on the rope, it is

obvious that if exceptionally large stresses are indicated by such formulas at the breaking load, the error will be even greater proportionally at lower values of the direct stress.

The nicking effect of one wire on another has been emphasized clearly, and the reduction in area (and, hence, in ultimate load) is appreciable. Although care must be taken in interpreting tests on specimens of this nature after being stressed almost to failure, it is apparent that the loss in the strength of the rope must be affected by this nicking of certain of the outer wires. In any cross-section, however, the number of such wires is not large, being limited to those in the outer layer of a strand where it touches another strand. The use of a stress-strain curve for a wire that has been loaded practically to failure, over the entire range of a tensile test, does not seem to be justified. From Fig. 20, the percentage loss in strength of the wire in a tensile test is very close to zero, which means that, at failure, the wire should show an ultimate strength of about 219 000 lb per sq in. This strength is very close to that obtained in Curve *E* of Fig. 22, whereas Curve *C* shows a stress of only about 185 000 lb per sq in. at failure, or about 15% lower strength. Fig. 21 cannot be based on wires taken from a tension specimen and still be consistent with Fig. 20, and values taken from such a curve based on nicked wires from a bending specimen (which themselves are not typical of conditions prevailing over the cross-section) are of little help in correcting Fig. 22.

The correct stress-strain curve of the wire to use would be one based on a gradual nicking, such as takes place in the rope, but lacking this, the original stress-strain curve seems to give the best results. The difference in length between the chord length measured in a $\frac{1}{2}$-in. gage length on the wire and the actual center-line length is so small that it may safely be neglected. That the stress in the inner wires is greater than the average over the cross-section, is appreciated by wire rope manufacturers, who make the inner wires slightly larger to withstand this effect.

The need for more extensive research in this field, to explain the apparent inconsistencies of various experiments has been mentioned previously, and is emphasized by the discussions of this paper.

VARIED FLOW IN OPEN CHANNELS OF ADVERSE SLOPE

By Arthur E. Matzke[1], Jun. Am. Soc. C. E.

With Discussion by Messrs H. E. von Bergen, W. E. Howland, Arno T. Lenz, J. C. Stevens, F. T. Mavis, Hunter Rouse and Merit P. White, and Arthur E. Matzke.

Synopsis

A canal may be said to possess an adverse slope, if its bottom rises in the direction of the flow. When, as in the usual case, the bottom falls in the direction of flow, a channel may be said to possess a sustaining slope. An example of a layout with an adverse slope is a canal connecting a tidal basin, or an area to be drained, with the sea. Another case is the approach to a low spillway with a bed gently sloping over a considerable length. Although cases of this kind occur rather infrequently, there are instances in which a knowledge of the flow and methods of numerical computations is essential.

The general equations for varied flow in channels of adverse slope were originally developed by B. A. Bakhmeteff, M. Am. Soc. C. E., about 1910, the method of treatment being in general similar to that which he presented[2] in 1932. Practical application in engineering design, however, depends on knowing the numerical values of a function, similar to the "varied flow function", for canals of sustaining slopes.[3] The required function values were determined by graphical integration and are offered in the form of appropriate tables, together with a brief survey of the underlying theory and some numerical examples making clear the methods of practical applications.

General Equation of Flow in Canals of Adverse Slope

In general, the reasoning leading to the establishment of the general equation of flow in canals of adverse slope follows that developed by Professor

Note.—Published in February, 1936, *Proceedings*.

Bakhmeteff[4] for the case of sustaining slope. Since the derivation of the varied flow equation for canals of adverse slope is practically unknown, an outline of the development will be presented herein. The symbols used are defined as they occur and are summarized in the Appendix for convenience of reference.

With reference to Fig. 1(*a*), a discharge, Q, in cubic feet per second, is assumed to flow in a canal of given cross-section. The adverse bottom slope is denoted by the negative sign, thus, $-S_o$. The discharge is referred to a parametric depth value, y_0, which is the depth of uniform flow for the same

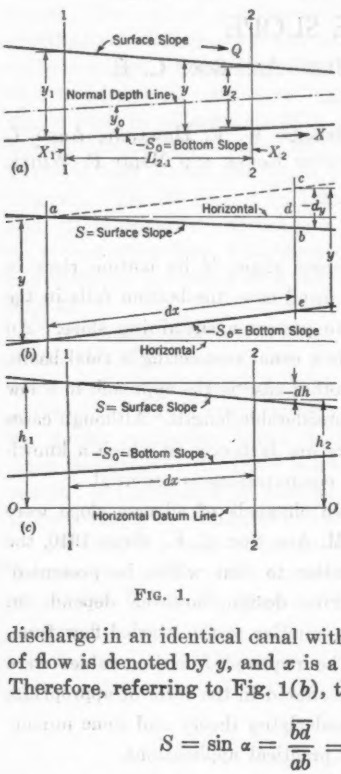

FIG. 1.

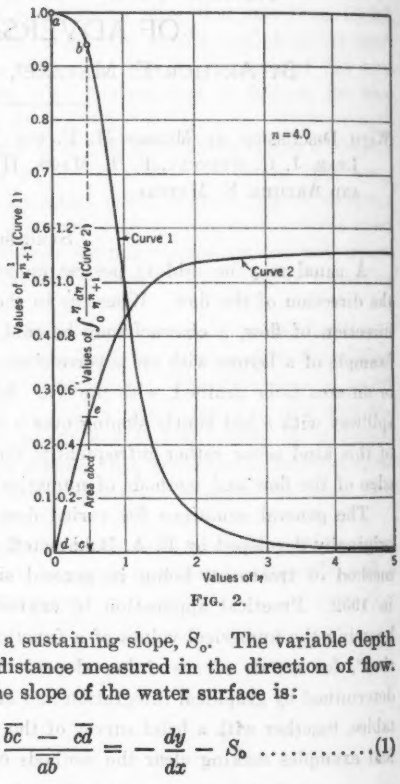

FIG. 2.

discharge in an identical canal with a sustaining slope, S_o. The variable depth of flow is denoted by y, and x is a distance measured in the direction of flow. Therefore, referring to Fig. 1(*b*), the slope of the water surface is:

$$S = \sin \alpha = \frac{\overline{bd}}{\overline{ab}} = \frac{\overline{bc} - \overline{cd}}{\overline{ab}} = -\frac{dy}{dx} - S_o \quad \text{.............(1)}$$

Referring to Fig. 1(*c*) and bearing Equation (1) in mind, the loss of energy head, de_r, over the distance, dx, becomes[4]:

$$\frac{de_r}{dx} = -\left(S_o + \frac{dy}{dx} + \frac{d}{dx}\left(\frac{V^2}{2\,g}\right)\right) \quad \text{.............(2)}$$

[4] "Hydraulics of Open Channels", Paragraph 12, Eng. Societies Monograph, McGraw-Hill Co., 1932.

Whereas[5], $\frac{de_r}{dx} = \frac{Q^2}{K^2(y)}$, in which $K(y)$ is the value of the conveyance or carrying capacity of a given canal cross-section for any surface depth, y, and[6] $\frac{d}{dx}\left(\frac{V^2}{2g}\right) = -\frac{Q^2}{g} \times \frac{b}{A^3} \times \frac{dy}{dx}$ in which A is the cross-sectional area of flow and b is the top width of the cross-sectional area of flow. Therefore, Equation (2) becomes:

$$-S_0 - \frac{dy}{dx} = \frac{Q^2}{K^2(y)} - \frac{Q^2}{g} \times \frac{b}{A^3} \times \frac{dy}{dx} \dots\dots\dots\dots (3)$$

Using the parametric depth, y_0[7], explained previously, and the hydraulic exponent, n[8], it follows that $\frac{Q^2}{K^2(y)} = S_0\left(\frac{y_0}{y}\right)^n$. Furthermore, as $\frac{Q^2}{g} \times \frac{b}{A^3}$ in Equation (3) may be expressed as being equal to $\beta\,\frac{K^2(y_0)}{K^2(y)}$ in which $\beta = \frac{S_0}{S_c}$[9] and S_c[10] is the critical slope at the varying depth, y, Equation (3) may be written as follows:

$$\frac{dy}{dx} = -S_0\,\frac{1+\left(\frac{K_0}{K}\right)^2}{1-\beta\left(\frac{K_0}{K}\right)^2} = -S_0\,\frac{1+\left(\frac{y_0}{y}\right)^n}{1-\beta\left(\frac{y_0}{y}\right)^n} \dots\dots\dots (4)$$

Equation (4) is the general differential equation of varied flow in canals with adverse slope. Separating the variables and designating $\eta = \frac{y}{y_0}$ (that is, $dy = y_0\,d\,\eta$), Equation (4) becomes:

$$\frac{S_0}{y_0}\,dx = -d\,\eta + (1+\beta)\,\frac{d\,\eta}{\eta^n+1} \dots\dots\dots\dots\dots (5)$$

The distance, $x_2 - x_1 = l_{2-1}$, between two sections with the respective depths, y_2 and y_1, which corresponds to $\eta_2 = \frac{y_2}{y_0}$ and $\eta_1 = \frac{y_1}{y_0}$, is obtained by integrating Equation (5); thus:

$$\frac{S_0}{y_0}\left(x_2 - x_1\right) = \frac{S_0}{y_0}\,l_{2-1} = -(\eta_2 - \eta_1) + \int_{\eta_1}^{\eta_2}(1+\beta)\,\frac{d\,\eta}{\eta^n+1} \dots (6)$$

Assuming that the value of β may be taken as a constant average value for the range of integration, and designating $\int_0^{\eta}\frac{d\,\eta}{\eta^n+1} = B'(\eta)$ (the

[5] "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., Eng. Societies Monograph, McGraw-Hill Co., 1932, Equation (14), p. 26.

[6] *Loc. cit.*, Equation (20), p. 31.

[7] *Loc. cit.*, p. 22.

[8] *Loc. cit.*, p. 84.

[9] *Loc. cit.*, p. 52.

[10] *Loc. cit.*, p. 47.

"varied flow function" for canals of adverse slope) Equation (6) becomes:

$$l_{2-1} = \frac{y_0}{S_0}\left[-(\eta_2 - \eta_1) + (1 + \beta)\left\{B'(\eta_2) - B'(\eta_1)\right\}\right] \ldots\ldots(7)$$

which is the general equation of varied flow for channels of adverse slope.

For comparison, in the case of sustaining bottom slope:

$$S = S_0 - \frac{dy}{dx} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(8)$$

the varied flow equation is[11]:

$$l_{2-1} = \frac{y_0}{S_0}\left\{(\eta_2 - \eta_1) - (1 - \beta)\left[B(\eta_2) - B(\eta_1)\right]\right\} \ldots\ldots(9)$$

In other words, the formulas for adverse flow (Equations (1) and (7)) differ from those for sustaining flow (Equations (8) and (9)) only in the signs and in the form of the varied flow function, the essential structure of both being similar.

Integration Procedure

For practical computations it is imperative to know the value of the varied flow function,

$$B'(\eta) = \int_0^\eta \frac{d\eta}{\eta^n + 1} \ldots\ldots\ldots\ldots\ldots\ldots(10)$$

within the practical range of the hydraulic exponents, which usually lies between $n = 3$ and $n = 4$. For the particular value of $n = 3$ and $n = 4$, $B'(\eta)$ may be obtained analytically. The forms of the respective quadratures are:

For $n = 3$, substitute $z = -\eta$ so that $\int \frac{d\eta}{\eta^3 + 1} = \int \frac{dz}{z^3 - 1}$. Then,

$$\int \frac{dz}{z^3 - 1} = \frac{1}{6}\log_e \frac{(z-1)^2}{z^2 + z + 1} + \frac{1}{\sqrt{3}} \operatorname{arccot} \frac{2z + 1}{\sqrt{3}} \ldots\ldots(11)$$

For $n = 4$,

$$\int \frac{d\eta}{\eta^4 + 1} = \frac{1}{4\sqrt{2}}\log_e\left(\frac{\eta^2 + \eta\sqrt{2} + 1}{\eta^2 - \eta\sqrt{2} + 1}\right) + \frac{1}{2\sqrt{2}}\left[\arctan\left\{\eta\sqrt{2} + 1\right\} + \arctan\left\{\eta\sqrt{2} - 1\right\}\right] \ldots\ldots(12)$$

For intermediate values of n, one could take recourse to computation by series, but this is a laborious and lengthy procedure scarcely warranted by the character of the problem. It seemed that results sufficiently accurate for engineering practice might be obtained by graphical integration. The method is illustrated by Fig. 2 which gives the curves for the particular case of $n = 4$. For values of η, the corresponding values of $\frac{1}{\eta^n + 1}$ are found, which when plotted against η give Curve 1.

[11] "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., Eng. Societies Monograph, 1932, Equation (84), p. 87.

For each η-ordinate, the value of $\int_0^\eta \frac{d\eta}{\eta^n + 1}$ is the numerical value of the area under the curve to the left of that ordinate. These areas may be computed by a planimeter or simply by counting squares. Curve 2 is drawn so as to represent for each η-ordinate, the corresponding area to an appropriate scale as Ordinate ce = Area $abcd$. The writer compared values of $B'(\eta)$

TABLE 1.—COMPARISON OF GRAPHICAL AND ANALYTICAL VALUES OF INTEGRAL

Curves were made then for intermediary exponents at intervals of 0.2 and the results summarized in Table 2. Values of $B'(\eta)$ for exponents between the tabular values can either be taken by interpolation or, if desired, in each particular case, a special curve of $\frac{1}{\eta^n + 1}$ and $\int_0^\eta \frac{d\eta}{\eta^n + 1}$ may be computed and traced.

Such curves and tabular values allow a simple and rapid solution of practical problems. With reference to Fig. 1(*a*) the distance, $l_{2\text{-}1}$, between two selected depths, with $\eta_2 = \frac{y_2}{y_0}$ and $\eta_1 = \frac{y_1}{y_0}$, is determined from Equation (2) by inserting the values of $B'(\eta_2)$ and $B'(\eta_1)$ from Table 2.

Types of Surface Curves

Due to the direction of the slope, the motion in the canal takes place at the expense of the specific energy available in the initial section, which is dissipated in the course of the movement. Only two types of surface curves are possible: (1) For depths above the critical ($y > y_c$), a drop curve (see Fig. 3) of the M_2-type[13] which is characterized by a decreasing depth, y, termi-

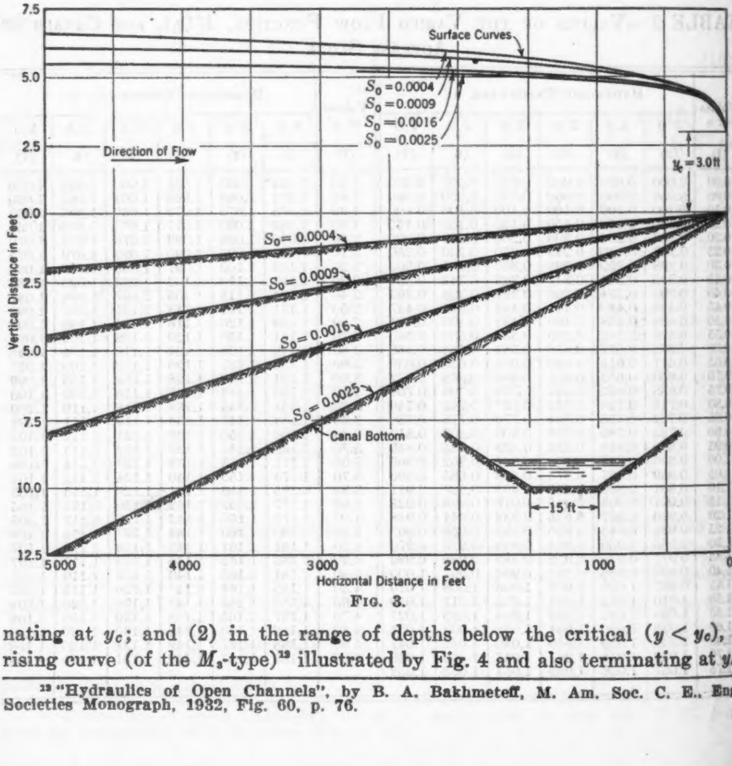

Fig. 3.

nating at y_c; and (2) in the range of depths below the critical ($y < y_c$), a rising curve (of the M_3-type)[13] illustrated by Fig. 4 and also terminating at y_c.

[13] "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., Eng. Societies Monograph, 1932, Fig. 60, p. 76.

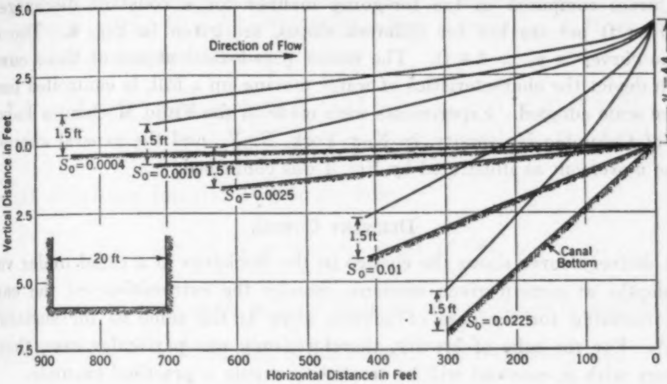

FIG. 4.

PRACTICAL EXAMPLES

Example 1.—M'_2-Curve.—Assuming a discharge of $Q = 519$ cu ft per sec, and a slope, $S_o = 0.0004$, following the usual procedure, the value of $y_0 = 6.56$ ft[13]. The critical depth is $y_c = 3$ ft. The hydraulic exponent is taken at $n = 3.80$; and the average value of β is 0.06. At the point of critical depth, $\eta_c = \dfrac{3}{6.56} = 0.457$, and, by interpolation, from Table 2, $B'(\eta_c) = 0.452$.

Calculating the distance from $y_c = y_2$ to a point at which the depth is $y_1 = 5.0$ ft, with $\eta_1 = \dfrac{5.0}{6.56} = 0.762$ and $B'\ (0.762) = 0.715$, by Equation (7) $l_{2\text{-}1} = \dfrac{6.56}{0.0004}\ [-\ (0.457 - 0.762) + 1.06\ (0.452 - 0.715)] = 459$.

A similar procedure determines the respective distance from $y_c = 3$ ft to a section with $y_1 = 4$ ft, 6 ft, etc. Thus, the entire surface curve may be traced. Fig. 3 gives the curves for the same discharge and cross-section, but for different values of the adverse slope, ranging from $-\ 0.0004$ to $-\ 0.0025$.

Example 2.—M'_3-Curve (Fig. 4).—Assume a discharge of $Q = 1\,080$ cu ft per sec, and $y_c = 4.4$ ft[14]; and, with $-\ S_o = 0.0004$, $y_o = 8.65$ ft. Furthermore, let $n = 3$ and $1 + \beta = 1.17$; and assume that a sluice-gate maintains an initial depth, $y_1 = 1.5$ ft. The rising curve is to be computed from these data. To illustrate, determine the distance from the section with $y_1 = 3.0$ ft to a section with $y_2 = 3.50$ ft; thus: $\eta_1 = \dfrac{3.0}{8.65} = 0.347$; and $\eta_2 = \dfrac{3.50}{8.65} = 0.405$. Accordingly, from Table 2, $B'(\eta_1) = 0.342$; and $B'(\eta_2) = 0.398$. Substituting these values into Equation (7),

$$l_{2\text{-}1} = \frac{8.65}{0.0004}\ [-\ (0.405 - 0.347) + 1.17\ (0.398 - 0.342)] = 160 \text{ ft}$$

[13] "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., Eng. Societies Monograph, 1932, Canal Type *D*, p. 321.

[14] *Loc. cit.*, p. 320, Canal Type *C*.

Curves computed in the foregoing manner for a constant discharge of 1 080 cu ft per sec but for different slopes, are given in Fig. 4. The end of the curves is $y_c = 4.4$ ft. The rather paradoxical aspect of these curves, which depict the characteristics of water moving up a hill, is controlled partly by the scale adopted. Experiments were made in the Fluid Mechanics Laboratory of Columbia University, in New York, N. Y., and the general character of the movement as illustrated by Fig. 4 was confirmed.

Delivery Curves

A delivery curve shows the change in the discharge in a canal under varying depths at certain given sections—usually the extremities—of the canal. The reasoning for the case of adverse slope is the same as for sustaining slope[15]. For the sake of brevity, therefore, only one particular case, that of delivery with y_2 constant will be treated to supply a practical example.

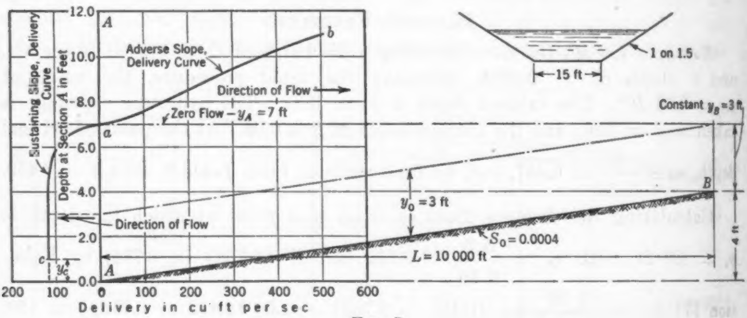

FIG. 5.

Example 3.—Assume that a canal of the cross-section shown in Fig. 5[15], has a length of 10 000 ft and connects the open sea at Section A with a large inland reservoir at Section B. The level of the latter is taken to be invariable, which gives a constant depth at Section B assumed to be $y_B = 3$ ft. The bottom slope is 0.0004. Obviously, when y_A happens to be 7 ft the surface is level and there is no flow through the canal. When the depth at Section A exceeds 7 ft there will be flow from Section A to Section B, the motion taking place against an adverse slope. A delivery curve (Curve ab, Fig. 5) indicates the value of the discharge, Q, for corresponding values of the variable depth, y_A.

To find a point of the delivery curve assume $y_0 = 5$ ft, which with K (5 ft) = 15 200, corresponds to a discharge, $Q = K\text{ (5 ft)}\sqrt{S_o} = 304$ cu ft per sec. Assume that $1 + \beta = 1.06$ and $n = 3.80$. The problem now is reduced to that of Fig. 3, namely, to find the depth, $y_A = y_1$, which, with

[15] "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., Eng. Societies Monograph, 1932, p. 143.

$l_{2\text{-}1} = 10\,000$ and $y_0 = 5$ ft, will correspond to $y_2 = y_B = 3$ ft, as given. Equation (7) may be rewritten in the form:

$$l_{2\text{-}1} \frac{S_0}{y_0} = [-\eta_2 + (1+\beta) B'(\eta_2)] - [-\eta_1 + (1+\beta) B'(\eta_1)]$$
$$= z'(\eta_2) - z'(\eta_1) \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

in which $z'(\eta)$ is a function of η of the form,

$$z'(\eta) = -\eta + (1+\beta) B'(\eta) \ldots\ldots\ldots\ldots\ldots (14)$$

In the present case, with y_2 (and thus η_2) given, the only unknown in Equation (13) is $\eta = \frac{y_1}{y_0}$ implicitly contained in the function, $z'(\eta_1)$.

For $y_0 = 5$ ft, therefore, $l_{2\text{-}1} = \frac{S_0}{y_0} = 10\,000 \times \frac{4 \times 10^{-4}}{5} = 0.8$; $\eta_2 = \frac{3}{5} = 0.60$; and $B'(\eta_2) = 0.584$. Consequently, by Equation (14), $z'(\eta_2) = -0.600 + 1.06 \times 0.584 = 0.019$. The solution of the problem involves finding the value of $\eta_1 = \frac{y_A}{y_0}$ which satisfies the equation:

$$z'(\eta_1) = z'(\eta_2) - l_{2\text{-}1} \frac{S_0}{y_0} = -0.781 \ldots\ldots\ldots\ldots (15)$$

The most practical way to solve Equation (14) is to build an auxiliary curve of $z'(\eta)$ plotted against η.

The value of η_1 which is sought is 1.912 and, thus, $y_A = \eta_1 \times y_0 = 1.912 \times 5 = 9.56$ ft. Hence, a point of the delivery curve is established with $y = 9.56$ ft and the corresponding discharge of 304 cu ft per sec. By assigning other values to the normal depth, y_0, other points of the delivery curve may be obtained, resulting in the curve, *ab* (Fig. 5).

When the depth at Section *A* becomes less than 7 ft, the flow will be in the direction of the sustaining slope. The corresponding delivery curve is *ac*.

Conclusions

The case of flow in channels of adverse slope completes the scope of application of the Belanger equation of varied flow based on the assumption of parallel flow to practical engineering design. It is hoped that the varied flow equation (Equation (7)) and the tables of values of the varied flow function will provide a direct and convenient method of solving some of the hydraulic problems connected with the design of open channels of adverse slope.

Acknowledgments

The writer wishes to express his sincere appreciation to Boris A. Bakhmeteff, M. Am. Soc. C. E., for aid and guidance during the course of the work.

APPENDIX

Notation

c = a subscript denoting "critical";
l = length; distance between two given sections; $l_{2\text{-}1}$ = distance between Section 2 and Section 1;
n = an hydraulic exponent;
S = slope of the water surface; S_o = sustaining slope of a channel bottom; $-S$ = adverse slope of a channel bottom; S_c = critical slope of water surface;
x = a variable distance measured in the direction of flow;
y = a parameter denoting variable depth of flow; y_0 = normal depth, or the depth in the case of uniform movement; y_c = critical depth;
z = a function; $z'(\eta)$ = a function of η referred to the case of adverse slope;
A = area;
B = a function; $B(\eta)$ = the varied flow function $= \int_0^{\eta} \frac{d\eta}{\eta^n - 1}$, for sustaining slope; $B'(\eta)$ = varied flow factor for adverse slope;
M = a type of surface curve: M_2-curve, M_3-curve, etc.;
Q = rate of discharge, or flow;
V = average velocity in a section;
α = slope angle = $\sin^{-1} S$;
β = the relation between the bottom slope, S_o, and the critical slope, S_c;
η = the relation of the varying depth of flow, y, to the normal depth, y_0 $\left(\text{that is, } \eta = \frac{y}{y_0}\right)$.

DISCUSSION

H. E. von Bergen,[16] Assoc. M. Am. Soc. C. E. (by letter).—The science of obtaining the depth directly at any point in a channel of adverse grade and uniform section, for steady non-uniform flow, has been advanced appreciably by this paper. In the field of hydraulics, however, this case is rather rare and in the event of flow below critical depth the hydraulic jump is produced. Furthermore, unless the engineer has occasion to make numerous computations, using the author's formulas and "varied flow functions", he may find the method somewhat involved and cumbersome.

The writer has found it more practical and convenient to dispense with the author's analytical treatment beyond his Equation (3) and, solving for $\frac{dy}{dx}$, to make a graphical integration of the resulting differential equation as suggested[17] by Harold A. Thomas, M. Am. Soc. C. E. For example, using the notation of the paper:

$$\frac{dy}{dx} = \frac{-S_0 - \dfrac{Q^2}{K^2(y)}}{1 - \dfrac{Q^2 b}{g a^3}} \quad \text{(16)}$$

and, since $\frac{Q^2}{K^2(y)} = S$, which may be obtained quickly from various prepared charts or tables, and $\frac{Q^2 b}{g a^3} = \frac{V^2 b}{g a}$ (and for rectangular channels may be further simplified) Equation (16) may be reduced to:

$$\frac{dy}{dx} = \frac{-S_0 - S}{1 - \dfrac{V^2 b}{g a}} \quad \text{(17)}$$

To integrate, graphically, use the reciprocal of Equation (17), compute four or five values of $\frac{dx}{dy}$ over the desired range of depths, and plot the depth, y, as ordinate and $\frac{dx}{dy}$ as abscissa. Then, by graphical summation of the area to the left of the curve, the water-surface profile may be drawn over the desired range of depths.

The negative sign of S_0 was introduced from Equation (3), but for the general case the sign of S_0 is positive and, by substituting a minus value for "adverse" slope and a positive value for "sustaining" slope, the sign of S_0 will take care of itself automatically.

[16] Water Master, Div. of Water Resources, State Dept. of Water Rights, Sacramento, Calif.

[17] "Hydraulics of Flood Movements in Rivers", by Harold A. Thomas, *Engineering Bulletin*, Carnegie Inst. of Technology, 1934, p. 13.

The writer believes the graphical solution is more practical and efficacious and, except for accidental errors in plotting, is more correct than the elaborate analytical treatment given by the author.

W. E. HOWLAND,[18] ASSOC. M. AM. SOC. C. E. (by letter).—This extension of the theory of varied flow to open channels of "adverse" slope furnishes additional proof of the power of the fundamental methods presented by Professor Bakhmeteff[2], and is, in itself, a valuable contribution to the practical tools of the hydraulic engineer. The concise presentation of theory and the numerous illustrative problems serve to make the methods available to students and practitioners alike.

A few suggestions may be helpful in gaining familiarity with the terminology. When the depth is y, the term, $K\ (y)$, is defined as $C\ A\ \sqrt{R}$, in which C is the constant in the familiar Chezy formula, $V = C\sqrt{R\,S}$; R is the hydraulic radius; and A is the area of the cross-section of the moving stream. It is thus a part of the total expression for the carrying capacity of the channel, but not all of it. The term, "conveyance, as a name for $K\ (y)$ is a good one, because it is not used for any other quantity, but the expression, "carrying capacity", seems to mean Q, or an expression for Q, and, therefore, may be misleading as applied to $K\ (y)$.

The term, "hydraulic exponent", or n, can be defined by the equation $K^2(y)\ =$ a constant $\times\ y^n$. It is obtained by plotting the logarithms of the computed values of $K^2(y)$, for a given cross-section against y, the depth, as abscissa. The slope of the line so plotted is the value of n.

There are two assumptions made in Mr. Matzke's study which might introduce small errors. A useful addition to the paper would be an estimation of the approximate limits of these errors as affecting computed depths in one or more of the illustrative problems. These two assumptions are: (1) That of the constancy of n previously mentioned; and (2), that of the constancy of η defined in the paragraph following Equation (4).

It is interesting to note that a more elementary method of solving problems involving changing velocities does sometimes yield results of sufficient precision with little labor. The writer has used one such method to check the results of Example 1. It involves the consideration of the canal as made up of six sections of variable length, but of constant difference in surface elevation of 1 ft. The effect on the surface curve due to the differences in velocity head can be considered exactly. The effect on the surface curve of friction in each section was obtained by computing the value of the energy gradient at the extremity of each section and then using the harmonic average (a reciprocal average of reciprocals) of the two extreme values in estimating the effect of friction in that section. The variable length of each section is then computed from the following self-evident expression (the nomenclature used is that of the paper):

$$l_{1\text{-}2} = \frac{\text{Difference in depths (1-2)} - \text{difference in velocity heads (2-1)}}{\text{Bottom slope} + \text{energy gradient}}$$

[18] Associate Prof., Civ. Eng., School of Civ. Eng., Purdue Univ., West Lafayette, Ind.

or,

$$l_{1\text{-}2} = \frac{(y_1 - y_2) - \dfrac{Q^2}{2\,g}\left\{\dfrac{1}{(a_2)^2} - \dfrac{1}{(a_1)^2}\right\}}{s + \dfrac{Q^2}{k^2_{(\text{ave.})}}} \quad \ldots\ldots\ldots\ldots\ldots(18)$$

For Example 1, Equation (18) becomes:

$$l_{1\text{-}2} = \frac{1 - \dfrac{519^2}{64.4}\left\{\dfrac{1}{(a_2)^2} - \dfrac{1}{(a_1)^2}\right\}}{0.0004 + \dfrac{519^2}{k^2_{(\text{ave.})}}} \quad \ldots\ldots\ldots\ldots\ldots(19)$$

The values of a and k have been obtained for this section from Professor Bakhmeteff's work[18]. Substituting the values of $a_2 = 58.5$ ft^2 when $y = 3$ ft. and $a_1 = 84.0$ ft^2 when $y = 4$ ft, the numerator of Equation (19) becomes 0.373. Using the average of the values of $k^2 = (58.2 \times 10^2)^2$, which is the value when $y = 3$ ft, and of $k^2 = (99.4 \times 10^2)^2$, which is the corresponding value when $y = 4$ ft, the denominator of Equation (19) becomes 0.004062 and $l_{1\text{-}2}$ is 84 ft. Owing to the very small differences in the functions given in Table 2, it is almost impossible to check this value thereby.

Likewise, the writer has computed the distance from the place where $y = 4$ ft to where $y = 5$ ft, etc., and then, by addition, the distance from where $y = 3$ ft to where $y = 5$ ft, etc., and obtained the results listed in Table 3. The value, 426 ft, does not agree with the one given by Mr. Matzke, but it is more closely in agreement with the arithmetic values he himself has given; that is, $\dfrac{6.56}{0.0004}\left\{ -(0.457 - 0.762) + 1.06\,(0.452 - 0.715) \right\} = 426.$ The agreement between the results of the two methods is striking and really surprising, considering that the approximate method involves so little work.

TABLE 3.—COMPARISON OF HORIZONTAL DISTANCES (UNITS IN FEET)

DEPTH AT SECTIONS BETWEEN WHICH HORIZONTAL DISTANCES ARE GIVEN:		COMPUTED HORIZONTAL DISTANCES	
From:	To:	By approximate method:	By Matzke's method:
3	4	84	.....
3	5	425	426
3	6	1 170	1 180
3	7	2 320	2 335
3	8	3 830	3 860

It is also interesting to note that if the arithmetic average of energy gradients (or what amounts to the same thing, the average of $\dfrac{1}{k^2}$) were used in the foregoing computation instead of the harmonic average of energy gradients (or average value of k^2) at the two extremities of a given section, the agreement would not have been nearly so good. This would suggest that, at least for this type of problem, the harmonic average should be used.

From the application of this particular approximate method to this problem and also from studying the somewhat similar graphical method presented by H. Addison[19], the writer is led to believe that the harmonic average is preferable to the arithmetic average of slopes in approximate methods of this nature. If further study on this point were thought to be desirable, Mr. Matzke's method would serve as an exact standard of comparison on regular channels. In natural channels with irregular sections, in which some kind of an approximate method must be used, great precision could be secured by the use of a large number of sections or small increments of depth.

The writer has attempted to apply this approximate method to Example 2, but has obtained a result of 127 ft instead of 160 ft. Mr. Matzke's result might be in error almost to this extent. A change in the last significant figure of one of the numbers from Table 2 would change the result of his computation as much as 13 per cent. It seems that this table is not satisfactory when applied to sections so close to one another. Indeed, this lack of precision in computations with close sections is the most serious limitation to the application of the method. The approximate method increases in precision as the sections become closer and would appear to be more satisfactory for these cases.

Applying the approximate method to the third problem the writer has obtained a value of $l = 11\,150$ ft from the right-hand end of the canal to the place where $y = 10$ ft. (In making these computations a value of $k^2 = 19.35 \times 10^8$, when $y = 9$ ft., and $k^2 = 23.95 \times 10^8$, when $y = 10$ ft., was used, in addition to the values for the lower depths given by Bakhmeteff.) Then, subtracting from 10 ft the value, 11 150 − 10 000, times the value of $\frac{dy}{dx}$ at the 10-ft depth, or $1\,150 \times 0.000425 = 0.49$, the writer obtains 9.51 ft as the depth of the water at the lower end of the canal. (Here, the water-surface slopes are very small and are very nearly constant.) This agrees very well with the values of 9.56 ft given by the author. This method probably involves no more labor than that of Mr. Matzke in solving this problem.

In the statement of this problem it is to be noted that the upper end of the canal level is held fixed at 3 ft; and that the reservoir surface elevation at Section *B* is invariable. It is impossible to maintain both conditions when the water is flowing to the left since the water line in the canal must be at least one velocity head lower than that in the reservoir. This velocity head at the highest flow amounts to 0.61 ft. The solution given is consistent with the assumption that the levels indicated at Sections *A* and *B* are canal levels and not reservoir or ocean levels, unless, in some case, they might happen to be the same.

ARNO T. LENZ,[20] JUN. AM. SOC. C. E. (by letter).—An interesting extension of the work of B. A. Bakhmeteff, M. Am. Soc. C. E.[3], on open channels is contained in this paper. The examples show its practical application in an excellent manner. In mathematical derivations of this type, however, there

[19] "Hydraulics", by H. Addison, N. Y., John Wiley & Sons, 1934, p. 135.
[20] Instr., Dept. of Hydr. and San. Eng., Univ. of Wisconsin, Madison, Wis.

are certain basic assumptions which must be made. These assumptions may be said to be the foundation upon which the structure is built, and they must be sound. They should be checked in every manner possible.

In the derivation of the general differential equation for varied flow, the hydraulic exponent, n, is used, based on the fact that "the conveyance function, $K = a\,C\,\sqrt{R}$, within a reasonable range of depths, follows sufficiently close the exponential relations: $K^2\,(y) = a^2\,C^2\,R =$ constant y^{n}"[18]. This exponential relation is of extreme importance in all that follows.

It is evident that the best check of this relation would be to plot the conveyance, K, against the depth, y, on logarithmic paper, which plotting should give a straight line. Unfortunately, practically all published experimental discharge measurements omit the slope measurement necessary to determine the value of K from the discharge, $Q = K\,s^{\frac{1}{2}}$.

An approximate check might be made, however, by considering that when a number of stream gagings are taken, some will be made at times when the surface slope is greater than normal and at others when it is less than normal, with the average of a number probably about normal. Furthermore, the gage height as recorded is a measure of the depth, y. With these approximations in mind, discharge was plotted against gage height for ten streams picked at random from the *Water Supply Papers* of the U. S. Geological Survey, from all sections of the country. The curves are plotted on Fig. 6.

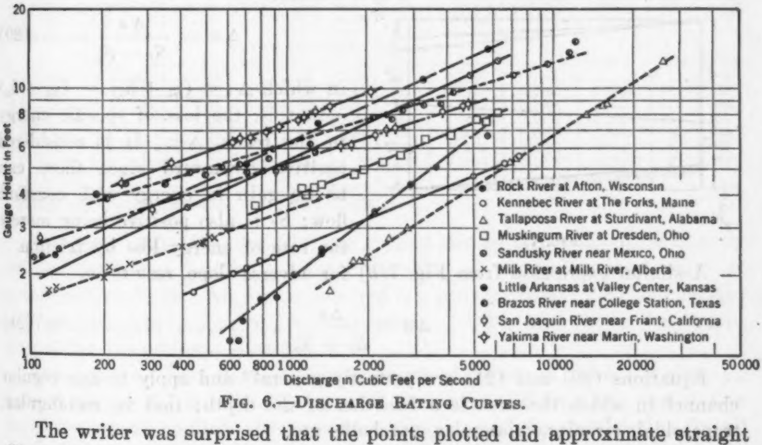

FIG. 6.—DISCHARGE RATING CURVES.

The writer was surprised that the points plotted did approximate straight lines. It is recognized that for canals it is likely that the exponential law holds even more closely than for natural channels. Therefore, the curves are a logical proof of the validity of the use of the hydraulic exponent as assumed by the author.

When flow spreads out over flood-plains there will be a sharp break in the line, and care must be exercised under such conditions. A check such as that presented herein is relatively easy to make and will show quickly whether the theory may be applied to any particular river or canal.

The author is to be congratulated on his extension of the theory presented by Professor Bakhmeteff, which should be a tool of great usefulness to those working on the hydraulics of open channels.

J. C. STEVENS,[21] M. AM. SOC. C. E. (by letter).—There seems to be little use for injecting the "varied flow function" into the computations of surface curves. Such functions are not only more laborious to apply, but they are full of inaccuracies as a result of the many basic assumptions and approximations entering into their development

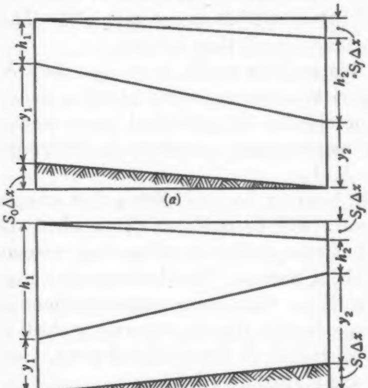

FIG. 7.

Fig. 7 shows the relationships that must obtain between two adjacent sections a distance, Δx, apart. The distance, Δx, is finite, the only limitation being that the surface curve is considered to have a uniform slope in that length. For a sustaining bed slope, Fig. 7(*a*) yields $S_0 \Delta x + y_1 + h_1 = y_2 + h_2 + S_f \Delta x$; whence,

$$\Delta x = \frac{\Delta \epsilon}{S_f - S_0} \quad \ldots\ldots (20)$$

in which $\Delta \epsilon = (y_1 + h_1) - (y_2 + h_2)$—that is, the loss of specific energy in the reach, Δx. It is considered positive downward since there can be no gain in energy with constant flow; S_f is also positive being merely the rate of energy loss by friction.

A similar expression from Fig. 7(*b*) for adverse slope, results in,

$$\Delta x = \frac{\Delta \epsilon}{S_f + S_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Equations (20) and (21) are perfectly general[22] and apply to any regular channel in which the area is a function of the depth; that is, rectangular, trapezoidal, circular, triangular, parabolic, etc.

If there are energy losses in addition to friction, such as impact or eddy losses, they are deducted from the total energy losses. Thus, the general surface curve formula as indicated in Fig. 7(*c*), may be written,

$$\Delta x = \frac{\Delta \epsilon - i}{S_f \mp S_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

[21] Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

[22] "New Method of Computing Backwater and Drop Down Curves", by Alva G. Husted, *Engineering News-Record*, April 24, 1924, p. 719.

depending on whether the bed slope is sustaining or adverse. In Equation (22), i = head losses due to impact and eddies.

Whenever velocities are diminishing as in expanding conduits, there is an inherent eddy loss, i, in addition to the normal channel friction. The varied flow functions necessarily assume full recovery of velocity head which is never realized.

* Energy head above the channel bed. † For $n = 0.025$.

Equations (20), (21), and (22) are applied step by step, computing directly without trial—the length, Δx, corresponding to successive increments or decrements of depth. All that is required is a starting point; the computations may proceed either up stream or down stream. Table 4(*a*) shows the computations for the author's Example 1.

There are no "conveyance" factors involved; nor are normal depths, y_o, normal slopes, S_o, or critical slopes, S_c, required. Before the varied flow functions can be applied, all the various functions of the cross-section for all depths within the range must be computed[23] and curves must be drawn in order to determine the normal depth parameter; the normal and critical slopes, from which to find the constant, β, must also be obtained. The exponent, n, must be found or assumed, and, therefore, a set of computations as complete as those of Table 4(*a*) must be made before one begins to apply the varied flow function—and then one must have the varied flow tables.

[23] See "Hydraulics of Open Channels", by B. A. Bahkmeteff, M. Am. Soc. C. E., p. 321, for the system of curves required for Example 1.

All that is required for Table 4(*a*) is a slide-rule and a table of Kutter coefficients. The distance between depths of 3.0 and 5.0 ft by the method herein outlined, 440 ft—the author gives 459 ft—a fair agreement.

The curves of Fig. 4 of the paper are certainly in error because the varied flow functions assume complete recovery of velocity head in the expanding water prisms from the gate to the end of the critical depth. Moreover, for the channel and flow given, the critical depth is 4.5 ft instead of 4.4 ft as given by the author.

Table 4(*b*) shows the computations by the method herein outlined. The total length between depths of 1.5 and 4.5 was found to be 734 ft, whereas between depths of 3.0 and 3.5, it is 123 ft. This length, using smaller depth increments, was found to be:

Depth increment, in feet	Distance, in feet, between depths of 3.0 and 3.5 feet
0.5	123
0.2	125
0.1	126

In Example 2 the author gives 160 ft for that distance. In searching for these discrepancies, the writer finds the varied flow functions very sensitive, even to dropping fourth place decimals in interpolation. He also finds[24] that the exponent, n, for this channel is 3.1 for depths less than 4.0 ft, and 2.75 for depths greater than 4 ft. The author used 3.0 throughout.

Table 5 shows the writer's findings for the distances from the gate to the critical depth in the author's Example 2, using the varied flow function. The last value (756 ft) compares favorably enough with the 734 ft of Table 4(*b*).

TABLE 5.—Distances from the Gate to the Critical Depth in Example 2

Exponent, n	Critical depth, y_c, in feet	Distance, in feet, from gate to critical depth
3.0	4.4	821
3.0	4.5	842
3.1 and 2.8	4.5	756

The writer found the distance between depths of 3.0 and 3.5 and $n = 3.1$ by differently interpolating the function, but confining the results to three decimal places: $y_1 = 3.0$; $\eta_1 = 0.374$; $B'(\eta_1) = 0.342$ or 0.343; $y_2 = 3.5$; $\eta_2 = 0.405$; and, $B'(\eta_2) = 0.398$ or 0.399; hence, by the author's Equation (13),

$$l_{2-1} = \frac{8.65}{0.0004}\left[-(0.405 - 0.347) + 1.17\,(0.398 - 0.343)\right] = 130 \text{ ft}$$

or,

$$l_{2-1} = \frac{8.65}{0.0004}\left[-(0.405 - 0.347) + 1.17\,(0.399 - 0.342)\right] = 195 \text{ ft}$$

This shows a variation of 50% in the computed length.

[24] See "Hydraulics of Open Channels", by B. A. Bakhmeteff, M. Am. Soc. C. E., p. 318.

The author gives this length as 160 ft, whereas the writer found 126 ft by his method. All methods (including those of the writer) are in error, however, because complete velocity-head recovery was assumed, and such recovery is impossible of realization.

The simple method outlined herein can readily take into account these eddy losses. They are usually estimated to be some percentage of the negative change in velocity head between adjacent sections. This percentage may be any value from 10 to 100, depending on the character of the channel and the judgment of the engineer; 10% to 20% may be used for artificial channels such as are treated herein, whereas 50% is a fair value for ordinary river channels. The effect of including eddy losses is to shorten the length between given depths.

If the varied flow function is to be used, the tables should be extended to at least four decimal places in order to avoid discrepancies due to interpolation.

F. T. MAVIS,[25] M. AM. SOC. C. E. (by letter).—Depending upon the reader's point of view this paper may be considered either as a valuable supplement to previous discussions of steady, non-uniform (or varied) flow in open channels, or as an academic treatment of a special case of the broadly general back-water problem. In the first category the paper is so much a part of its antecedent[3] as to be scarcely legible except by frequent reference to it. In his practical examples the author leaves his reader to glean from other sources that, in Fig. 3, Kutter's n is 0.025 and, in Fig. 4, 0.013. Needless reference to authority for definitions of such terms as "the hydraulic exponent, n", and the critical slope, S_c, seems to be unwarranted when these terms are so readily definable. (For a given depth of flow, S_c is the normal (or neutral) slope required to produce a velocity head equal to one-half the hydraulic mean depth; $S_c = \frac{g p}{C^2 t}$, in which g = acceleration of gravity; p = wetted perimeter; C = the Chezy coefficient; and t = width of water surface; n is twice the slope of the curve on logarithmic paper, showing $K = C A \sqrt{R} = \frac{Q}{\sqrt{S}}$ as ordinates, and the corresponding depth of flow, y, as abscissas.)

In the "Synopsis" the author states that "practical application [of the general equations for varied flow in channels of adverse slope] depends on knowing the numerical values of a function, similar to the 'varied flow function', for canals of sustaining slopes."

It is the writer's opinion that the practical solution of back-water problems cannot be safely discussed in the abstract. In important practical problems one may well be wary of the better-known back-water functions, except as general guide-posts. Ignoring the simple, academic problems, the practical solutions withstand the tests of future observations and the Courts, rather on the strength of reliable basic data and the experience and sound judgment of a competent engineer than on the details of the methods of computation.

[25] Prof. and Head, Mechanics and Hydraulics, and Cons. Engr., Iowa Inst of Hydr. Research, Univ. of Iowa, Iowa City, Iowa.

Among the essentials to the practical solution of back-water problems it may be stated that:

(1) The engineer must be thoroughly acquainted with the conduit. Given adequate profiles, cross-sections, and field data, he must draw on a rich background of experience in the assignment of roughness factors and effective flow sections in curved and irregular conduits.

(2) The relation between flow and corresponding head losses must be assumed. In the simpler cases this is usually expressed as a formula for the mean velocity of flow in terms of the roughness factor, hydraulic radius, and the friction slope.

(3) Obviously, the computer must be well-grounded in the fundamentals of hydro-mechanics—work and energy (Bernoulli's theorem), and impulse and momentum—and in their application. It is desirable that he possess an aptitude for simplifying and idealizing a given problem for purposes of computation without introducing significant or uncertain errors.

In practice, those who must solve back-water problems of importance are likely to develop their own methods of analysis—based generally on the equivalent of the author's Equation (2) and applied to the effective conduit.

In back-water problems of rivers the distances between valley cross-sections are usually fixed by the surveys. Therefore, explicit relations for length of reach, similar to Equation (7), may not be as convenient as a more elementary form of equation, based on steady flow within a short reach, solved by trial.

Fundamentally, there is no difference between the author's method of computing back-water curves by the so-called "varied flow functions" and methods of successive approximation applied to short reaches of a stream. For a short reach, a regular channel, and steady flow, Fig. 1 and Equation (2) apply equally well to all methods.

In the method of successive approximations each reach presents a definite problem of determining for a given discharge the relation between water-surface elevation and slope at the mean section. Furthermore, the water-surface elevations at the common sections of adjacent reaches must coincide. A consistent water profile is obtained by successive trial computations. The difference in water-surface elevations at two sections is found simply by the numerical addition of the products of each intervening length of reach and its corresponding surface slope.

In the author's method the problem which involves definite physical factors, such as discharge, in cubic feet per second, elevations (or depths), in feet, and slopes of water surfaces, is early obscured by the introduction of the dimensionless ratios, $\eta = \dfrac{y}{y_0}$, $\beta = \dfrac{S_0}{S_c}$, and $n = 2\,\dfrac{y}{K}\left(\dfrac{dK}{dy}\right)$. Each of these ratios is a function of y, the depth of flow in the conduit, although there may be no significant error introduced by assuming β and n to be constant for purposes of integration. Although integration is often a convenient method of finding the sum of a column of figures that represent some regular, analytical (or graphical) array of numbers, the integration leading to the

B' (η)-functions replaces, in part, the numerical addition of products of each length of reach, and the corresponding surface slope aforementioned—nothing more.

For the solution of back-water problems in regular, artificial conduits, such as canals, sewers, etc., it may be that the so-called "varied flow functions" may effect a saving in time over the more elementary method of successive approximations. However, for practical river problems in which back-water curves are important, the author's method seems to be distinctly inferior to the method of successive approximations in which there is no necessity for overlooking such factors as roughness and effective sections, and obscuring such physical quantities as elevation, slope, and discharge, by introducing dimensionless ratios.

HUNTER ROUSE,[26] ASSOC. M. AM. SOC. C. E., AND MERIT P. WHITE,[27] JUN. AM. SOC. C. E. (by letter).—An effort such as this, to make available to hydraulic engineers additional means of simplifying open-channel design, should be welcomed by the hydraulic world. Although the subject of sustaining slopes has been covered amply elsewhere, this is the first successful attempt to provide both an outline of procedure and tabular values for the solution of problems of adverse slope. The labor of determining the numerous values of the B' (η)-function is not to be under-estimated, although the many hours given by the author to this tedious computation have been well spent.

It seems to the writers that the author's method of arriving at what should be a general equation of varied flow does not lend full clarity to the physical principles involved, for the procedure adopted with respect to signs tends to conceal the basic nature of the problem rather than to explain it. Indeed, the use of an upward—and hence negative—slope at times as a positive value is often confusing.

Mr. Matzke has designated a downward slope as positive and an upward slope as negative; to be consistent, this notation must apply as well to the slope of the water surface and of the energy line as to the slope of the channel bottom. The symbol for the slope of the water surface, S_w, for instance, therefore, denotes either a downward slope or an upward slope, depending upon whether its value is greater or less than zero. Referring to Fig. 8, the elevation of the free surface at any section, regardless of slope, is equal to the depth, y, plus the elevation of the channel bottom, h_0. Letting H_p represent the total potential head, or the vertical distance from the assumed geodetic datum to the water surface:

$$H_p = y + h_0 \qquad (23)$$

The rate of change of this surface elevation in the positive direction of flow is then simply the derivative of the potential head with respect to x:

$$\frac{dH_p}{dx} = \frac{dy}{dx} + \frac{dh_0}{dx} \qquad (24)$$

[26] Asst. Prof. of Fluid Mechanics, SCS, California Inst. of Technology, Pasadena, Calif.

[27] Asst. Engr., SCS, Iowa Inst. for Hydr. Research, Iowa Univ., Iowa City, Iowa.

Since a downward slope is positive (that is, greater than zero), and signifies a negative rate of change of elevation,

$$\frac{dH_p}{dx} = -S_w = \frac{dy}{dx} - S_0 \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Equation (25) is offered in preference to Equation (1), for it is mathematically correct for both positive and negative slopes of the water surface and for both sustaining and adverse slopes of the channel bottom.

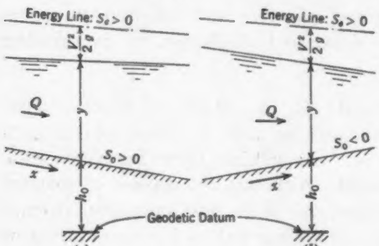

FIG. 8.

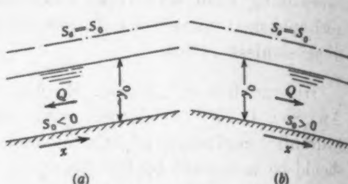

FIG. 9.

Proceeding in a similar fashion, the total head, H, above the arbitrary geodetic datum at any section is equal to the sum of the velocity head and the potential head (refer to Fig. 8):

$$H = \frac{V^2}{2\,g} + y + h_0 \ldots\ldots\ldots\ldots\ldots\ldots (26)$$

The rate of change of total head in the positive direction of flow is then simply the derivative of this expression, with respect to x:

$$\frac{dH}{dx} = \frac{d}{dx}\left(\frac{V^2}{2\,g}\right) + \frac{dy}{dx} + \frac{dh_0}{dx} \ldots\ldots\ldots\ldots\ldots (27)$$

Since the positive rate of change of total head is equal to the negative rate of loss of total head, $\frac{dH}{dx} = -\frac{d\,e_r}{dx}$, the latter derivative being used in Equation (2); and since a positive rate of loss corresponds to a positive or downward slope,

$$\frac{dH}{dx} = -S_e = -\frac{d\,e_r}{dx} = \frac{d}{dx}\left(\frac{V^2}{2\,g}\right) + \frac{dy}{dx} - S_0 \ldots\ldots\ldots (28)$$

Equation (28) is offered to replace Equation (2); it is quite as general as Equation (25).

The Chezy equation,

$$Q = A\,C\,\sqrt{R\,S_e} \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

expresses the rate of discharge, Q, in terms of the cross-sectional area of flow, A; a coefficient, C; the hydraulic radius, R; and the slope of the energy line, S_e. The first three terms, A, C, and R, depend only upon the cross-sectional shape and roughness of the channel and the variable depth of flow, and may all be determined as functions of y for a given channel. As shown by Bakhmeteff[9], the product, $A\,C\,\sqrt{R}$, as a function of y may conveniently be given the symbol, K, to denote the "conveyance" of the channel; hence,

$$Q = K\sqrt{S_e} \qquad (30)$$

If the discharge and the conveyance are such that for the given bottom slope, S_o, the depth of flow is uniform over the entire channel, then $y = y_o$ and the slope of the energy line, S_e, is equal to both the surface slope, S_w, and the bottom slope, S_o. For such conditions,

$$Q = K_o\sqrt{S_o} \qquad (31)$$

The term, K_o^2, is used as a convenient relative parameter for flow on sustaining slopes, and has been adopted by the author for adverse slopes as well. Since uniform flow on adverse slopes is an artificial condition, such usage may well bear further analysis.

Although S_w and S_o may be either positive or negative with flow in the positive x-direction, a negative value of S_e can only signify flow in the negative x-direction, for the energy line must invariably slope downward in the direction of flow. Hence, the equation of uniform flow,

$$Q = A\,C\sqrt{R}\sqrt{S_o} = K_o\sqrt{S_o} \qquad (32)$$

when used as a flow parameter, must be such that for negative values of S_o the discharge will also be negative (that is, it will still be in the direction of decreasing energy and downward bottom slope (see Fig. 9)). Thus, Q^2 and $K_o^2\,S_o$ are invariably positive, regardless of whether the numerical value of S_o is positive or negative.

A plot of $S_o = \dfrac{Q^2}{K_o^2} = \dfrac{\text{constant}}{K_o^2}$, shown schematically in Fig. 10, indicates clearly the fact that for negative values of S_o the conveyance, K_o, must be imaginary, since its square is negative. This may be true only if the coefficient, C, becomes imaginary for all negative values of S_o, since A and R are invariably positive. In the relationship, $Q^2 = K_o^2\,S_o$, used by the author following the procedure outlined by Bakhmeteff[9], the imaginary root, $i = \sqrt{-1}$, contained in K_o for negative values of S_o, therefore, cannot be neglected.

Such discontinuity in the conveyance function will be more clearly understood if one recalls that as the slope of a channel approaches zero, the discharge thereby remaining constant, the uniform depth must approach infinity in order that the slope of the energy line may also approach zero. If the slope of the bottom continues to decrease, once it is less than zero uniform conditions are quite impossible unless the flow reverses in direction.

Continued use of the uniform flow relationship of Equation (32) as a parameter for varied flow in the positive x-direction naturally requires that this equation be mathematically consistent.

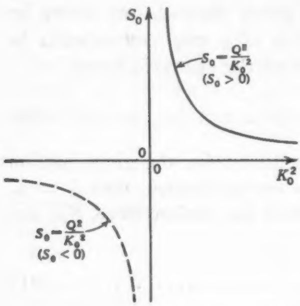

FIG. 10.

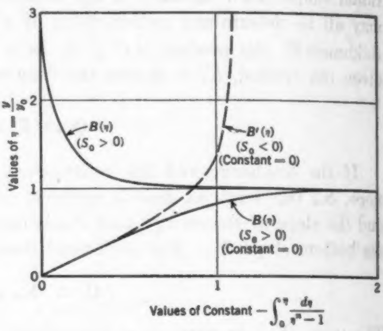

FIG. 11.

The following substitutions are now in order, after the method taken by the author from the cited text[2]:

$$S_e = \frac{Q^2}{K^2} = S_0 \frac{K_0^2}{K^2} \qquad \text{.....................(33)}$$

$$\frac{d}{dx}\left(\frac{V^2}{2\,g}\right) = -\frac{Q^2}{g}\,\frac{b}{A^3}\,\frac{dy}{dx} = -\frac{S_0\,K_0^2}{g}\,\frac{g}{S_c\,K^2}\,\frac{dy}{dx} = -\frac{S_0}{S_c}\,\frac{K_0^2}{K^2}\,\frac{dy}{dx} \qquad \text{..(34)}$$

and,

$$\beta = \frac{S_0}{S_c} \qquad \text{...........................(35)}$$

Introducing Equations (33), (34), and (35) in Equation (28),

$$-S_0\,\frac{K_0^2}{K^2} = -\beta\,\frac{K_0^2}{K^2}\,\frac{dy}{dx} + \frac{dy}{dx} - S_0 \qquad \text{.............(36)}$$

and, since K^2 varies as y^n:

$$\frac{dy}{dx} = S_0\,\frac{1 - \dfrac{K_0^2}{K^2}}{1 - \beta\,\dfrac{K_0^2}{K^2}} = S_0\,\frac{1 - \left(\dfrac{y_0}{y}\right)^n}{1 - \beta\left(\dfrac{y_0}{y}\right)^n} \qquad \text{...........(37)}$$

Equation (37) is quite general, applying to positive and negative slopes of the water surface and sustaining and adverse slopes of the channel bottom; as such it is offered as an improvement on Equation (4). One need only remember that when S_0 is negative, K_0^2, and hence, y_0^n, must have negative numerical values owing to the square of the imaginary i. That β will, of itself, become negative is quite evident, since it then represents the quotient of two slopes of unlike sign, S_c always being positive.

From the relationships, $\eta = \frac{y}{y_o}$ and $dy = y_o\, d\eta$:

$$\frac{y_o}{S_o}\frac{d\eta}{dx} = \frac{1 - \frac{1}{\eta^n}}{1 - \beta\frac{1}{\eta^n}} = \frac{\eta^n - 1}{\eta^n - \beta} \quad \ldots\ldots\ldots\ldots\ldots\ldots(38)$$

which becomes, through division,

$$\frac{S_o}{y_o}\, dx = \frac{\eta^n - \beta}{\eta^n - 1}\, d\eta = d\eta + (1 - \beta)\,\frac{d\eta}{\eta^n - 1} \quad \ldots\ldots\ldots(39)$$

Equation (39) is offered to replace Equation (5). The term, η^n, now becomes negative with negative values of S_o, again owing to the imaginary value of C.

Integration of Equation (39) between the limits, x_1 and x_2, and η_1 and η_2, will be as follows:

$$\frac{S_o}{y_o}(x_2 - x_1) = \frac{S_o}{y_o}\, l_{2-1} = \eta_2 - \eta_1 + \int_{\eta_1}^{\eta_2} (1 - \beta)\,\frac{d\eta}{\eta^n - 1} \quad \ldots\ldots(40)$$

Equation (40) is completely general, and as such is to be recommended instead of Equation (6). For positive values of S_o, after Bakhmeteff[9].

$$\int_o^{\eta} \frac{d\eta}{\eta^n - 1} = \text{constant} - B(\eta) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(41)$$

When $\eta < 1$, the constant has been taken as zero in computing the values of $B(\eta)$ given by Bakhmeteff[9]. Equation (40) then becomes, for $S_o > 0$,

$$l_{2-1} = \frac{y_o}{S_o}\left[\eta_2 - \eta_1 - (1 - \beta)\left(B(\eta_2) - B(\eta_1)\right)\right] \quad \ldots\ldots\ldots(42)$$

For negative values of S_o and hence of η^n, following the same designation as to sign,

$$\int_o^{\eta} \frac{d\eta}{\eta^n - 1} = -B'(\eta) \quad \ldots\ldots\ldots\ldots\ldots\ldots(43)$$

in which the numerical values of the function, $B'(\eta)$, are correctly given in Table 2. Thus, when $S_o < 0$,

$$l_{2-1} = \frac{y_o}{S_o}\left[\eta_2 - \eta_1 - (1 - \beta)\left(B'(\eta_2) - B'(\eta_1)\right)\right] \quad \ldots\ldots\ldots(44)$$

which is fully commensurate with Equation (42), and as such is offered in preference to Equation (7). The form of the function, $-\int_o^{\eta} \frac{d\eta}{\eta^n - 1}$, for values of S_o and η^n greater and less than zero is indicated in Fig. 11.

The writers believe that adherence to the foregoing rigorous and general development will avoid confusion in the future treatment of varied flow; this development will also explain the apparent dissimilarity in the equations for adverse and sustaining slopes in the paper.

In closing, two essential points already discussed at length by Professor Bakhmeteff[2] might well be emphasized. First, the development of the varied flow relationships is based entirely upon the assumption of motion in which the curvature of the stream lines is not appreciable, and in which the pressure distribution, therefore, is hydrostatic. The surface curve is thus a function of varying resistance and is independent of the dynamic effects of rapid acceleration or deceleration. In the neighborhood of the critical depth, however, curvature actually becomes of major importance, and only because of the great length of channel involved in the resistance curve can this phenomenon of local transition be disregarded.[28] Second, success in applying these relationships in the accurate design of channels depends entirely upon the proper determination of the Chezy coefficient, C. At present, this must depend upon one or another of the several empirical relationships for C, not one of which can stand a rational analysis. Only when resistance in open channels is as well understood as that in circular pipes can the treatment of open-channel flow be improved by more sound physical relationships; however, although pipe resistance depends largely upon wall roughness, the open channel introduces as further variables the cross-sectional form and the non-uniformity of longitudinal profile, both of which can influence C to an appreciable degree. This is probably the most fertile field of present-day hydraulic research—surely the most imperative.

ARTHUR E. MATZKE,[29] JUN. AM. SOC. C. E. (by letter).—The case of varied flow in open channels of adverse slope occurs rather seldom in practice. The extent of the discussion, therefore, was rather surprising and most pleasing. The rarity of occurrence also made the fact that the method presented in the paper was applied in such an important structure as the Cape Cod Canal even more gratifying. The kind reference made by Captain E. C. Harwood[30], Corps of Engineers, U. S. Army, would seem to offer ample compensation for the time spent.

The approach of most of the discussers was from a rather general point of view without direct reference to any particular practical application. In fact, much of the discussion extended beyond the scope of the problem actually treated and compared methods to be used in handling general cases of varied flow. Messrs. Stevens and von Bergen centered their remarks on the relative merits of computations by means of the varied flow function by comparison with the method of successive approximations.

Historically, the method of successive approximations begins with the work of Belanger (1827). In fact, his treatment is so complete that, fundamentally, nothing has been added since. It is interesting to note, however, that the tendency and the endeavor in the past hundred years on the part of Belanger's pupils and legatees was to substitute for the treatment by approximations a more analytical solution obtained by integrating the varied flow equation. The work of Dupuit (1848), Bresse (1860), Rühlmann (1880).

[28] See "Discharge Characteristics of the Free Overfall", by Hunter Rouse, *Civil Engineering*, April, 1936, p. 257.

[29] Research Asst., Dept. of Civ. Eng., Columbia Univ., New York, N. Y.

[30] "Proposed Improvement of the Cape Cod Canal", *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1473.

Tolkmitt (1892), Schaffernak (1914), and Professor Bakhmeteff (1932), might be viewed as the gradual development of this idea. Indeed, Professor Mavis seems to characterize this application of integral calculus as nothing more than a convenient method of summation of a column of figures that represent some regular, analytical (or graphical) array of numbers.

There is another point which should be mentioned in the hope of clearing up a misconception. The comparison of methods by Messrs. Stevens and Mavis is presented principally with regard to natural watercourses. As far as the paper is concerned, natural watercourses were not mentioned. In fact, Professor Bakhmeteff specifically mentions the method of successive approximations as particularly applicable to computing back-water curves in rivers. It may be interesting to remember that, in the past, back-water curves in rivers constituted the principal practical subject in the realm of varied flow. However, at present, the complex cases arising from irrigation, water power, and navigation projects, with canals working under different levels and discharges, have practically transferred the problems connected with them into a different field. As an example, one may cite the delivery problem (Example 3). Any one who would try to solve it by approximations instead of the varied flow function would soon realize the actual state of affairs.

The writer is grateful to Messrs. Stevens and Howland for demonstrating the inaccuracy in part of the tables of values of the varied flow function. The simple graphical method which was used in obtaining these tables is presented in the paper. This was done to enable those who found the tables inadequate for their purposes to obtain satisfactory values. Since the method was graphical, the limit of accuracy of the values is a function of the scale of the drawing.

In deriving Equation (21), which is described as "perfectly general", Mr. Stevens refers to Fig. 7(a) which depicts a sustaining slope. He then writes a formula (Equation (20)) in which $\Delta\epsilon$ is defined as "the loss of specific energy in the reach, Δx." Consideration of the specific energy curve and the fact of the existence of surface curves of the type referred to by Professor Bakhmeteff as S_1, S_2, S_3, and M_3 shows conclusively that it is possible for $\Delta\epsilon$ to be a gain in specific energy as well as a loss. Wherever the work done by gravity in transporting a quantity of water over the distance, Δx, is greater than the work done by friction, etc., in the same process, it follows necessarily that the difference between the two must be stored in the water in the form of an increase of specific energy. This is fundamental and highly important. In Fig. 1 and throughout the paper, S_0 is a symbol for bottom slope just as it is in Mr. Stevens' discussion, and does not refer to a "normal slope."

Thanks are due Mr. Lenz for his investigation and verification of the exponential relation between K and y. The regular behavior of his discharge rating curve is most convincing. It answers in part, at least, the doubts concerning the behavior of n expressed in other discussions. The writer is also deeply grateful to Messrs. Rouse and White for their truly rigorous development and generalization of the solution.

With Discussion by Messrs. Bayard F. Snow, Ole Singstad, Verne Gongwer, and Stanley M. Dore.

Note.—Published in March, 1936, *Proceedings*.

FOREWORD

By Frank E. Winsor[1], M. Am. Soc. C. E.

The Metropolitan Water District is one of the oldest districts of its kind in the United States, having been established in 1895, following previous investigations which had shown conclusively that many of the communities of which Boston, Mass., is the center could no longer cope with the problem of independent water supplies. Metropolitan Boston is the fourth most populous center in this country, and probably has more independent political units than any other. In addition to 35 cities and towns within a 10-mile radius of the State House in Boston, there are many other communities with populations of from 15 000 to 100 000 within 30 miles. The Metropolitan Water District originally included Boston and thirteen other municipalities to which seven have since been added. Since 1919 this District has been administered by the Metropolitan District Commission. A population of about 1 500 000 is being supplied with Metropolitan water, 15 communities with a population of about 400 000 are entitled legally to join the District, and it may be reasonably expected that other communities with substantial populations will be permitted to join when their needs demand.

From 1895 to 1905 the District acquired the collecting sources and aqueducts owned by the City of Boston and extended the water supply for the District from the Sudbury River sources westward to the Wachusett Reservoir on the Nashua River, at Clinton, Mass., this reservoir having, since completion, furnished the major portion of the water for the District. Water is supplied by wholesale to each community and the community distributes it, fixes its own water rates, and pays its own bills. Payment for the water is based, two-thirds on the metered quantity used and one-third on assessed valuation, all the water being metered.

In 1926, following about eight years of investigation and reports, the Legislature created the Metropolitan District Water Supply Commission, charged mainly with the construction of a major addition to the water supply to be obtained from the Ware and Swift Rivers, which rivers form a part of the drainage area of the Connecticut River. The diversion from these rivers was opposed by the State of Connecticut, and following several years of litigation the Supreme Court of the United States, in March, 1931, fixed certain conditions under which the diversion is being effected with due regard to interstate rights.

The main features of the additional supply, the estimated cost of which was $65 000 000, are: (1) A tunnel, known as Quabbin Aqueduct, 24.6 miles in length, of the horseshoe type, with a waterway of 127 sq ft, extending westerly from Wachusett Reservoir to the Swift River; and (2) a reservoir, known as Quabbin Reservoir, in the valley of the Swift River, which reservoir will flood 25 200 acres to an average depth of about 50 ft, the capacity being 415 000 000 000 gal, or 1 270 000 acre-ft. At about midway of its length the

[1] Chf. Engr., Met. Dist. Water Supply Comm., Commonwealth of Massachusetts, Boston, Mass.

Quabbin Aqueduct passes 260 ft below the Ware River where diversion is effected through a shaft. After the completion of Quabbin Reservoir, water from the Ware River may be diverted either easterly or westerly and stored in either the Wachusett Reservoir or the Quabbin Reservoir. The Quabbin Aqueduct will be controlled by gates at Wachusett Reservoir, the relative elevations, in feet, above tide-water being: Wachusett, 395; Ware, 656; and Quabbin, 530.

The Ware River was first diverted in March, 1931, and the Quabbin Aqueduct was completed in 1935 sufficiently to permit diversion of the Swift River although such diversion is not contemplated unless the needs of the District require it, until the Quabbin Reservoir is completed probably late in 1939. The construction program has been planned to keep pace with the increasing demands for water and to delay capital expenditure and consequent increase in carrying charges as long as prudently possible.

The paper by Stanley M. Dore, M. Am. Soc. C. E., relates mainly to the foundations of the two earth dams of the Quabbin Reservoir, one known as the Dike with an embankment of about 2 500 000 cu yd, and the other known as the Main Dam with an embankment of about 4 000 000 cu yd. The valleys in which these dams are located are both filled with porous glacial drift to a maximum depth of 125 to 130 ft, and it was deemed necessary to build cut-off walls to rock to prevent seepage. The work of building these cut-off walls by the sinking of concrete caissons under air pressure, and the lowering of the ground-water by pumping, to reduce the air pressure required, are described in detail in Mr. Dore's paper. The work on these two dams illustrates the importance of thorough preliminary exploration. The feasibility of lowering the ground-water was demonstrated by exploratory caissons at both sites before bids were invited for building these structures. The uncertainties as to air pressure which would be required to sink the caissons, were eliminated to a great extent, resulting in more dependable and lower bids from contractors and a consequent material saving in the cost of the work to the Commission. So far as the writer is aware, unwatering of the ground on the scale and to the depths accomplished at these two dams is somewhat unique. The paper is a valuable contribution to the knowledge of the flow of ground-water through materials of varying permeability.

The paper by Frank E. Fahlquist, Assoc. M. Am. Soc. C. E., relates mainly to the geological and engineering investigations which were made preliminary to the location of the tunnel and to the tunnel construction. Adequate geological investigations coupled with intelligent sub-surface exploration are essential as a guide to the engineers in the location of such structures as the Quabbin Aqueduct and the dams of Quabbin Reservoir. The location of Quabbin Aqueduct was determined after a most thorough geological investigation supplemented by borings to determine the location and character of ledge rock. Several pitfalls which might have been very costly were thereby avoided, and in the tunnel excavation excellent rock was encountered for the entire 25 miles, with a negligible amount of timber support.

PERMEABILITY DETERMINATIONS, QUABBIN DAMS

By Stanley M. Dore[2], M. Am. Soc. C. E.

Synopsis

Several methods of determining the permeability of an earth over-burden which forms the foundation for a proposed dam are outlined in this paper. They are based on the assumption that either or both of two general sources of information is available: (1) Dry samples from bore-hole investigations; and (2) the effect of pumping upon the ground-water conditions in that overburden. These methods were developed in connection with permeability determinations at the sites of the Main Dam and Dike of Quabbin Reservoir,[3] 65 miles west of Boston, Mass., so that in order to describe fully and clearly the methods and their practicable applications much of the text deals with the particular conditions at those sites. The methods were developed primarily for use with materials of glacial origin, in cases where the earth cover is thick and the ground-water surface high in that earth cover, and if carefully applied, they can be adapted to give reasonable determinations under similar conditions elsewhere. Moreover, the principles involved may be adapted for use in cases where the materials are of a different nature, or where some of the other conditions are dissimilar.

Introduction

A major item in the construction of the Ware River and Swift River developments[3] for increasing the water supply for the Massachusetts Metropolitan Water District, which is comprised of the City of Boston and nineteen neighboring cities and towns, is the Quabbin Reservoir, formed by the construction of two similar earth dams named, for convenience, the Main Dam and the Dike. These two dams have been located in the low portions of the rim of the storage basin, the former being across the valley of the Swift River and the latter across the valley of Beaver Brook, a branch of the Ware River. Both of them are designed as earth dams to be placed by hydraulic methods, the Main Dam being about 2 640 ft long, 160 ft high above the original ground surface, and containing 4 000 000 cu yd of embankment, and the Dike being about 2 140 ft long, 135 ft high above the original ground surface, and containing 2 500 000 cu yd of embankment.

[2] Associate Civ. Engr., Massachusetts Met. Dist. Water Supply Comm., Boston, Mass.

[3] Described by Karl R. Kennison, M. Am. Soc. C. E., in "Boston Metropolitan Water Supply Extension", *Journal*, New England Water Works Assoc., Vol. XLVIII, No. 2, and by Frank E. Winsor, M. Am. Soc. C. E., in "Boston's New Water Supply", *Civil Engineering*, June, 1934, p. 283.

The foundations for these dams are in glacial materials, the deepest point in the underlying rock gorge at the Main Dam being about 120 ft below the river level and the Dike, 130 ft below the brook level. The ground-water surface in the valleys is approximately at the river or brook level for some distance on either side of the stream.

The location of bed-rock and the character of the over-burden were investigated at both sites by a large number of bore holes, which were made by driving $2\frac{1}{2}$-in. pipes by wash-boring methods supplemented by core-boring methods through the larger boulders or into ledge. So-called dry samples of the over-burden were obtained about every 5 ft by driving a sampling tool into the materials below the bottom of the pipe-casing. Cores of boulders and ledge also were secured.

The rock valley cross-sections (shown in Figs. 1 and 2) are found to be the usual smooth, rounded, inverted-arch shape of valleys eroded by glacial action. In general, the rock is not decayed; nor is it badly seamed or broken. The types of rock appear to be gneisses, ranging from hornblendic to granitic types, but generally hard and sound.

The dry samples taken show the over-burden to be a glacial drift accumulation, mostly silts, sands, gravels, and boulders or mixtures of them. Later excavations show that these materials lie in pockets or lenses generally horizontal, but absolutely void of any stratification or orderly relation. Occasional streaks or pockets of rock flour were present usually running through the finer sandy deposits, and streaks, pockets, and lenses of very coarse gravel exist elsewhere. Geological sections are shown in Figs. 3 and 4. The names given to the numbered classes, which are those of the Kendorco classification described subsequently herein, in these sections differentiate them according to their relative pervious qualities, and each "variable" class contains a considerable number of larger particles. The meaning of the term, "uniform", is that only a small percentage of the material has particles larger or smaller than the average. The meaning of the term, "variable", on the other hand, is that a considerable number of particles is larger and smaller than the average. These materials are such that they would offer firm and stable support for the earth dams, but the desirability of a cut-off to ledge through these deep over-burdens depends upon their water-tightness. Studies were made to investigate their permeable qualities. The rock in the valley floors, being sound, is assumed to be water-tight, as its water-carrying capacity is negligible compared to the capacity of any of the materials in the over-burdens.

Preliminary investigations indicated that a water-tight cut-off would probably be desirable. Various types of cut-offs were considered, including open-cut trench to ledge, the driving of steel sheet-piling to ledge, the grouting of the foundation materials with cement grout or dobie, a concrete core wall to ledge by sheeted trench methods, and a concrete core wall to ledge by open or by pneumatic caisson construction. Preliminary estimates indicated that some kind of caisson core-wall construction would probably furnish the most economical cut-off.

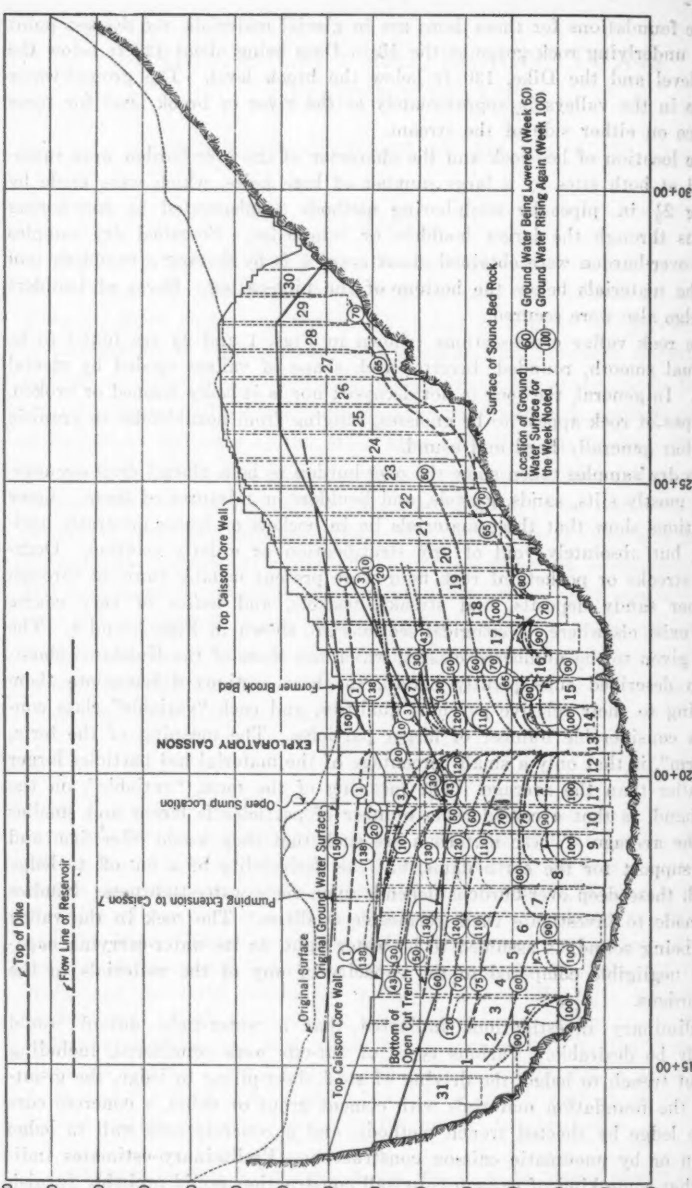

FIG. 1—CROSS-SECTION OF BEAVER BROOK AT THE SITE OF QUABBIN DIKE

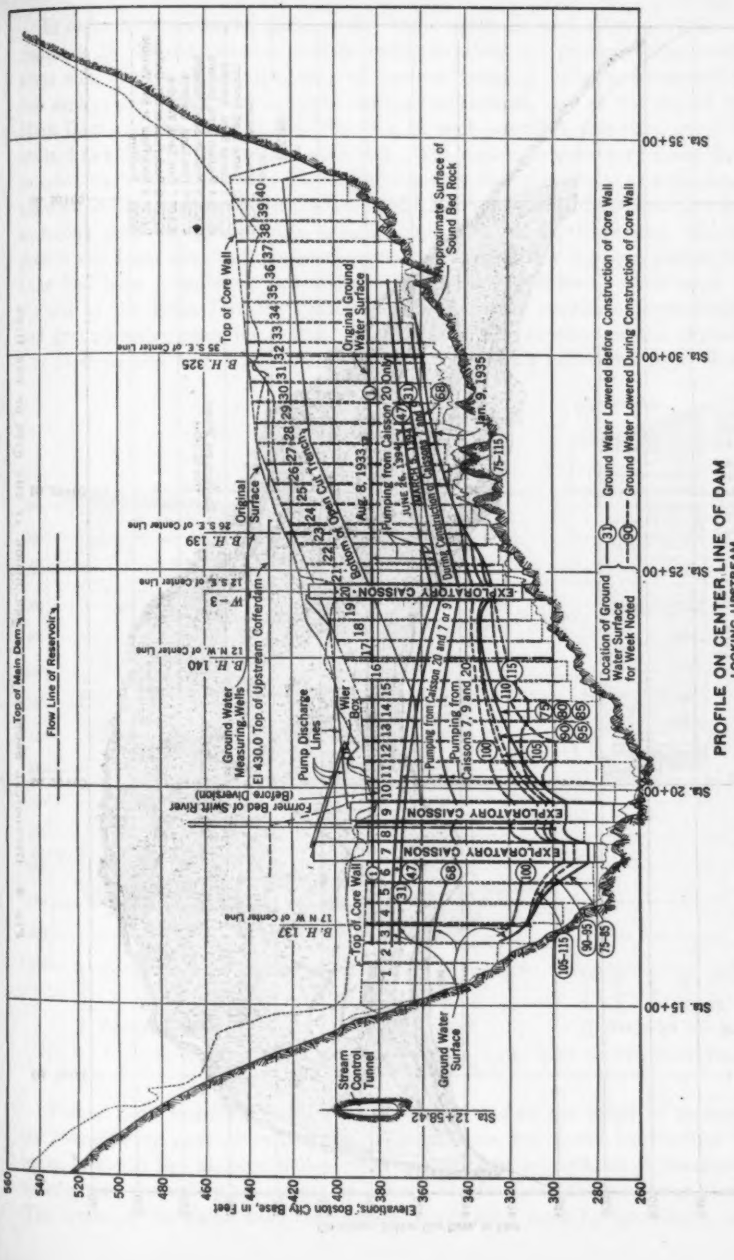

FIG. 2.—CROSS-SECTION OF SWIFT RIVER VALLEY AT THE SITE OF THE MAIN DAM

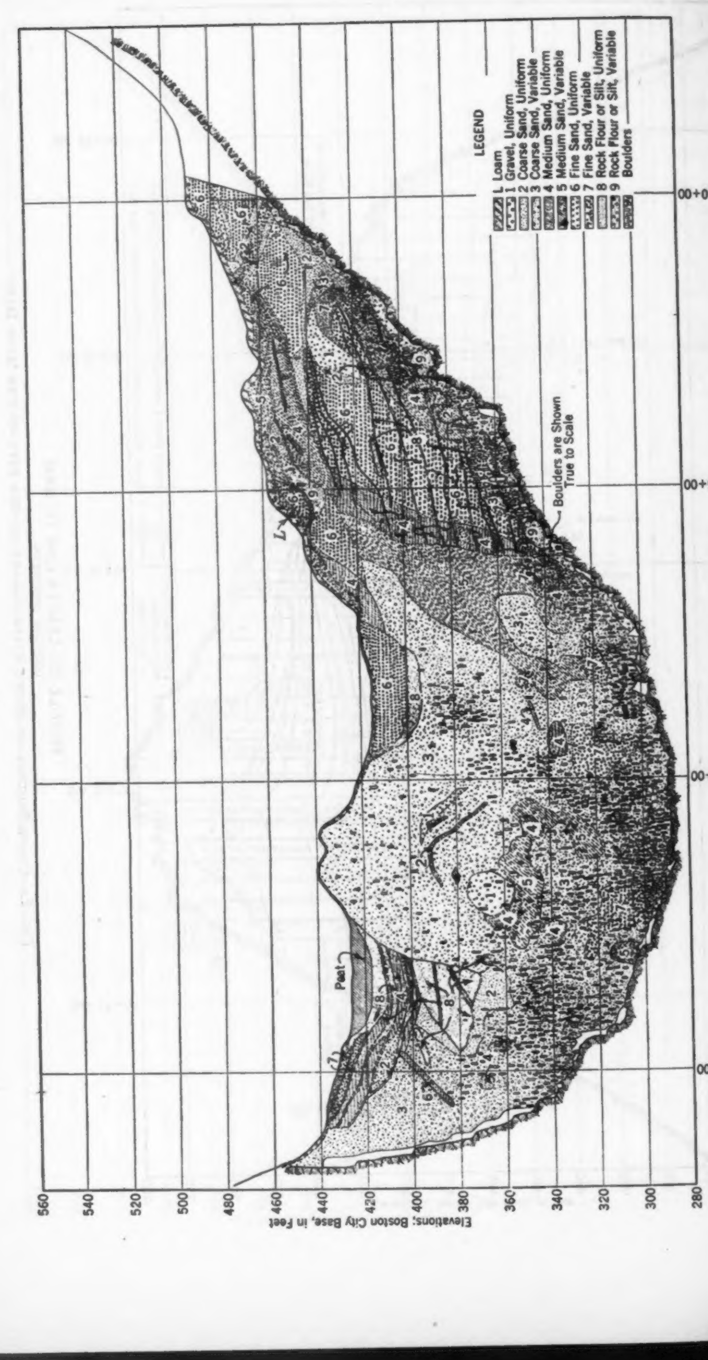

FIG. 3.—GEOLOGICAL SECTION OF BEAVER BROOK AT THE SITE OF THE DIKE

In order to investigate, further, the water-tightness and other qualities of materials in the over-burden, and in order to study the ground-water conditions and the feasibility and cost of various types of caisson construction, two exploratory reinforced concrete caissons were sunk, one at the site of the Main Dam and the other at the Dike site, in such positions that each could be utilized as a part of the finished core-wall. The materials excavated from these caissons were examined very thoroughly, and it was possible to obtain much more satisfactory information regarding the characteristics of the over-burden, including data concerning the number and sizes of boulders and cobbles, than it was from the small bore-hole samples. Later, after the core wall of the Dike had been completed, two additional exploratory caissons were sunk at the site of the Main Dam to assist in the exploratory studies of over-burden and ground-water pumping. Figs. 1 and 2 show the location of the exploratory caissons and Fig. 4 shows a chart of the materials excavated from them.

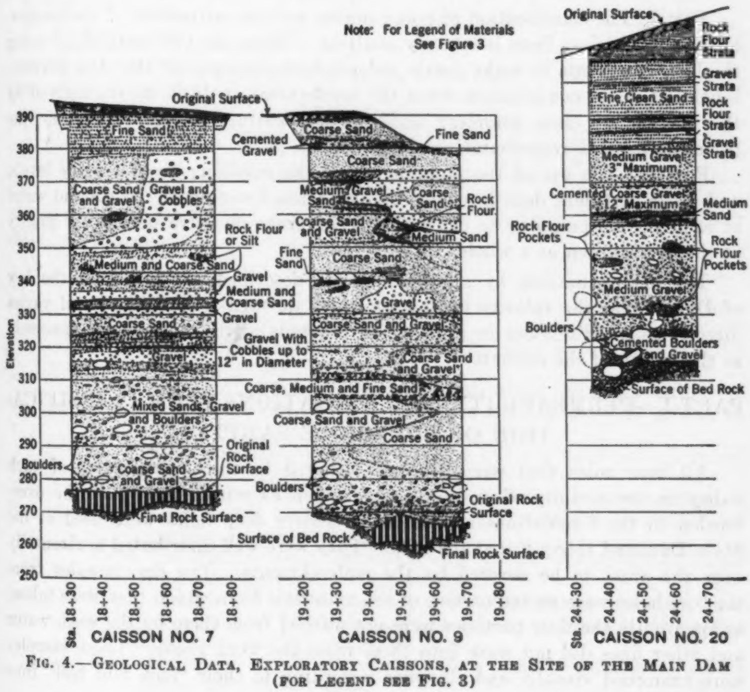

FIG. 4.—GEOLOGICAL DATA, EXPLORATORY CAISSONS, AT THE SITE OF THE MAIN DAM (FOR LEGEND SEE FIG. 3)

Pumps were installed in caissons at each site, and the effect of pumping the surrounding ground-water from these caissons was noted by reading the water levels in 2½ - in. pipe wells driven by wash-boring methods at designated locations in the valley up stream and down stream from the pumping plants. The levels of the water were read several times each week by lowering a cup-

shaped washer into the wells. In addition to aiding in the determination of the effective water-tightness of the glacial materials in the valley over-burden, the effect of pumping also demonstrated the feasibility of unwatering the over-burden, and the extent to which it would be practicable and economical so to do.

As used in this paper, the term, "permeability", measured in units of million gallons per acre per day at 50° F, for a slope of unity, denotes the rate at which soils, sands, and gravels will transmit water. "Porosity" is the expression used to denote the percentage of a given volume composed of air and water pockets or "voids" in the materials in that volume.

Characteristics of the Over-Burdens

The permeability of the over-burden at each site is determined by two general methods given in Parts I and II, as follows:

Part I: The classification of bore samples and the estimation of the permeability of each class from laboratory analyses. There are two methods of using the laboratory data to make partly independent estimates of the class permeabilities: (*a*) By computation from the mechanical analysis curves derived by the sieving of class samples; and (*b*) by testing in the laboratory the permeabilities of representative class samples.

Part II: The use of the pumping rates, the resulting ground-water levels, and other pertinent data in connection with the lowering of the ground-water at each site by pumping to determine the average effective permeable quality of the over-burden as a whole.

The determinations by all the methods described are based on the law of Darcy[4] that the velocity of flow of water through a column of soil varies directly as the difference in pressure on the ends of the column and inversely as the length of the column.

PART I.—PERMEABILITY DETERMINATIONS FROM CLASSIFICATION OF BORE-HOLE SAMPLES

All bore holes that were properly situated in the deeper parts of each valley in the vicinity of each site were taken as representative of the over-burden in the foundations at that site. Thirty deep holes were used at the Main Dam and thirty-five at the Dike. They were well distributed horizontally over the areas to be covered by the embankments. The dry samples from the bore-holes were representative of the materials from which they were taken, as apparently the finer particles were not washed from them by the wash water and other fines did not wash into them from the work above. These samples were examined visually and classified according to their "look and feel" into nine arbitrary divisions.

The Classification

This classification is named the "Kendorco Classification" and was developed for use on this project to denote and describe roughly the general kinds

[4] "Les fontaines publiques de la ville de Dijon", by H. Darcy, 1856.

of the glacial soils in the vicinity. Of course, there are no distinct divisions between the classes, but attention is called to the general differences in physical characteristics given in Table 1 and to the arbitrary limits set for the

TABLE 1.—Physical Characteristics of Soil Samples

Class	Name of class	Average Sizes of a Typical Sample, in Millimeters			Computed permeability, in million gallons daily per acre, at 50° F for slope of unity	Average of Laboratory Determinations

classes as shown in Fig. 5. The types of material in Table 1 may be further described, as follows:

Class	Description

1.—A material that contains large particles of gravel and very coarse sand, and very few fines.

2.—A uniform coarse sand that contains only a few fines and no gravel or stones.

3.—A material of which the part controlling the permeability is coarse sand, but in which there are a few fines, some gravel, or both.

4.—A uniform medium sand containing but few fines and no gravel or stone.

5.—A material of which the part controlling the permeability is medium, but in which there are finer and coarser sands and possibly gravel or stones.

6.—A uniform fine sand containing only a small percentage of larger or smaller grains than the average.

7.—A material of which the part controlling the permeability is a fine sand but in which there is a large percentage of coarser materials, possibly gravel or stone.

8.—A rock flour or silt containing only a small percentage of grains larger than the average.

9.—A material of which there is a large quantity of rock flour or silt but in which there is a large percentage of coarser materials, possibly gravel or stone.

The values in Column (6), Table 1, were computed for the tested porosity shown in Column (7). The average of all determinations for porosity was 35%; the straight average porosity of the nine classes was also 35%;

the weighted mean porosity for material at the Main Dam was 37% and at the Dike, 39%; and the mean effective porosity (obtained from the permeability of the over-burden as a whole) at the Main Dam was 33%, and at the Dike, 37 per cent.

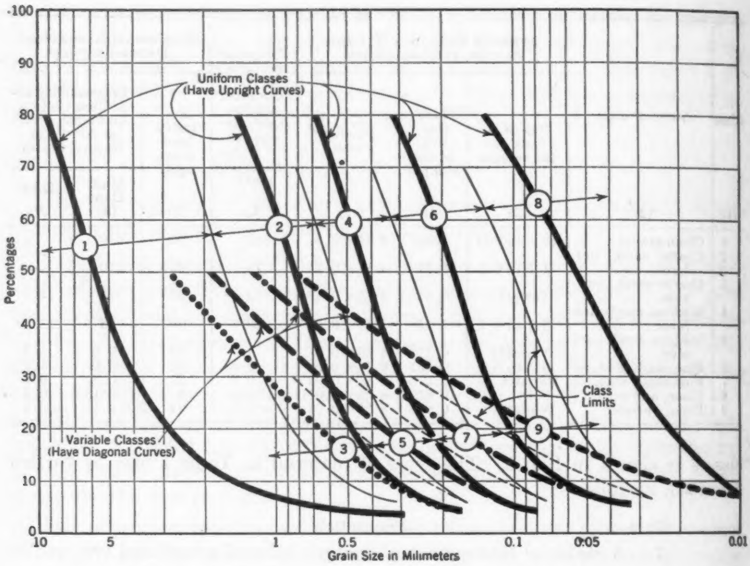

FIG. 5.—DEFINITIONS OF LIMITS, KENDORCO SOIL CLASSIFICATION

When the classification of all dry samples was complete, five were chosen carefully from each class at each site to show the range of all the samples of that general class. In choosing these samples, three were selected to represent the average of the entire classification, a fourth the coarser extreme, and the fifth the finer extreme. Sieve analyses were made on the five samples of each class (forty-five samples for each site). Such data were used as the basis for the diagram of class curves shown in Fig. 5. This system of general classification is easy to apply and fairly accurate in its results, even when applied by those relatively inexperienced with it, although there are always certain to be differences in opinion regarding border-line samples.

CLASSIFICATION OF THE OVER-BURDENS

Materials in the over-burdens at the Main Dam and at the Dike were assigned in both plan and elevation to the nine classes. This assignment was made according to the number of linear feet of the bore holes of each class of material encountered, each hole being weighted according to its plan location so that it represents its share horizontally of the entire valley.

PERMEABILITY OF THE CLASSES (COMPUTED FROM SIEVE ANALYSES)

The permeability of each class of material was computed from the mechanical analyses curves representing the averages of those classes by use of the formula introduced by Charles S. Slichter.[5] In applying Slichter's formula for determining ground-water flow, it has been the practice of many engineers to use erroneously in place of the "mean diameter" defined by Slichter, the effective size (10% size) defined by the late Allen Hazen,[6] M. Am. Soc. C. E., although the two, by definition, are different. Stearns,[7] King,[7] Melcher,[7] Slichter, and others, failed to find any consistent agreement between the 10% sieve size and the coefficient of permeability for most types of mixed sands and gravels. It is believed that the 10% size used by Hazen is applicable only to the filter sands with which he worked, and that for "variable" glacial materials the controlling size depends upon local characteristics of the materials, such as the shape of grains and the combination of sizes.

If permeability of a material or of an over-burden is to be computed by this formula it is recommended that, if practicable, many permeability tests be made on samples from that over-burden to determine the size, from sieve analyses curves, that will give dependable results when used instead of the mean diameter in Slichter's formula, otherwise, the determination may be very misleading.

Several hundred permeability tests were made on materials from overburdens of the Main Dam and the Dike, at known porosities and temperatures, and a sieve analysis curve of each of the samples was plotted. The size producing the tested permeability was obtained by substituting the permeability result in Slichter's formula in each case. The percentage grain size was chosen by inspecting the sieve analysis curve of that sample. From the large number of tests and inspections made, the size to be substituted in the formula to produce the tested permeabilities varied for these sites from the 5% to the 26% size, although the majority of the results were confined to closer limits, between the 8% and the 15% size. For these sands and gravels, the reasonable mean of all results seems to be the 12% size.

In order to compute the permeability of any material from its mechanical analyses curve, its porosity must be known. A large number of field tests were conducted at many locations in the excavations at the sites of the Main Dam and the Dike to determine the porosity of the materials in the overburden in general and particularly to determine the proper porosity that will be applicable to each classification. The results of these tests are shown in Table 1.

The temperature of the ground-water for any locality must also be known, and for these locations it was approximately 50° F. Fifty-six observations of ground-water flowing into the Quabbin Tunnel, which runs about parallel to the sites and about 6 miles to the north, were made at locations 80 to 600 ft below the ground surface and at intervals in a length of 10 miles of the tunnel. The average of all observations was 51° F, the lowest being 48° F, and the

[5] *Water Supply Papers Nos. 67* and *140*, U. S. Geological Survey.
[6] Rept., Mass. State Board of Health, by Allen Hazen, 1892.
[7] See *Water Supply Paper 596-F*, by N. D. Stearns.

highest, 53½° F. The water pumped from the caissons at both the Main Dam and the Dike maintained a fairly constant temperature very close to 50° F, throughout the year (between 48° and 52°). Therefore, 50° F would be the proper value to use, especially as it is approximately the mean annual temperature for the climate of this region.

The permeabilities of the nine classes were then computed for the tested porosities at a temperature of 50° F, using Slichter's formula and the 12% size from the theoretical curve for each class as the mean diameter (such curve representing the average of materials in that class). The results of such computations are shown in Table 1.

Tested Permeability of the Classes

A large number of samples of materials belonging to each of the nine classes was taken directly from open-cut, or caisson, excavations in the over-burden of the Main Dam and Dike and were tested for permeability. Care was taken to select samples representing the class averages. For the most part these were small can tests made at 68° F, the material being packed by hand to known porosities with as little mixing as possible.

Several permeability tests of each sample were made at different porosities, and a permeability-porosity curve for that sample was plotted. From this curve, the permeability was read for the average porosity of that class previously determined, and the result was corrected[8] to a temperature at 50° F. The permeabilities thus obtained are shown in Table 1.

Permeability of the Over-Burden from the Classification Permeabilities

The over-burdens were composed of heterogeneous glacial materials, in the valley inverts being forms of modified drift. The various classes of materials were not laid in strata or layers or with any order at all, but seem to be deposited in random lenses or pockets. In view of this lack of order, the question arises (assuming that the permeabilities of the respective classes and quantities of each class of material in the over-burden are satisfactorily computed or known) as to how best to obtain the permeability of the over-burden as a whole. For instance, the maximum total permeability of a given quantity made up of an equal quantity of each class would be for a condition in which the amounts of each class are laid in horizontal layers parallel to the flow, and the minimum would be for a condition in which the quantities are placed in vertical layers perpendicular to the flow. In the former case, herein termed "in parallel", the direct sum of the quantities carried by each layer will give the total carried by the mass, and from this the unit permeability of the mass can be computed. The average effective unit permeability of the whole mass, for that case, will be equal to the unit permeabilities of the component parts averaged and weighted in accordance with the relative quantities of the parts. In the latter case, herein called "in series", the average effective permeability of the mass is only a fraction of the "parallel" quantity, as the finer layers control the amount of flow through the coarser layers and prevent them from carrying larger quantities. However, any contact or linking

[8] Correction factors are given in "Smithsonian Physical Tables—Viscosity of Water in Centipoises *vs.* Temperature Variation", the permeability being varied inversely with the viscosity.

of coarser classes, although by links of relatively smaller volumes, will so increase the effective permeability of the entire mass over that obtained by the "series" method that such permeability will be found to be a very large percentage of the "parallel" method, and except for extremely small linking volumes, this percentage is very close to 100. In random glacial deposits there is usually no uniform tendency for complete separation of the coarser parts by the finer. On the other hand, during the period of deposition and in the following washing periods, water tends to open passages of flow between pockets, if they do not already exist. Therefore, it is believed that approximately close results can be obtained for glacial materials if the average effective permeability is computed from the unit class permeabilities by the "parallel" combination. Such an approximation is on the safe side as far as percolation or seepage quantities are concerned, and probably is not far from being representative of true conditions in the over-burden.

As the permeability of the over-burden as a whole is so dependent upon the manner in which the permeabilities of the various classes are combined, too much emphasis cannot be placed upon the importance of obtaining as much information as practicable regarding the existence and manner of occurrence of the various classes in the over-burden.

In the case of these sites, investigations of existing excavations in the open and in the caissons, of the bore-hole data, and of other geological data, indicate that probably numerous interconnections and intermeshings of the coarser lenses, streaks and pockets with the finer exist, and that there is no tendency toward segregation of lenses in such manner that the finer would separate and isolate the coarser. Thus, the resulting permeabilities at the sites of the Main Dam and Dike are estimated, using 100% of the results obtained by the "parallel" method.

Although the results of these classification methods may be open to criticism owing to the many arbitrary assumptions necessary to obtain them, it is believed that such results are adequate in this case and will be in similar cases, as the results for both these sites are confirmed by the determinations of permeability made by the pumping methods described subsequently herein, under Part II. The pumping results do not depend upon arbitrary assumptions or decisions and, therefore, this confirmation of results may be used as an independent check of those made for the bore-hole classification methods. The over-burdens at these sites have no conditions which are unusual or uncommon to glacial-formed valley deposits and, consequently, there seems to be no reason why such similar methods will not give equally good results elsewhere.

Although such methods are approximations in many respects and although the computed results cannot be treated with too much exactness, they can be used to obtain more comprehensive opinions of the permeability of any extensive glacial materials than any other methods known to the writer except the pumping methods described subsequently. Any determination should be used within the limits of accuracy considered reasonable, and for permeability of an over-burden these limits are quite elastic. For instance, limits between 50% and 200% of a result computed by these methods may not be unreason-

able, although the writer believes that the results for these sites and for other similar sites may be computed within much closer limits. However, even a result with wide elastic limits is much better than no determination and to the engineer considering seepage possibilities, such limits are usually close enough for his purposes.

PART II.—PERMEABILITY DETERMINATIONS FROM EFFECTS OF GROUND-WATER PUMPING OPERATIONS

Pumping at the Dike Site

For examining the materials in the over-burden and for experimenting with pumping of ground-water, Caisson 13 was sunk at the Dike in a location where the ground-water surface was practically at the original surface, which is about 130 ft above ledge (see Fig. 1). During the sinking, if material below the ground-water level was being excavated under pneumatic pressures, it was impracticable to lower the ground-water outside the caisson by pumping from within, for two reasons: (1) The presence of air in the pores of the surrounding soils materially reduced the volume of the pores available for the flow of ground-water toward the caisson; and (2) the use of air (probably because it tended to break up and separate the fines) seemed to accelerate the flow of the fine particles near the pumping intakes into the intakes, and thereby clogging them quickly. As a head of water of 130 ft would give unreasonably high pressures for pneumatic work (50 lb per sq in. being the legal limit in Massachusetts), it was necessary to lower the ground-water level near the caisson in order to sink it completely.

When the caisson had been sunk 63 ft below the brook level, sinking operations were suspended and pumps were installed in the working chamber of the caisson in order that the ground-water level might be lowered to provide for the sinking of an open external sump, to be used for pumping while the caisson was being sunk. The water was pumped from the working chamber of the caisson at that depth at an average rate of about 1 600 gal per min. for a period of about seven weeks. The sump, about 26 ft square, of wooden sheet-piling, was sunk at a location about 100 ft from the caisson, to below the lowered water level, the depth being about 50 ft below the brook level. In that period of seven weeks the water level had been lowered to a depth of about 38 ft below the brook level, the sump being completed in the wet below that depth by additional pumping at a small rate and by driving the sheeting as far ahead of the excavation as boulders would permit.

The pumps were then removed from the caisson and installed in the open sump until after the caisson was completed. Pumping intakes were built under the cutting-edge in the underpinning foundations of the caisson. During this period of about thirteen weeks the water drawn from the open sump averaged about 1 100 gal per min; in the sump, the minimum water level was about 45 ft below, and at the caisson about 30 ft below, the brook level. The highest air pressure used in sealing the caisson to ledge was about 48 lb per sq in. Pumps were then installed in the working chamber of the caisson utilizing the intakes previously built, and the ground-water was drawn from the caisson and the sump jointly for a period of five months at an average rate of about 1 600 gal per min.

At the start of the core-wall construction (January, 1933), greater pumping capacity was installed in Caisson 13 and pumping from the open sump was abandoned. Pumping continued from that caisson for about four months at the increased rate of about 3 200 gal per min, at which time Caisson 18 (see Fig. 1) had been sunk to a depth near ledge. Pumps were installed in the working chamber of Caisson 18 to supplement those of Caisson 13 and water was drawn at an average of about 3 000 gal per min from both caissons (about 2 600 gal from Caisson 13 and 400 gal from Caisson 18). This work was continued for ten weeks more.

During the sinking of Caisson 13, to aid the pumping operations, Beaver Brook was carried past the site in a wooden flume extending from a point 200 ft up stream from the center line of the Dike to a point about 160 ft down stream. During the construction of the core-wall this brook was dammed off about 500 ft up stream, the pumping discharge being deposited 400 ft down stream. The subsequent pumping operations dried up the brook up stream and lowered the level of Morton Pond, which is about 1 500 ft up stream, a maximum of about 9 ft (see Fig. 6).

Other caissons were sunk below the ground-water gradient and more water was pumped from the working chambers at intervals when no material was being excavated. When they were sealed to ledge many of the caissons were equipped with pumping intakes which were also used to lower the ground-

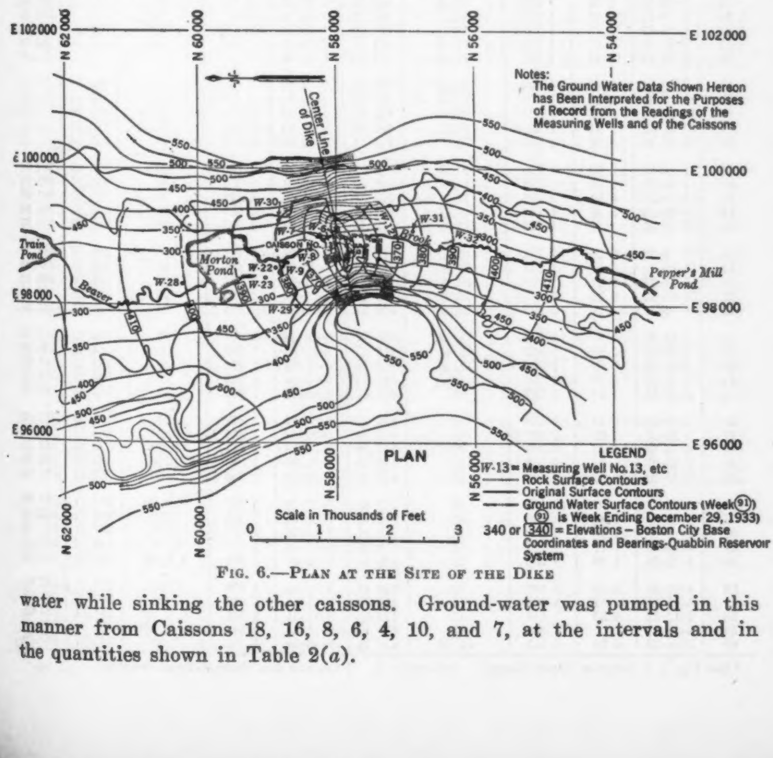

FIG. 6.—PLAN AT THE SITE OF THE DIKE

water while sinking the other caissons. Ground-water was pumped in this manner from Caissons 18, 16, 8, 6, 4, 10, and 7, at the intervals and in the quantities shown in Table 2(*a*).

The extent to which the ground-water was lowered, as read in the measuring wells and in the caissons, can be seen by inspection of Figs. 1 and 7 and of the data given in Table 2. In general, the ground-water was lowered more than 90 ft below the brook level over the deeper parts of the valley. The maximum air pressure used in sinking caissons other than Caisson 13 was 25 lb per sq in., only about 2% of the sinking requiring pressures in excess of 18 lb per sq in. (the legal limit in Massachusetts for 8-hr work). Altogether, 70% of the caisson sinking was accomplished in free air, and an additional 20% under pressures of less than 10 lb per sq in.

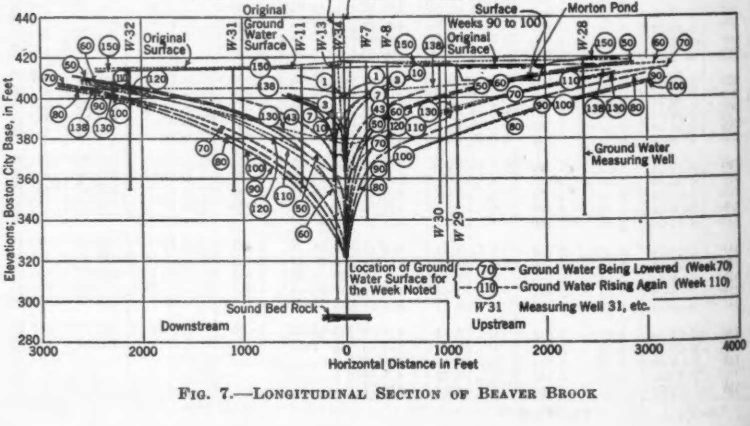

FIG. 7.—LONGITUDINAL SECTION OF BEAVER BROOK

As the core-wall of the concrete cassions neared completion, the pumping rate was decreased and the water level was allowed to rise again slowly while work progressed on the re-fill in the open trench excavated for caisson construction (see Figs. 1 and 7). In November, 1934, pumping was abandoned, and, in February, 1935, the water level was very close to its original position.

Permeability Determinations for Over-Burden from Pumping Operations at the Dike Site

Several determinations of the permeability of the materials in the over-burden were made from the data pertaining to pumping and ground-water lowering. The permeability was computed in various ways, but all determinations depended basically on the formula,

$$q = k\,p\,A\,S \qquad (1)$$

in which q = quantity of water flowing past any cross-sectional area, in cubic feet per day; k = the velocity of the water through the pores, in feet per day; and p = the porosity of the over-burden. Then $0.3267\,k\,p = K$, the permeability coefficient, in million gallons daily per acre for a slope of unity; A = area of cross-section, in square feet; and S = slope of the ground-water gradient (expressed as a decimal).

The value of q used in all determinations is based on the pumping rate. The total rate was composed of two general parts—infiltration and reduction of storage. The former consisted of surface infiltration of water from rainfall and from surface supplies, such as brooks, ponds, etc., and of sub-surface infiltration supplied by slow percolation from underground volumes previously unwatered of all that would flow out relatively quickly and easily. The latter consisted of the quantities taken from storage, which would immediately affect the readings of the ground-water measuring wells. (Estimates for pumping at the Main Dam and Dike indicated that about 90% of the water in the pores was taken quickly from storage by the pumping. Of the remainder, part would stay permanently in the pores by capillary action and part would be slowly underdrained.) The value of the flow, Q (in gallons per minute), at any location varies from the total quantity pumped at the station to practically zero at the radius of influence. The true value of the flow at the radius of influence depends upon the natural ground-water slope and the permeability (which is being determined). In some problems it may be necessary to make a preliminary assumption of this value to obtain a reasonable value of Q, but for this site the actual figure for the permeability finally obtained and for the slope would be less than 100 gal per min, so that the accuracy of the determinations will not be noticeably affected by the assumption.

The location of the radius of influence can be obtained by estimating visually, from the ground-water data, the distance from the pumping center at which the lowered ground-water surface will be tangent to the original ground-water surface. The value thus obtained, although approximate, is

usable, because the exact location does not materially affect the permeability results. The values of Q at various locations between the pumping center and the radius of influence must be estimated as the first step in making a determination. Although, theoretically, an exact determination depends upon the exact variation in flow estimated, actually equivalent results will be obtained for any reasonable distribution of these differences of flow. The most reasonable distribution that was used in the Dike determinations was that Q was assumed to vary proportionately as the two factors—infiltration and storage reduction. The first varied as the surface drainage area, weighted for ponds and watercourses; and the second according to the rate at which the increment volumes of over-burden were being depleted of ground-water storage. Other arbitrary variations of Q also gave good results; for instance, Q can be varied from P to zero according to the distance from the pumping center, without seriously affecting the value of the determination. The empirical formula,

$$Q = P\left(1 - \frac{r^2}{r_i^2}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

seems to give a distribution of differences in flow very close to those obtained by the more careful and logical distribution first described. In Equation (2), P = the total pumping rate, in gallons per minute; r = a radius measured from the weighted location of pumping operations; and r_i = the radius that defines the influence of pumping and is the distance from the weighted pumping center to the limit where the pumped ground-water surface is tangent to the normal ground-water surface.

The symbol, A, denotes the area of the surface of the section through which the water flows, this section being curved to be taken perpendicular to the lines of flow. Near the pumping locations, this area has a bulbous shape due to the fact that the flow of water is not approximately horizontal near the intakes because: (1) There are several pumping intakes; and (2) these intakes are in the deeper parts of the valley. However, as the distance from the pumping center increases, these surfaces approximate very closely the surfaces of concentric vertical cylinders with axes passing through, and with radii taken from, the weighted center of pumping operations (herein termed the "pumping center"). The upper limits of these surfaces in determining the value of A are taken at the ground-water surface, as shown by readings in the measuring wells and the lower limits at the surface of the rock valley beneath, as determined from bore-hole investigations (see Figs. 1, 6, and 7). The use of these cylindrical areas does not introduce an approximation influencing the results, as the permeability determinations do not include volumes close to the pumping center.

The slope, S, is read directly from the ground-water curve used and is taken as a straight line between adjacent points on the curve. To avoid the introduction of errors (due to the use of the slope as a straight line, to the use of the average of end areas as the area of the volume considered, etc.), each determination was made by computing the permeability of sufficiently small increment volumes of the over-burden. Cylindrical cross-sections were

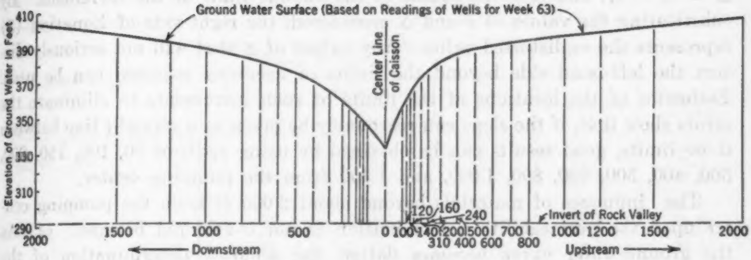

FIG. 8.—DEFINITION OF INCREMENTS FOR PERMEABILITY DETERMINATIONS

chosen at certain radii, as shown in Fig. 8, and each increment is the volume between cylindrical surfaces (see Table 3(*a*)). The effect of the size of the increment can be seen from the mathematical relation,

$$\frac{2\,\Delta}{2\,r + \Delta} = 2.3026\left(\log\frac{r_1 + \Delta}{r_1}\right)\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

in which r_1 = the radius of the inside limit of the volume increment;

* Values in parentheses are averages. † In millions of gallons per acre per day at 50° F for a slope of 1.

$\Delta = r_2 - r_1$; and r_2 is the radius of the outside limit of the increment. By substituting the values of r and Δ considered, the right side of Equation (3) represents the undistorted value. Any values of Δ that will not seriously distort the left-hand side beyond the limits of accuracy required can be used. Estimates of the locations of the limits of such increments to eliminate the errors show that, if the slope can reasonably be taken as a straight line between those limits, good results can be obtained by using radii of 50, 100, 150, 200, 300, 400, 500, 600, 800, 1 000, and 1 300 from the pumping center.

The influence of materials beyond about 2 000 ft from the pumping center upon the permeability determination is not considered because: (1) As the ground-water curve becomes flatter, the accurate determination of the permeability for that region becomes more difficult, slight differences in elevations of readings making material differences in results; (2) such materials are out of range of the immediate site; (3) the ground-water level near the radius of influence is more sensitive to fluctuations due to rainfall and seasonal influences than those due to the pumping; and (4) for the foregoing reasons, ground-water elevations were not read at this site.

Furthermore, volumes close to the caissons were not considered for four reasons: (1) There were no ground-water measuring wells near the caissons because of the open-cut trench and, therefore, the elevation of the ground-water surface at that point was not determined accurately; (2) cylindrical cross-sectional areas cannot be used accurately as the areas of flow; (3) the pumping operations and the compressed-air work during the sinking of the caissons so distributed the permeability of the materials immediately surrounding the caissons that those portions of the over-burden should not be considered as representative in obtaining the effective average; and (4) these portions represent relatively small volumes, and as the permeabilities of increments are weighted according to their volumes, the resulting determination would not be seriously influenced by the values obtained for these volumes in any event.

The shape of the rock valley at this site naturally divides the ground-water flow toward the pumps into two parts, that from up stream and that from down stream. A study of the rainfall and run-off conditions at the site and of the storage depletions up stream and down stream from the pumping center indicated that on the average about 57% of the total pumpage comes from the valley over-burden up stream and the remaining 43% from the valley over-burden down stream. Whether or not this indication is true, the result for the average effective permeability of the valley as a whole is affected but slightly by it, due to the compensating effect of the averaging of the two values to obtain the result, as can be seen from an examination of Table 4.

Using the factors, q, A, and S, the permeabilities of increment volumes of the over-burden can be obtained for any ground-water surface conditions and the corresponding pumping rate. By combining the permeabilities of the increments thus obtained, and weighting each increment according to its volume, the effective average permeability of the whole material is obtained, this method being called herein the "slope quantity" method.

TABLE 4.—COEFFICIENTS OF PERMEABILITY

Determination for:	Assumed Percentages of Total Pumping		K=Coefficient of Permeability		
	From up-stream volumes	From down-stream volumes	Up stream	Down stream	Weighted average
Week 63	70	30	37.7	16.7	27.9

	70	30	43.3	17.8	31.8
	57	43	35.2	25.5	30.9
	50	50	31.0	29.7	30.4

Fig. 8, with Table 3, shows the details of such a determination for Week 63 of the pumping. The best results can be obtained by choosing a week among those for which conditions (such as the pumping rates, depletions of storage, and uniform surface infiltrations due to normal rainfalls and run-offs) have been running constant or varying uniformly. The measuring wells register sensitively the changes in ground-water surface. For a period when the rainfall is uniformly distributed, the quantity of infiltration is probably constant. If the pumping plant operates at a constant rate, the reduction in storage is a constant volume from week to week. For such periods accurate estimates of the quantity of water furnished by storage depletion and by surface infiltration can be made. Such estimates can be used in determining accurately, the quantity of water flowing toward the pumps at various vertical cross-sectional areas (see Fig. 8 and Table 3). As the quantity flowing between any two vertical cross-sections and the loss of head are then known, the permeability of any corresponding increment volume can be determined accurately. Weeks 63 and 91 are of that nature and, therefore, are used. Table 5, introduced subsequently, gives certain of the better determinations made as described herein. That the value of K is constantly increasing as the water level recedes is accounted for by the fact that the upper portions of the glacial valley over-burden consist of finer sands containing streaks of rock flour and the lower portions contain the coarser lenses. Thus, as the ground-water level is lowered beneath the finer portions, the resulting average permeability of portions under the ground-water surface is greater.

It is interesting to note that in all determinations practically the same result can be obtained by using Q = three-fourths of the up-stream pumpage, P_u, as the flow for the up-stream increments, and three-fourths of the down-stream pumpage, and P_d, as the flow for the down-stream increments. This is probably due to the facts that: (*a*) The K-values of the increments do not vary to such degrees as to upset the results; (*b*) the manner for distributing the infiltration is approximately a formula the equation of which is of the second degree; and (*c*) the storage depletion increments vary roughly as the square of the distance from the caisson (the rock valley being not far from a constant cross-section). It can be inferred, therefore, that reasonable approximations can be made for like conditions by adopting a constant value of Q instead of the variable one used in the more exact determinations.

The results of the work done by this increment permeability ("slope-quantity") method can be checked by a second cut-and-try method described subsequently as the "graphical method". In the former an estimate of the portions of the total pumpage coming from up stream and down stream is necessary. Although the accuracy of such an estimate does not seem to affect the average effective permeability of the over-burden as a whole, it will affect the relative values obtained for the up-stream and down-stream permeabilities. In the latter an assumption is made that the average effective permeabilities of the up-stream and down-stream portions are equal, which may or may not be true for any location considered. However, the results by either method are confirmatory, showing that the manipulation of these considerations within the reasonable limits indicated will not seriously affect the workability of the methods.

Another more approximate method of obtaining the permeability from ground-water pumping data is by an adaptation of the formula[9] used generally for determining available ground-water yield from wells:

$$y^2 = \frac{q}{k\,p} \log_e \frac{x}{r} + h^2 \quad \text{.....................(4)}$$

in which x and y are co-ordinate locations of any point on the ground-water curve in reference to co-ordinate axes, one axis being made to pass vertically through the pumping center and the other horizontally at the average elevation of rock. Furthermore, h = the y-co-ordinate at the pumping well; p = porosity; and k = the velocity of the ground-water through the pores, in feet per day, for a slope of 1 on 1 at 50° F.

Equation (4) can be used only in its present form for an accurate determination in a case where the pumping curve has reached a stable position, q being a constant flow from beyond the radius of influence to the pumps with no depletion in storage and with no infiltration within the radius of influence, and for a condition which considers a level rock floor under the over-burden extending 360° in plan around the pumps and to the radius of influence. (Even then the formula is for well-points and assumes horizontal flow near the pumping intakes.) Approximations in the field, of such theoretical conditions, for any dam location, or for any reasonable pumping or unwatering program, are extremely unlikely.

Approximate and useful results, however, might be obtained for some cases by adapting the principles of the formula, as follows: The average of the up-stream and down-stream ground-water curves can be obtained, as illustrated in Fig. 9. An equivalent rock floor, which will extend 360° around the pumping center, can be estimated by summing the areas up stream and down stream for various radii and dividing by $2\pi r$; and the horizontal plane which best averages the location of this rock floor so determined can be estimated roughly by eye, as shown in Fig. 9. A constant Q-value of three-fourths P can be used. Then, by substituting values of x and y (of any two points on the average ground-water curve in relation to the base fixed) twice

[9] For derivation see "Public Water Supplies", by F. E. Turneaure, Hon. M. Am. Soc. C. E., and H. L. Russell, M. Am. Soc. C. E., Second Edition, p. 279.

in Equation (4), two equations, with values, $K p$ and h, unknown, can be obtained. These equations can be solved simultaneously for $K p$ by subtraction. A weighted mean of a number of such determinations would give the average effective permeability. In Equation (4) h is usually a difficult

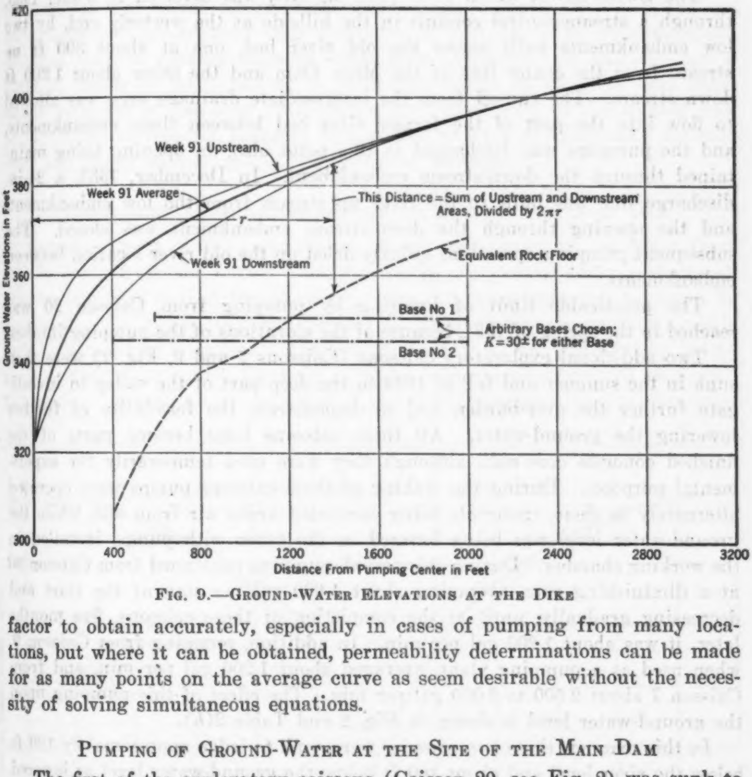

Fig. 9.—Ground-Water Elevations at the Dike

factor to obtain accurately, especially in cases of pumping from many locations, but where it can be obtained, permeability determinations can be made for as many points on the average curve as seem desirable without the necessity of solving simultaneous equations.

Pumping of Ground-Water at the Site of the Main Dam

The first of the exploratory caissons (Caisson 20, see Fig. 2) was sunk to a depth of 75 ft below the river level, at a location which was not in the deeper part of the rock valley. This caisson was equipped with intakes for pumping and two pumps with capacities of 300 gal per min were installed. Ground-water was pumped for two months in 1932 at an average rate of about 650 gal per min and the ground-water surface was lowered only about 7 ft in the vicinity of this caisson, because of the lack in capacity of the pumping intakes. Pumping was then abandoned at this site for about a year, and the ground-water surface returned to its original position. The capacity of the pumping intakes was increased in July, 1933, mainly by the forcing of well-points out into the surrounding materials through holes drilled in the sides of the caisson. Two additional pumps (capacity, 800 gal per min) were installed, and pumping was started at an increased rate. An average of

about 2 100 gal per min was pumped over the period of the next eleven months, the water level being lowered about 30 ft near the caisson. The pumping rates and the progressive lowering of the ground-water may be seen in Fig. 2 and Table 2(*b*).

The Swift River, which flows past the site, was diverted in June, 1933, through a stream-control conduit in the hillside at the westerly end, by two low embankments built across the old river bed, one at about 800 ft up stream from the center line of the Main Dam and the other about 1 300 ft down stream. The run-off from the intermediate drainage area was allowed to flow into the part of the former river bed between these embankments, and the pumpage was discharged at this point also, an opening being maintained through the down-stream embankment. In December, 1933, a 24-in. discharge line was built to the river up stream from the low embankment, and the opening through the down-stream embankment was closed. The subsequent pumping operations quickly dried up the old river location between embankments.

The practicable limit of lowering by pumping from Caisson 20 was reached in the spring of 1934, because of the elevations of the pumping intakes.

Two additional exploratory caissons (Caissons 7 and 9, Fig. 2) were then sunk in the summer and fall of 1934 in the deep part of the valley to investigate further the over-burden and to demonstrate the feasibility of further lowering the ground-water. All these caissons later became parts of the finished concrete core-wall, although they were used temporarily for experimental purposes. During the sinking of these caissons pumps were operated alternately in them, materials being excavated under air from one, while the ground-water level was being lowered in the other with pumps installed in the working chamber. During this period, pumping continued from Caisson 20 at a diminishing rate, averaging about 1 600 gal per min at the start and decreasing gradually, until at the completion of these caissons, five months later, it was about 1 200 gal per min. In addition, pumping from Caisson 9, when used as a pumping plant, averaged about 1 200 gal per min, and from Caisson 7 about 2 500 to 3 000 gal per min. The effect of this pumping upon the ground-water level is shown in Fig. 2 and Table 2(*b*).

In this manner, these two caissons were sunk to ledge approximately 120 ft below the river level and about 100 ft below the ground-water level as lowered at the beginning of sinking, the maximum air pressure used in Caisson 7 being 37.5 lb per sq in. and in Caisson 9, 34 lb per sq in. When these caissons had been completed, pumping was continued from them and from Caisson 20. The average total rate at the start was 5 000 gal per min (3 100 gal per min from Caisson 7, 1 000 gal per min from Caisson 9, and 900 gal per min from Caisson 20). Two months later, in February, 1935, the rate had decreased to 3 400 gal per min (2 200 gal per min from Caisson 7, 1 000 gal per min from Caisson 9, and 200 gal per min from Caisson 20), and the ground-water level had been lowered about 75 ft in the vicinity of Caissons 7 and 9, as shown in the curves of Fig. 2.

Pumping was continued at approximately this rate for several months, maintaining the ground-water in its lowered position. The work of con-

structing the caisson core-wall began in May, 1935, and was practically completed by December, 1935, during which period the contractor pumped an average total of about 3 400 gal per min from Caissons 7 and 9 and other caissons, and such pumping did not materially lower the ground-water gradients, except that in the center of the rock valley, as shown in Fig. 2, further local lowering was secured near Caissons 12 and 14. The maximum air pressure used in sinking caissons other than Caissons 7, 9, and 20, was a little in excess of 25 lb per sq in., although nearly all caissons were sunk under pressures of less than 18 lb per sq in. About 82% of the sinking was accomplished in free air, Caissons 1, 2, and 32 to 40, inclusive, being entirely sunk and sealed without the use of air under pressure.

Permeability Determinations from Pumping at the Main Dam

Determinations of the permeability of the over-burden at the Main Dam can be made from the curves plotted showing the ground-water surfaces at various intervals during the pumping. The determinations can be made in addition to the "slope quantity" method described previously by "the graphical" (a cut-and-try) method. The procedure may be demonstrated by reference to Fig. 10, in which Curve A is plotted from measuring-well readings; Curves B, C, and D, for the values of K indicated, represent the total pumpage

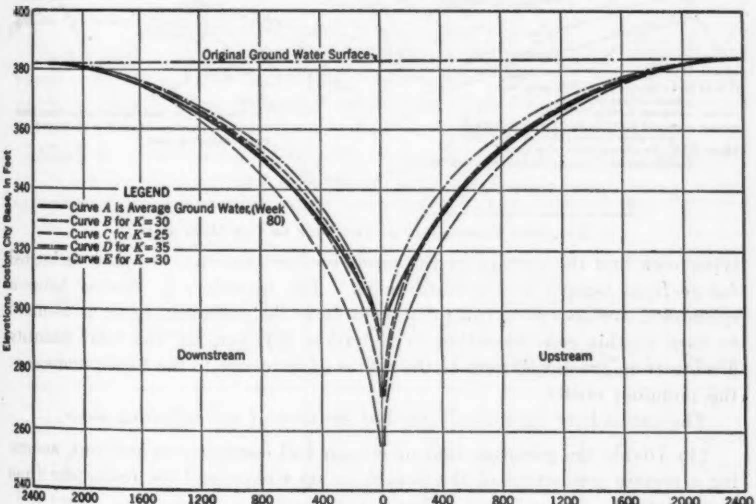

Fig. 10.—Pumping at the Site of the Dam

divided by 54% from up stream and 46% from down stream; and Curve E, for $K = 30$, represents the total pumpage divided by 60% from up stream and 40% from down stream. Preparation for a determination by this method consists of plotting in plan over the rock contours of the valley floor, the con-

tours of the ground-water level from the readings of the ground-water measuring wells (see Fig. 11). A pumping center is chosen as in the other methods, in this case a point about 140 ft northeast of Caisson 7 on the center line of the Main Dam being taken. With this center, radii of 150, 200, 300, 400, 500, 600, 800, 1 000, and 1 300 ft are used, these radii being taken so as to give increments small enough to eliminate errors as described previously. The cylindrical surface, cross-sectional areas between the surface of the under-

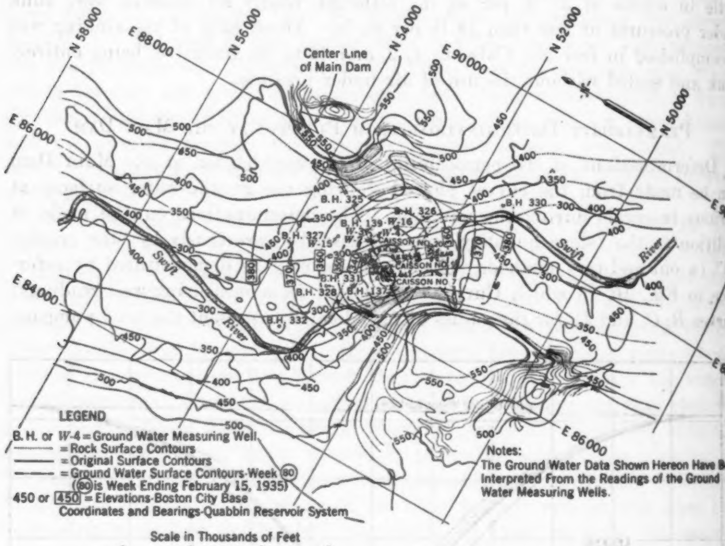

FIG. 11.—TOPOGRAPHY AT THE SITE OF THE MAIN DAM

lying rock and the surface of the ground-water contours, are then estimated for sections located at the radii taken. The quantity, Q, flowing between cylindrical surfaces at various distances from the pumping center is assumed to vary in this case according to Equation (2), varying the total quantity flowing from practically zero at the radius of influence to the total pumpage at the pumping center.

The cut-and-try "graphical" method consists of the following steps:

(1) Divide the pumpage into up-stream and down-stream portions, assuming a certain percentage of the total from up stream and the remainder from down stream.

(2) Assume that the average effective permeabilities of the down-stream and up-stream over-burdens are the same.

(3) Assume a value of K which seems reasonable.

(4) Using these assumed factors, and the computed cross-sectional areas obtained from the ground-water surface for which the determination is made, theoretical ground-water curves up stream and down stream can be plotted

in a vertical plane running longitudinally to the valley, starting at the radii of influence (as determined from the pumping curve data) and plotting in toward the pumping center (see Fig. 10). These curves are found by computing the lost head between each set of cylindrical surfaces by use of the formula:

$$H = \frac{62.88\, Q\, (r_2 - r_1)}{\frac{a_2 + a_1}{2} K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

(5) The curves of Step (4) are then superimposed on the curve of the ground-water surface formed by the intersection of the vertical longitudinal plane with the ground-water surface contours plotted (see Fig. 10).

(6) If all the points so plotted come above the observed ground-water curves, the permeability assumed is too large; if they are below, the permeability is too small. If the up-stream points are plotted below, and the down-stream points above, the division of the percentage of flow is incorrectly assumed.

(7) By repeating assumptions, a closer and closer solution for the permeability can be obtained, as well as a better idea of the division of flow coming from up stream and down stream. The nearness of the solution to the correct average effective permeability will be demonstrated graphically by the manner in which the computed curves coincide with the observed ground-water curves.

In all cases where determinations were made by the two methods, the results obtained with the "graphical" method check very nicely those obtained by the analytical "slope quantity" method (see Table 5).

Comparison of Permeability Determinations

An inspection of Table 5 shows that the coefficient of permeability at 50° F of the entire over-burden of the Dike is about 20 mgd per acre and of the lower parts of the over-burden about 30 mgd per acre; and that it is about

30 to 35 mgd per acre for the entire over-burden of the Main Dam. The result of all methods, whether obtained by the use of the bore-hole samples and laboratory work, or by the use of the pumping and ground-water data, substantiates these figures. Considering that a permeability determination within the limits of accuracy of 50% to 200% is extremely useful and sufficiently close for most design purposes, the results in Table 5 demonstrate the adequacy of the different methods for making determinations well within desired limits.

The accuracy of determinations made from the classification of bore-hole samples depends to a great extent upon the manner in which bore-holes are located and the samples taken and collected, upon the skill with which the field and laboratory work is conducted, and upon the judgment as to the manner in which the various classes of material exist in the over-burden. From experiences with the work described herein, the writer is confident that a similar application of the "bore-hole sample classification" method will give valuable results at other locations if reasonable care is exercised in the application.

The use of ground-water pumping to secure a permeability determination is much simpler, provided there is sufficient information regarding the pumping rates, the location of the ground-water surface, and the location of the rock valley. The ground-water surface is extremely sensitive and measures accurately the loss of head between points in the valley. This registration of lost head makes a determination by any of the foregoing methods a comparatively simple and accurate one, because very small differences in permeability will give large differences in readings of the ground-water surface in the measuring wells. Unreasonable determinations can easily be proved unworthy because the loss of head for such conditions will not agree with those observed. These pumping methods can be used elsewhere where the rock and ground-water surfaces are known, to determine the effective permeability of foundations below the ground-water surface.

Conclusions

There seems to be a scarcity of data concerning the permeable characteristics of soils and there are few, if any, definite methods in common use for making satisfactory determinations of the permeability of an over-burden. In many cases permeable qualities of foundations have been a matter of extremely rough estimate, of guess, or merely of conjecture. The aforementioned methods, although not entirely satisfactory, will be found useful in that connection for conditions similar to the ones described, and such methods or adaptations of them may prove helpful elsewhere where conditions are dissimilar. Although the results of determination by such methods may not stand too rigid tests for complete exactness, they will prove their value if only they can be used to serve as satisfactory guides in formulating the opinions or judgment of the engineer confronted by the problem of how large is the permeability of the foundations under consideration.

ACKNOWLEDGMENTS

Most of the information used for the preparation of this paper was obtained from data secured by the Engineering Department of the Metropolitan District Water Supply Commission of Massachusetts, of which Frank E. Winsor, M. Am. Soc. C. E., is Chief Engineer and Karl R. Kennison, M. Am. Soc. C. E., is Assistant Chief Engineer. The writer is indebted to many members of this organization for aid in preparing and compiling much of the information and for constructive suggestions on, and pertinent criticisms of, the substance of the paper itself.

GEOLOGIC FEATURES, QUABBIN AQUEDUCT

BY FRANK E. FAHLQUIST[10], ASSOC. M. AM. SOC. C. E.

SYNOPSIS

The geological studies which were of importance in constructing the Quabbin Aqueduct, of the Metropolitan Water Supply of Boston, Mass., are presented in this paper. The general geology of the area, including that of the surface and that of the underground, is discussed in relation to the several practical problems encountered during the location studies. Data pertaining to the behavior of the different rocks during construction and the cost and progress of excavation through them, are also included.

INTRODUCTION

Construction of the Quabbin Aqueduct is one of several steps in extending the water supply system of the Boston Metropolitan District beyond the Wachusett water-shed in Central Massachusetts (see Fig. 12). In the past

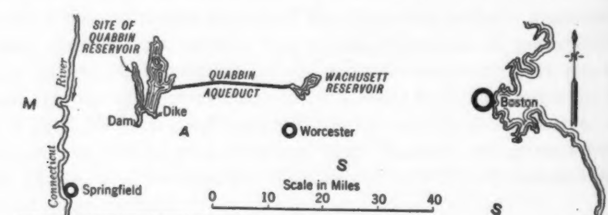

FIG. 12.—LOCATION OF QUABBIN AQUEDUCT AND SITE OF QUABBIN RESERVOIR.

water has been obtained from several minor sources and the major supply of Wachusett Reservoir, formed by impounding the flow of the Nashua River, at Clinton, Mass. In extending this system westward to the Swift River Valley additional storage and supply are made available. Completion of the easterly portion of the aqueduct, extending between the Wachusett Reservoir and the Ware River, near Coldbrook, Mass., marked the first step in this project. Construction of this section was sufficiently advanced by March, 1931, to permit diversion of the water of the Ware River to the Wachusett Reservoir. Construction of the western portion of the aqueduct, extending from the terminus of the East Tunnel section to the portal and intake at the Quabbin Reservoir, was completed during the summer of 1935. The result

[10] Geologists, War Dept. at Large, U. S. Engr. Office, Providence, R. I.

is a continuous aqueduct, 24.6 miles long, connecting the Quabbin Reservoir with the Wachusett Reservoir.[11]

Geologic Setting

The tunnel crosses a part of the central upland of Massachusetts known as the Worcester County Plateau, a large part of which stands between 1 000 and 1 200 ft above sea level. Geologists[12] have noted an unusual uniformity in the horizon line of the district, and have recognized in the general correspondence of the summits of the parallel ridges the former existence of an ancient and nearly uniform surface, or peneplain, sloping gently toward the southeast.

In general, the hills and valleys are oriented in a north-south direction, which is closely parallel to the folds of the rock formations of the area. There are exceptions, however, which are sufficiently numerous to indicate that dissection or erosion of the ancient surface, or peneplain, was not controlled entirely by the distribution and structure of the underlying rock formations. An explanation for this irregularity has been advanced by W. O. Crosby[13], who concluded that, at the time of its fullest development, the peneplain was covered by a thick mantle of sediment, upon which a drainage pattern was developed without much regard for the structure and distribution of the underlying hard and soft rocks. At this stage the stream gradients were steepened and the rivers rejuvenated as the result of crustal disturbances. As a result the rivers became deeply entrenched in the thick mantle of unconsolidated deposits. By the time these deposits were removed, the streams had been superimposed on the older crystalline rock floor. The pattern of this ancient drainage system can be traced and reconstructed, in part, except in those areas where the valleys have been completely blocked, and where features of the bed-rock topography have been buried too deeply by glacial deposits.

As the glacier advanced during the succeeding epoch known as the Glacial Period, several of these valleys were slightly deepened and widened, and the topography was modified somewhat by ice erosion. As it retreated from the area large quantities of rock material, which had been gathered by, and frozen into, the ice, were deposited. In general, this glacial drift material was deposited to rather shallow depths in the higher elevations, but accumulated to considerable thickness within the valleys.

Pre-Glacial Drainage Courses

Many of the streams of this section are too small in size to have excavated the broad and deep depressions which they now occupy. There are also

[11] Accounts by Frank E. Winsor, M. Am. Soc. C. E., and Karl R. Kennison, M. Am. Soc. C. E., have appeared recently in engineering literature, as follows: "Boston's New Metropolitan Water Supply", by Frank E. Winsor, *Civil Engineering*, Vol. 4, No. 6, June, 1934; "Ware River Intake Shaft and Diversion Works", by Karl R. Kennison, *Civil Engineering*, Vol. 4, No. 8, August, 1934; and "Boston Metropolitan Water Supply Extension", by Karl R. Kennison, *Journal*, New England Water Works Assoc., Vol. XLVIII, No. 2, June, 1934.

numerous notches or gaps, situated across divides which are now unoccupied by streams. These features, which are duplicated many times throughout New England and other sections of the United States, have long been recognized by geologists as being related to the pre-historic or pre-glacial river systems developed before the Glacial Period.

Reconstructing the pre-glacial drainage pattern was important in the tunnel location studies in indicating areas where the underlying rock floor might be lower in elevation than was apparent from a study of surface geological conditions. The limits of many of the pre-glacial valleys are obscured by extensive glacial drift deposits of uncertain thickness. Because of the uncertainty in the position of the rock floor, such areas were recognized as being more important than others, where geologic conditions were more easily interpreted. These preliminary investigations outlined the critical areas throughout which more detailed investigations should be made by borings. Certain areas thus outlined were eliminated from serious consideration at an early stage of the investigations, as the gaps or notches situated within some of the valleys occur at such high elevations that there was little possibility of a gorge extending to the tunnel grade. The most important pre-glacial drainage courses are shown in Fig. 13, together with the boundaries of the two principal types of glacial drift deposits.

Glacial Drift Deposits

The greater part of the area traversed by the tunnel is covered by a glacial soil known to the geologist as a ground moraine and sometimes to the engineer as hardpan. This deposit occurs as a heterogeneous mixture of rock flour, sand, gravel, and boulders. In general, it is found in areas of higher elevation, and is usually deposited to relatively shallow depths. Recognition of the fact that, in general, the ground moraine is a shallow deposit, was found helpful in estimating bed-rock configuration, and also in delineating the less critical areas where explorations by borings were not necessary.

When the glacier was receding, many of the valleys were blocked periodically by glacial drift and ice. Water derived from the melting ice was thus ponded, forming temporary glacial lakes which received large quantities of well assorted deposits. This phase of the glacial history may be recognized in the character and mode of occurrence of the deposits, which consist largely of stratified fine sand and banded clay or rock flour. The surface topography within these lake areas is generally flat. One of the most notable examples of such a temporary lake was the glacial Lake Nashua, cited by Crosby[11], which covered a part of the Nashua River drainage area. The present Wachusett Reservoir occupies a part of the bed of this lake.

Valleys with outlets that were kept open throughout the period of glacial recession contain deposits of a modified character, the irregular structure and coarseness of which indicate an origin other than that in the quiet waters of a glacial lake. The lower sides and bottoms of these valleys contain irregularities in the general surface topography in the form of ridges and terraces composed chiefly of sand and gravel. These deposits indicate deposition by glacial stream action. Some were deposited in front of the retreating glacier

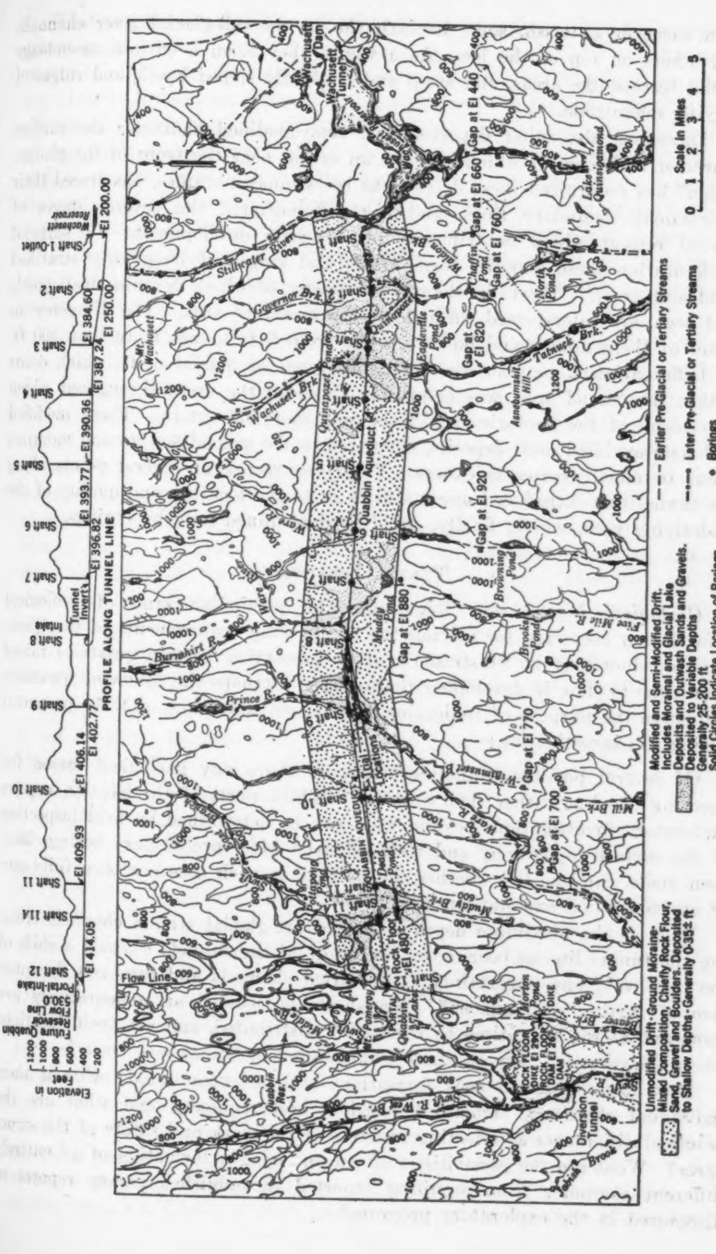

FIG. 13.—DISTRIBUTION OF GLACIAL DRIFT AND PRE-GLACIAL DRAINAGE COURSES.

as a sheet or outwash, some beneath the ice in sub-glacial river channels, and others on top of the ice. As a whole, they form a curious assemblage of flat terrace-like areas, and steep and gradually sloped knolls and ridges of varying magnitude.

There are also other deposits of a semi-modified character the surface character and form of which indicate an origin near the front of the glacier. Alden[12] has recognized these deposits as recessional moraines, has traced their approximate boundary lines, and has differentiated the several stages of glacial retreat which contributed toward their development. In surficial configuration these deposits form knolls and ridges of irregularly stratified sand and gravel. Bowl-like depressions, many of which contain small ponds and bogs, are interspersed throughout the morainal area. The difference in relief of these humps and hollows range from 5 ft to not more than 100 ft.

Differentiating between the foregoing types of glacial drift, which occur within the tunnel area, was helpful in choosing the areas throughout which knowledge of the geologic conditions was more uncertain. These modified and semi-modified drift deposits, compared to the unmodified ground moraine, occur in much greater thickness. Their occurrence at several points along the tunnel line introduced uncertainties as to the location and quality of the underlying rock, which, finally, could be determined only by borings.

Tunnel Locations

Geological Information Required.—The particular kind of geological information necessary for solving the engineering requirements of the Quabbin Aqueduct may be illustrated best by presenting certain questions raised from time to time in developing the project. Perhaps the following questions will serve the purpose of indicating the nature and range of those presented during the investigation:

Of several possible tunnel locations, is there any geological reason for choosing one line rather than another? Which parts of the location require exploratory investigations beyond what can be determined by field inspection of the surface topography and rock ledges? After preliminary borings have been made, can one tell whether the purpose in each case has been fully met or are additional explorations necessary?

What is the maximum depth of buried pre-glacial stream channels crossing the tunnel line as bearing on the grade of the tunnel? Would a shift of the line avoid any uncertainty as to buried channels and thus end the question of further explorations? Can shafts be located at comparatively low spots and at the same time be reasonably distributed, and yet avoid locations where the cover is heavy or where troublesome conditions may occur?

How many different rock formations will be encountered? what is their individual character, structural relation, and sequence, and what are the practical differences as affecting progress of the work and safety of the structures? What are the possibilities of encountering a formation of an entirely different character from anything reported in published survey reports or discovered in the exploratory program?

What are the possibilities of deep decay extending from the surface to tunnel grade, and of large inflows of water? How much timber is likely to be required? When exposed during the excavation of the tunnel, is the rock of any of these formations likely to cause trouble in the form of "popping rock", slaking, disintegration, or oxidation?

Is it likely that great faults or fault zones will be encountered in the tunnel, and, if so, are they likely to give particular trouble either on account of the quality of rock or the quantity of water? Is the rate of progress, due to changes in rock quality, likely to be different in certain sections of the tunnel?

Is there any feature, quality, difficulty, or combination of features that could make the tunnel project impractical; in other words, is the tunnel project feasible from a geological point of view?

Limitations for Suitable Shaft Sites.—The earlier investigational stages were concerned primarily with the location of the tunnel line and the selection of suitable shaft sites. In this connection it was important to recognize the limits of practicability of the information found in published reports, and to distinguish between those areas where the geological conditions could be reasonably and accurately inferred, and those where additional exploratory investigations would have to be made. Of chief concern was the thickness of glacial drift, the depth of buried channels, and their bearing on the location of the tunnel grade. Studies of the topographic map of the area, and more especially of the topographic forms in the field, revealed significant and helpful information which was used to advantage in the studies of tunnel alignment.

The engineering requirements of the project placed certain limits on the location of shafts and tunnel. These may be briefly summarized, as follows:

(1) The easterly terminus of the tunnel (Shaft 1, Fig. 13) was limited to some point adjacent to the Wachusett Reservoir, the westerly terminus (the portal at Shaft 12), to a suitable point along the east side of the proposed Quabbin Reservoir in the vicinity of Quabbin Lake.

(2) An intake shaft (Shaft 8) was to be constructed along the Ware River, near Coldbrook, the location of which was restricted not only by natural and engineering requirements, but also by legal limitations.

(3) The location of a shaft (Shaft 2) was selected near the junction of Trout Brook and the Quinapoxet River, in order that the combined flows of these streams could be diverted westerly for storage in the Quabbin Reservoir at such times as the Wachusett Reservoir was full or was being used for power purposes, if this was found desirable at some future time.

(4) As it was desired to have the easterly section, between Shafts 1 and part way to Shaft 9, completed by the early part of 1931, the tunnel was designed to be excavated from eight shafts, or fifteen headings. Shafts 3 to 7, inclusive, therefore, were located at points where the topography and bed-rock conditions were favorable to their economical construction. The shafts were spaced at as nearly equal intervals as the topography would allow. As finally arranged most of this section was excavated from twelve headings, or six shafts, there being only a small length of tunnel driven from Shafts 1 and 3.

(5) Fewer working headings, and consequently fewer shafts, were necessary for the westerly section as compared with the easterly section, because of the shorter tunnel length, and especially because more time was available for its construction. Because of this fact the westerly tunnel section was laid out to be constructed from only four shafts, or seven headings, Shaft 11-*A* being constructed as a waterway shaft.

Problems of the Rock Floor

The district through which the Quabbin Aqueduct is located is heavily covered with glacial drift and a large part of the bed-rock geology is obscured. Rock outcrops are sufficiently numerous, however, to determine certain major features concerning the underlying geologic structure. Geologic information previously published in Government *Bulletins*[14] was accepted as a working basis. These *Bulletins* proved to be immensely helpful, especially in the beginning of the applied studies; in reality, they became the ready-at-hand guide in the early reconnaissance studies. The scarcity of rock outcrops added to the difficulty of stating the problems in exact and quantitative terms. This feature made it important to re-study the entire related field and re-state the geology in terms suited to the special purposes of the project.

Information gained through geological investigations made it possible to answer, completely, some of the questions previously presented. It was readily determined, for instance, that there were at least seven important geologic units sufficiently uniform within their own boundaries, and yet varying enough, one from another, to be regarded as different geologic formations. It was also possible to determine the formational sequence from one end of the tunnel to the other, and to indicate the approximate distance of the tunnel within each formation. It was impossible, however, to make a definite statement as to the possibility of faulting, as no important faults were discovered in the exploratory work. However, it was necessary to take this feature into account in making an estimate of the amount of ground likely to exhibit unusual behavior, which might require timbering. Because of the crystalline character of the rock as a whole, there was no apparent reason to expect any unusual or rare features that might cause trouble.

It was apparent from the beginning of the project that the tunnel could be constructed successfully along any of the alternative lines as far as the rock formations themselves were concerned. Such structural weaknesses as might be encountered were expected to cross the tunnel line, and these would be encountered no matter what line was followed. The choice of lines was dependent, therefore, not upon the question of rock character, but upon the topography of the rock floor, especially in regard to the depths of buried channels.

Specific Geological Investigations

Geological investigations included briefly: (*a*) Field work which was required in the construction of an outcrop map; (*b*) delineating areas where the glacial drift was so thick that knowledge concerning the topography and

[14] "Geology of Massachusetts and Rhode Island", by B. K. Emerson, *Bulletin No. 597*, U. S. Geological Survey.

character of the rock floor was uncertain; (*c*) investigation of pre-glacial drainage courses; and (*d*) explorations by borings. Borings to, and into, rock were made in the conventional manner of doing such work. Particular care was taken, however, in being certain of the location of the underlying rock. It was recognized, in this connection, that boulders 5 ft or more in diameter are not unusual occurrences in the glacial drift covering crystalline rock formation. In order to avoid accepting an incorrect impression of the elevation of sound rock, borings were penetrated into ledge for distances varying between 10 and 20 ft. At several of the shaft sites, in addition, the rock formations were penetrated to a depth of 100 ft.

Quinapoxet Valley Investigations.—Great quantities of modified and semi-modified drift deposits occur within the Quinapoxet Valley between Shafts 1 and 2. These deposits form a continuous cover of an uncertain and variable thickness. Such outcrops as were located in the valley indicated that the present stream does not flow in its original channel. Not only was the exact depth of the drift unknown, but it was equally impossible to tell where the deepest channel in the old rock floor should be. A more extensive boring program than usual, therefore, had to be planned to secure the necessary data. The greatest depth of drift penetrated by any of the borings (see Fig. 14)

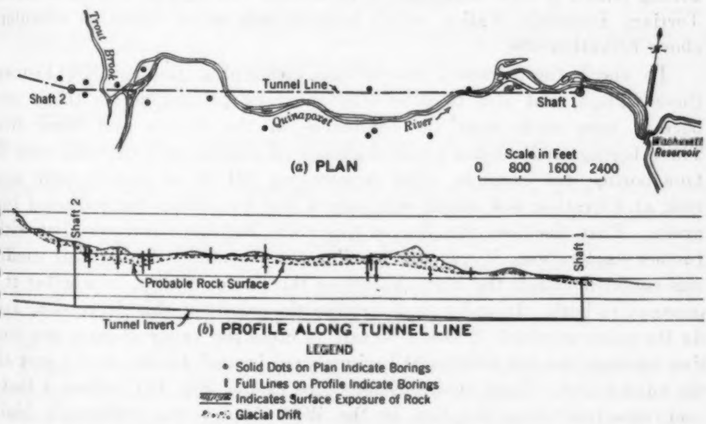

FIG. 14.—LOCATION OF BORINGS AND APPROXIMATE ROCK FLOOR ALONG TUNNEL LINE BETWEEN SHAFTS 1 AND 2, QUINAPOXET VALLEY.

was found to be 114 ft. At points within this valley, there is reason to believe that glacial drift is deposited to depths exceeding 175 ft. Finding the rock floor so low (approximately, Elevation 400) raised serious concern as to the thickness of rock cover over the tunnel as it was then located, and was the chief reason for depressing this section of the tunnel approximately 200 ft. Another indirect reason was that by building the tunnel at this lower elevation, the easterly end could be put under full pressure and could serve as a penstock in the development of power at Shaft 1.

This change of tunnel grade eliminated the question of precise depth of cover and the exact location of the deepest channel, for the greater depth fixed for the tunnel left a large margin of safety. The boring program was thus terminated by a modification of design.

Ware-Prince Valley Investigations.—The abrupt change of the Ware Valley, at Coldbrook, from a north-south to an east-west course, is a striking deviation from the normal trend of valleys throughout the district. One explanation of this behavior is based on the assumption that the Burnshirt-Ware and Prince-Ware River Valleys were originally separate systems. In the early stages of its history, the Burnshirt River flowed by way of the present Burnshirt-Ware Valley as far as Coldbrook, and thence southerly out of the district. The course of the Prince-Ware River at that time was directed the same as at present, but later the Burnshirt-Ware River was diverted into it.

A series of seven borings across the Ware River on the site of the diversion dam at Shaft 8, located the lowest point in the valley floor at about Elevation 607, which is approximately 40 ft lower than the flow line of the present stream. The high elevation of the floor at this point indicates that when the pre-glacial Burnshirt River was diverted, its valley floor was left at an elevation higher than 600 ft above sea level. This conclusion was checked by a boring placed ½ mile southeast of Coldbrook Springs, at a point within the Tertiary Burnshirt Valley, which located rock at an elevation considerably above Elevation 600.

To check the reasoned conclusions concerning the geologic history of these valleys, and also to determine the rock profiles across them, several borings were made near the confluence of the Prince and Ware Rivers. These borings indicated a great thickness of glacial drift over the rock floor. One boring, for example, after penetrating 161 ft of glacial drift showed rock at Elevation 434, which was only a few feet above the projected tunnel grade. That the floor was low at this point had been foreseen, but without further explorations it was not possible to determine whether this condition was confined within the Ware Valley or the Prince Valley, or whether it was common to both. In order to determine the extent of this depression, and to fix the point at which it would be safe to cross the valley along a new tunnel line location, several additional borings were located farther to the east along the tunnel line. These investigations (see profile, Fig. 15) indicated that the rock elevation along the line in the Ware Valley was sufficiently high to assure adequate rock cover over the tunnel, and also that the low floor section is confined to the Prince Valley. It became necessary then to select a crossing under the Prince Valley where a higher rock floor could be found. From the study of the erosional processes, river and glacial, which were responsible for the formation of this valley, it seemed evident that the floor of the valley would be appreciably higher farther north. Consequently, several borings were placed along a new location of the tunnel line and the results confirmed that conclusion. Subsequent investigations indicated a rock valley buried to a maximum depth of approximately 110 ft, with the lowest point of the valley floor at about Elevation 480.

One possible interpretation of the facts disclosed by these investigations, is that the low floor at the confluence of the Prince and Ware Rivers is a result of erosion of the Ware River alone. However, since there is a drop in the rock floor of at least 200 ft in less than 3 miles between Coldbrook and

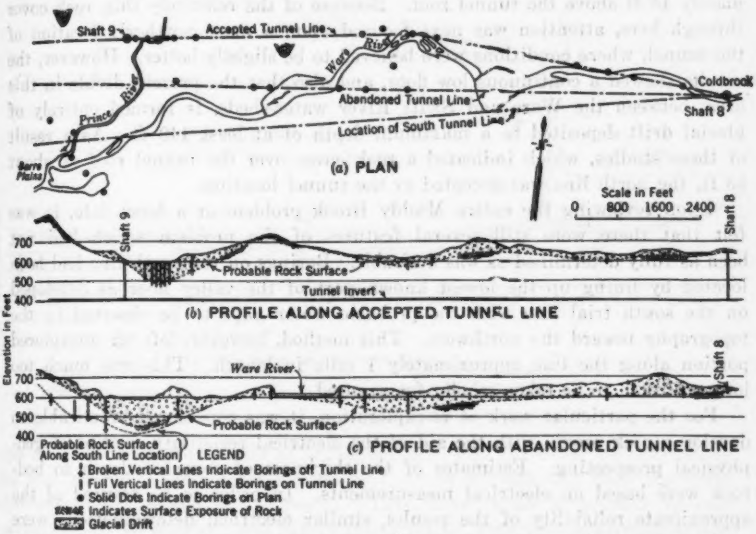

FIG. 15.—RELATION OF ALTERNATIVE TUNNEL LOCATIONS, TOGETHER WITH DISTRIBUTION OF EXPLORATORY BORINGS AND PROFILES, WARE-PRINCE VALLEYS.

Barre Plains, Mass., it is scarcely likely that the Ware River alone could have been responsible for such an abnormal gradient. Further explorations within the Ware Valley between Barre Plains and Coldbrook, showed rock to be considerably higher than would have been expected had the valley been eroded solely by the river. The most reasonable interpretation seems to be that local over-deepening by glacial scour is responsible for the low rock floor in the vicinity of Barre Plains.

Muddy Brook Valley Investigations.—Muddy Brook Valley is a fine example of a large valley now occupied by a stream apparently much too small to have accomplished such an extensive erosional effect. For more than $1\frac{1}{2}$ miles, the broad floor of this valley is covered with low sand and gravel ridges of glacial origin. Most of the drift is assorted and could be accumulated to almost any depth. There is nothing whatever to be seen in the valley bottom, from surface inspection, that would indicate either the form of floor profile or the quality of rock beneath it.

Preliminary investigation showed an irregular distribution of glacial drift, and suggested the conclusion that Muddy Brook Valley was the result of preglacial stream erosion, but that considerable deepening and widening may have been accomplished by glacial abrasion. How much of an effect these processes had on the final configuration of the rock floor it was impossible to foretell.

The first boring explorations in the valley were made along a trial location designated as the south line. A rock profile developed from several borings placed across a part of the valley near this line revealed a deeply buried valley. The lowest point of the floor along this line was determined at approximately 45 ft above the tunnel roof. Because of the relatively thin rock cover through here, attention was next focused upon a more northerly location of the tunnel, where conditions were believed to be slightly better. However, the results showed a continuous low floor, and also that the present divide in this area, between the Ware and Swift River water-sheds, is formed entirely of glacial drift deposited to a maximum depth of at least 140 ft. As a result of these studies, which indicated a rock cover over the tunnel roof of about 55 ft, the north line was accepted as the tunnel location.

Upon reviewing the entire Muddy Brook problem at a later date, it was felt that there were still several features of the problem which had not been as fully determined as was desirable. Borings on the north line had been located by lining up the lowest known part of the valley floor as developed on the south trial line with the probable water gaps to be observed in the topography toward the northwest. This method, however, left an unexplored portion along the line approximately 1 mile in length. This was much too long a stretch to be taken wholly for granted.

For the particular work of re-exploration, it was considered practicable to develop a rock profile with the aid of the electrical resistivity method of geophysical prospecting. Estimates of the thickness of cover or depth to bedrock were based on electrical measurements. In order to be assured of the approximate reliability of the results, similar electrical determinations were made at two points where the thickness of cover was already known from borings. In both cases the concordance of results was close.

A rock profile was thus developed across the valley floor, which considerably extended the reliable information. In Fig. 16, the profile is drawn along the north line (the final location) and defines the approximate rock floor as indicated by borings and geo-physical explorations. The group of borings farther south were located on a preliminary trial line which was abandoned in favor of a location farther north. Throughout the re-explored section in question, Fig. 16(*b*), the mantle of glacial drift was shown to be rather thick, but the elevation of the rock floor was considerably higher than in the adjoining section on the west. As a result of these investigations, successful excavation of the tunnel through the rock floor of this valley was made more certain.

Portal Site Investigations.—The first steps in the sub-surface investigations of the west portion of the Quabbin Aqueduct were made in Muddy Brook Valley, along a line referred to as the "south line." In the beginning, location studies of the west terminus of the tunnel were confined to the selection of a suitable portal site on the East Branch of the Swift River, somewhere south of Quabbin Lake. The portal of the south tunnel line was located about $\frac{1}{4}$ mile south of the lake at a natural site. It was noted, however, that the terrain along the east side of the lake would allow for considerable saving, in the length of tunnel—about $\frac{1}{3}$ mile—for a portal located farther north. Preliminary studies narrowed the list of possible sites to two,

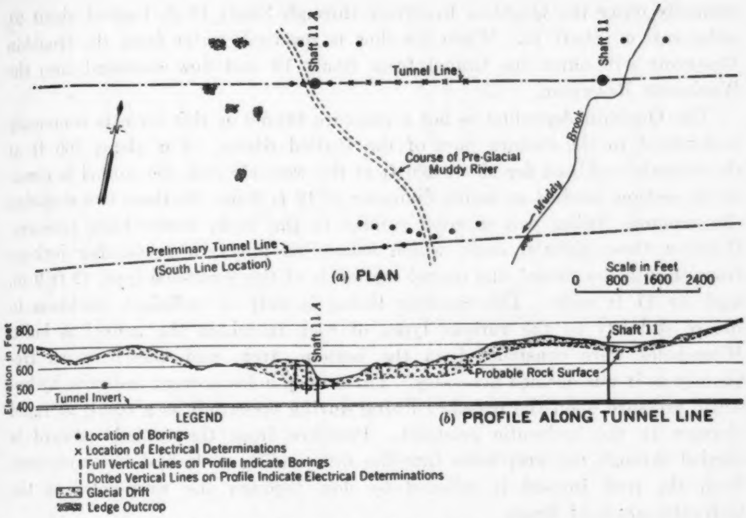

FIG. 16.—BORINGS IN MUDDY BROOK VALLEY.

one at the extreme north end of Quabbin Lake, and the other midway along the east section. After careful investigations by borings, the most northerly site was finally chosen as the portal. This choice made it possible to take advantage of the shortest possible tunnel location with its consequent saving in construction cost.

TUNNEL DESIGN AND LOCATION ADOPTED

As finally located, the Quabbin Aqueduct is oriented in a general east-west direction and extends from the northwest side of Wachusett Reservoir to Quabbin Lake (see Fig 13). Excavation was carried through rock for its entire length of 24.6 miles. The quantity of rock cover above the tunnel, as nearly as could be determined by borings, varies between 55 and 800 ft. In the easterly $3\frac{1}{2}$ miles, the tunnel level or invert lies between Elevations 200 and 385. For the remaining length it continues in a slightly inclined grade to the portal, where the invert is at Elevation 414. All elevations given herein and on the diagrams refer to the Boston City Base datum plane.

The completed tunnel will serve as an aqueduct which, because of the surface topography of the area and its design, will fulfill several functions: (*a*) It will furnish a means of bringing water from the Quabbin Reservoir which will have a maximum flow-line at Elevation 530; (*b*) at Shaft 8, at Elevation 656, it will permit diversion by gravity of the Ware River into the Quabbin Reservoir, or the Wachusett Reservoir; and (*c*) at Shaft 2, at Elevation 540, it will permit diversion of a considerable part of the Quinapoxet River flows into the Quabbin Reservoir if, and as, this is desired. The tunnel flow controlled by gates at the east, or the Wachusett Reservoir, end will

normally enter the Quabbin Reservoir through Shaft 11-*A*, located about $2\frac{1}{2}$ miles east of Shaft 12. When the flow is reversed, water from the Quabbin Reservoir will enter the tunnel from Shaft 12 and flow eastward into the Wachusett Reservoir.

The Quabbin Aqueduct is not a pressure tunnel as this term is commonly understood in the eastern part of the United States. For about 500 ft at the easterly end, and for about 200 ft at the westerly end, the tunnel is circular in section, having an inside diameter of 12 ft 9 in. In these two stretches the concrete lining was grouted solidly to the rock, under high pressure. Between these circular ends, which behave as plugs in preventing leakage from or into the tunnel, the tunnel section is of the horseshoe type, 12 ft 9 in. high by 11 ft wide. The concrete lining is only of sufficient thickness to insure stability in the various types of rock in which the tunnel is built. Weep-holes were constructed in the bottom, arch, and elsewhere, as frequently as it was deemed necessary. These weep-holes prevent excessive hydrostatic pressure upon the masonry lining during operation as a result of rapid changes in the hydraulic gradient. Pressure from the tunnel outward is carried through the weep-holes into the surrounding rock, and water pressure from the rock inward is relieved by flow through the weep-holes as the hydraulic gradient drops.

The tunnel portion from Shaft 8 to the Wachusett Reservoir, about 14 miles in length, has been operated under extreme conditions at intervals since 1931 without any signs of structural or other defects.

To determine the payment for rock excavation in the tunnel, certain reference lines were provided and designated as the *A* and *B* lines. The *A*-line was defined as that within which no excavated material of any kind was permitted to remain. In the normal tunnel cross-section, this line was placed at a minimum distance of 3 in. outside the neat line of the concrete side-walls, and of 8 in. above the neat line of the arch. The *B*-line was arbitrarily placed 12 in. outside the *A*-line in the side-walls and arch, and 2 in. below the *A*-line in the invert. Slight modifications of these distances were made where permanent timbering was required. All payment for excavation in the untimbered portions was for the volume bounded by the *B*-line, or normally about 6.8 cu yd per lin ft.

All shafts, except Shafts 1, 8, and 12, had an inside diameter of 14 ft The three exceptions were larger than this and were designed to serve not only for construction purposes, but also as waterway shafts. Shaft 1 was excavated as one shaft, but completed as two units, one unit being used as a water outlet, the other as a pump-well for dewatering the depressed tunnel section between Shafts 1 and 3.

Tunnel Excavation

Rock Formations Encountered.—From an engineering viewpoint, the rocks of the tunnel area can be divided into two major classes, schist and granite. Both these varieties are highly crystalline, the granite being of an igneous origin, and the schist being originally of sedimentary origin. Excavations

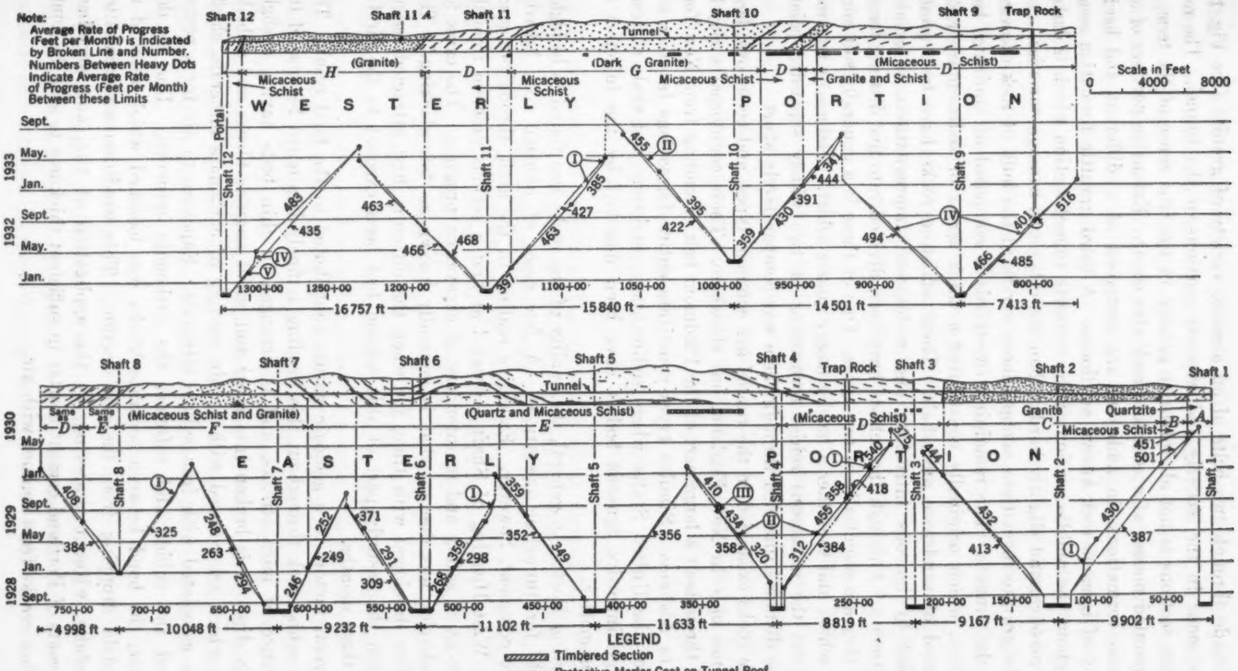

FIG. 17.—PROGRESS OF TUNNEL EXCAVATION AND GEOLOGICAL SECTION.

were made through two belts of an average variety of granite (see Fig. 17) which occur in the easterly and westerly portions of the tunnel. The rock in these sections is not all intrusive granite in the true sense of the term, as incorporated masses of a schistose rock also occur. Extensive portions of one of these formations, in addition, are composed of a different and harder variety of igneous rock known as diorite. A third granitic formation occurs throughout the middle portion of the westerly tunnel section which is darker, more massive, and slightly harder than the other two average varieties.

The granite formations occupy about one-third the bulk of rock excavated from the tunnels. The remaining two-thirds is composed of laminated beds of schist, which originally constituted a thick series of sedimentary rocks, composed of sandstone and shale. These schistose rocks have been greatly modified by igneous intrusions and widespread impregnations of granitic constituents. Although the schists have been divided into five distinct formations, they are essentially of two types. One of these is a generally soft micaceous schist, and the other a harder flaggy quartz schist. Diabase or trap-rock dikes cut the micaceous schist formations at two widely separated points, but the distance tunneled through them was comparatively short.

The rocks excavated in the tunnel are common types, and occur over large areas not only in New England, but elsewhere. Their counterparts may be traced throughout a large part of the Piedmont belt extending from New York State to Alabama. Similar types constitute entire formations in other sections of the United States where sedimentary sandstone and shale adjacent to large intrusive igneous bodies have been modified by the injection of igneous matter.

Scaling Rock.—In general, the quality of the rocks was found to be highly suitable for tunneling operations. A few cases of unusual rock behavior deserve comment, however. Excessive scaling in the arch, throughout much of the West Heading of Shaft 4 created at first a serious problem from the standpoint of safety and maintenance of excavation progress. The cause for this behavior was due to what is generally known as "air slacking." This condition developed with time, for when the difficulty first attracted serious attention the easterly part of this section had been exposed to the air for about three months.

Several factors of a geologic nature contributed to the final result. The quartz schist rock throughout this heading is finely laminated because of the occurrence of mica streaks, and is arranged in thin beds having a slight easterly dip. It is broken into large and small angular blocks and slabs by joints, which are covered with a thin coating of carbonate minerals, chiefly calcite, associated with iron sulfide minerals. Exposure to air for a period, oxidized the sulfide and softened the carbonate minerals. Due to this behavior, the bond between separate blocks was loosened which resulted in large slabs dropping from the roof section. This condition was combatted successfully, without timbering, by the application of two, and sometimes three, coats of Portland cement mortar in sufficient thickness to seal the joints and other cracks from contact with air.

The granite, throughout a short stretch in the easterly tunnel portion, also scaled, but this behavior resulted from a geologic condition which differed from that causing "air slacking." The grain of the granite and the orientation of incorporated masses of schist indicate a strong geologic structure, the rock lying in a nearly vertical position. The entire formation was under strain which, upon being released by excavation of the tunnel, developed new fractures causing slabs to fall from the arch. This condition commonly known as "popping rock" required constant attention and the frequent scaling of rock in the arch by the contractor. Covering the arch section with mortar would not have improved the situation in this case, and the condition was not sufficiently serious to require timbering.

Timbering.—A question of practical importance, always raised on a project of this kind, concerns the amount of timbering likely to be required, and which particular sections of the tunnel are most likely to require such construction.

No definite answer could be given in advance to this question, but it was thought that the rock would require timbering throughout possibly a maximum of 10% of the tunnel. In the estimates it was assumed that about 5% would require some form of timber support. The actual figures, including those for correcting the condition of "air slacking" in the arch, are as follows:

	Feet	Percentage
Permanent timber support	1 971	1.5
Temporary timber support	320	0.3
Protective mortar coat	12 050	9.3

Many intrusions of granite in the micaceous schist formations established conditions that were followed by alteration and gradual decay of the adjacent rock. Partings along bedding lines served as watercourses, so that the entire formation was affected, some sections more so than others. This condition caused the rock to scale and crumble, which made it necessary to construct timbering throughout the stretches where the formations were softest. The protective coat was sufficient to stabilize the rock in other sections where alteration and consequent decay were not so prominent.

Excavation was carried through several zones of crushing and close jointing without any abnormal rock behavior. At some points, however, overbreakage on the sides and in the arch resulted from such conditions. Timbering was constructed in some of these sections, especially where the removal of loose blocks did not appear to remedy the unstable situation. In a short stretch, near Shaft 12, the rock had a tendency to swell and move into the excavated space. This behavior was due to the occurrence of large quantities of clay derived by alteration of an intrusive igneous body containing much feldspar.

Progress of Excavation in Relation to Geologic Conditions

Schedule of Required Progress.—The first contracts, awarded in 1927, were those for the construction of Shafts 2 to 7 in the easterly tunnel portion. The award of two major contracts during the latter part of 1927, for construct-

ing the easterly tunnel section from and including Shaft 1, to 4 000 ft beyond and including Shaft 8, was delayed about five months by unforeseen legal difficulties. During this time the construction of six shafts was completed, and a considerable length of tunnel, in all 8 238 ft, was excavated with equipment used in sinking the shafts. The schedule of minimum progress in the first major contracts, required that excavation of 65 664 ft of tunnel should be completed within 26 months. The third major contract, for constructing the westerly portion of the tunnel, including four shafts and appurtenant structures, was awarded during the early part of 1931. The schedule of progress on this contract required all excavation in shafts and 54 845 ft of tunnel to be completed in 34 months. The contract requirements as to the minimum performance in excavating these tunnels may be summarized as shown in Table 6. As actually constructed, all but 836 ft of the tunnel between

* Minimum progress required in one or more headings to complete tunnel excavation in the specified time. † West Shaft. ‡ East Shaft. § Shaft 12 to West Portal.

Shafts 1 and 2 was excavated from Shaft 2, and the actual length of tunnel driven west of Shaft 8 was 5 000 ft. Furthermore, after being excavated, Shaft 3 was not used extensively as a construction shaft, and practically all the heading between Shafts 3 and 4 was excavated from Shaft 4.

The rates indicated in Table 6, especially those in Table 6(*a*), were estimated from the average performance attained on other tunnel projects throughout the eastern part of the United States. Those in Table 6(*b*) were based upon the average performance attained in excavating the eastern part of the Quabbin Aqueduct with liberal allowance for unforeseen construction difficulties. A few of these expected difficulties, which are essentially of a geologic nature, and of which complete information could not be obtained in advance may be thus summarized:

1.—As the tunnel crosses the general trend of several geologic formations, over a belt 25 miles wide, it was expected that some of the headings would pass through several faults and crush zones requiring timber support and in other ways creating serious difficulties. The results of studies of surface outcrops and core borings, made at critical and intermediate points, did not reveal the occurrence of such zones of weakness. It was realized, however, that this was not unusual because of the extent to which glacial drift deposits

had buried the underlying rock formations. It was believed expedient, therefore, to allow for the possibility that this condition might occur at least as frequently as once in every mile or so.

2.—An allowance was also made for possible occurrence of deep decay extending from the surface to the tunnel grade, or disintegration or slacking of the rock when exposed to air. The least troublesome of these conditions would require only precautionary measures during excavation, and if they were sufficiently extensive, timbering, cement mortar lining, or some other form of construction.

3.—The occurrence of rocks of a crystalline character was recognized, and also that they would not contain water, except within the space between joints, and other fractures and fissures. The tunnel passes under several river valleys and areas containing porous glacial deposits, and considerable leakage into the tunnel from these was anticipated, together with the attendant hazards of inflows temporarily beyond pumping facilities.

4.—Changes were made in the original location of the aqueduct in order to cross under two deeply buried valleys. The possibility of encountering serious difficulties in these stretches, because of the presence of faults or crush zones, deep decay, large inflows of water, or because other combinations of adverse considerations made it expedient to allow for considerable retardation of progress.

Methods of Excavation.—A description of the methods used in tunnel excavation is included in order to supplement the information presented in Fig. 17 and Table 7. The data concern only the performance attained after permanent tunnel equipment had been installed. The shorter tunnel stretches excavated with the equipment used in shaft sinking are not considered. Shaft 3 was eliminated as a construction shaft soon after construction began under the first major tunnel contracts, but access to it was maintained as insurance against difficulties encountered in excavating from Shaft 2. Only a short stretch of tunnel was excavated from Shaft 1.

The numerals within circles on the progress chart in Fig. 17 refer to geological or other conditions which appreciably affected the performance of the work, as follows: (I) Progress retarded by water; (II) increase in progress due to changes in organization; (III) progress retarded by "air-slacking" rock; (IV) progress retarded by unstable rock, requiring timbering; and (V) slow progress due to experiments on the dragline mucking machine.

The full-face method of excavation was used at Shafts 2, 4, and 9 to 12, inclusive. The headings at the first two shafts were advanced continuously by drilling and mucking crews, which worked on a schedule of three 8-hr shifts. By this plan the contractor hoped to obtain four advances in one day and five the next. This objective was realized at times, but not to the extent anticipated. Two 10-hr shifts were employed at Shafts 9 to 12, inclusive. The number of advances in one day was seldom less than four, and five advances per day were attained at times, except at Shaft 12, where there was one heading. Three advances were often made at Shaft 12, but in order to do this, the crews were required to work overtime.

The heading and bench method was used in the headings of Shafts 5 to 8, inclusive. At these points the work was organized on a basis of two 10-hr shifts in such a manner as to produce two rounds of excavation per day in each heading. This arrangement required drilling and mucking to be done together.

At Shaft 7 a different plan was used in which drilling and blasting of each heading and bench was completed during one shift and mucking during the other. The depth of holes was increased to 10 ft. The heading was blasted in two operations, the cut and bench holes being loaded and shot first.

Drilling and Blasting.—Holes were drilled in the full headings in much the same manner as on similar projects elsewhere. Two types of drill carriages were used. The drilling bars on one of these carriages were integral parts of the carriage, whereas those on the other were separate from the carriage and had to be blocked and wedged to the side-walls. Four drills, one on each bar, were mounted on the former carriages whereas five drills—three mounted on the upper and two on the lower bars—were used on the latter. Three drilling and three mucking crews, each working in an 8-hr shift, operated between the headings at Shafts 2 and 4. In the westerly tunnel section, a similar drilling and mucking organization was used, except that the crews worked on only a 10-hr per shift schedule.

As good, and in several cases even better, progress was attained in excavating the easterly section, under similar rock conditions. The integral type of drill carriage, compared to the other type, proved to be a time-saver and in this way contributed toward a better performance record. Holes in the top headings were drilled by two machines mounted on horizontal arms clamped to two vertical columns, which were blocked and wedged to the tunnel roof and bench. Bench holes were drilled by the same machines, mounted on one horizontal bar located in front of the bench, and wedged to the tunnel side-walls. Drilling and mucking were simultaneous operations in these headings.

The location and pointing of drill holes is illustrated in Fig. 18. A typical 31-hole drilling round, used in the granite and schist formations of Shafts 2 and 4, is shown in Fig. 18(*a*). In the harder varieties of granite, the number of holes was increased generally to 37, and in the softer varieties and throughout long stretches of micaceous schist, the number was reduced to 31 holes, or less. A similar diagram showing 36 drill holes (the number generally used in the granite formation of Shaft 12) is shown in Fig. 18(*b*). The variation in the distribution of holes, is due to several reasons, chief of which is the difference in locations of the drilling bars on the two drill carriages.

In blasting, the center or cut holes in both the full-face and top headings were generally loaded with 60% gelatine dynamite, and the remaining holes with dynamite of 40% strength. At times, dynamite of 40% strength was used in all holes, especially in stretches of soft rock. Throughout the westerly tunnel portion the contractor used a new explosive product, in strengths of 40, 47, and 60 per cent. The quantity of explosive used per cubic yard of excavation in the different kinds of rock is indicated in Table 7.

Mucking.—In all the full headings, except the single one at Shaft 12, blasted rock was loaded by means of electric power shovels. At Shaft 12, the contractor installed a dragline excavator of his own construction. This machine was equipped with a conveyor belt of sufficient length to allow a full

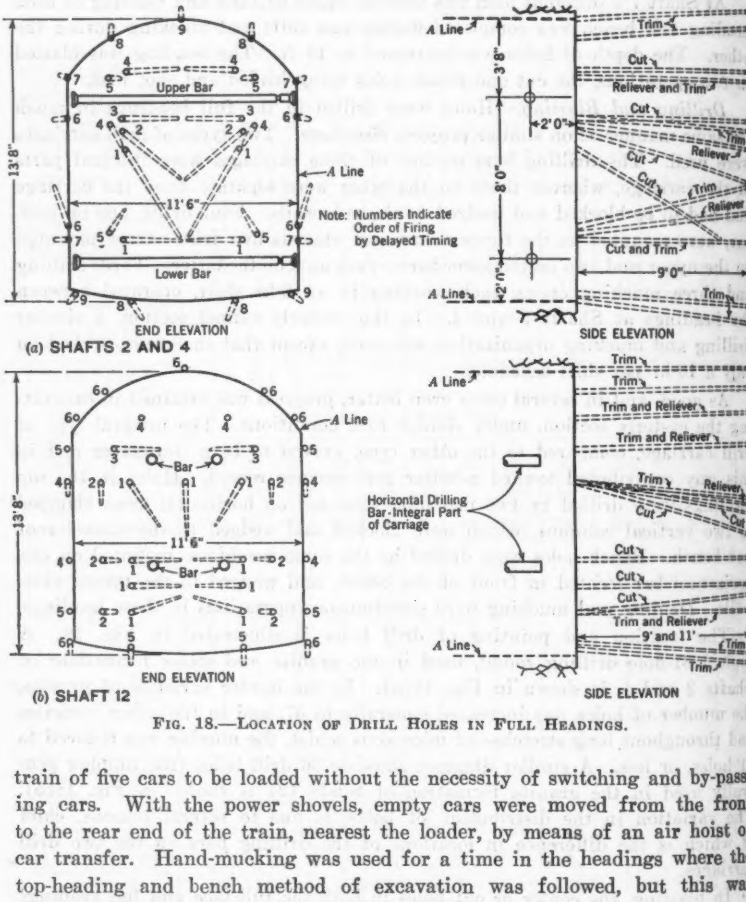

FIG. 18.—LOCATION OF DRILL HOLES IN FULL HEADINGS.

train of five cars to be loaded without the necessity of switching and by-passing cars. With the power shovels, empty cars were moved from the front to the rear end of the train, nearest the loader, by means of an air hoist or car transfer. Hand-mucking was used for a time in the headings where the top-heading and bench method of excavation was followed, but this was abandoned later in favor of mechanical mucking by air shovels.

The time required to remove rock from the headings varied. In the full headings, except those at Shafts 11 and 12, the average time was between 2.5 and 3.5 hr. At Shafts 11 and 12 it was between 3 and 5 hr. Where the top-heading and bench method was used the average time was between 5.5 and 6.5 hr.

Throughout the easterly portion, loaded muck cars were hoisted from the tunnel by means of cages, whereas, in the westerly portion, skips were used. Provision was made at Shafts 9 to 12, inclusive, for stocking rock of suitable quality and size for use as concrete aggregate. This was accomplished by wasting rock in those headings where the formations were soft, and by dumping rock from hard formations over a coarse screen or "grizzly." The portion passing through this separator was then crushed and conveyed by belt to the stock-pile. From experience on the Quabbin project, the method of stocking suitable rock material and wasting that of inferior quality is believed to be superior to that of dumping excavated rock on a spoil bank regardless of quality. This is especially true where tunnels are excavated through different geological formations, some of which may be soft or in other respects may have objectionable characteristics.

Hardness of Formations.—The relative hardness of the rocks is shown in Table 7(*b*) under the heading, "Speed of Drilling." A wide range of drilling behavior is indicated. The micaceous schist formations were the softest, the high mica content and soft condition, due chiefly to alteration of minerals, being conducive to fast drilling. Slower drilling in these formations was due to encountering quartzite beds and granite bodies.

The hardest rocks to drill, except trap-rock, were those contained in the granite formations. In general, the granitic rocks were about three times as hard to drill as the micaceous schists. Between the extremes represented by these formations there was a rather uniform hardness represented in the flaggy quartz schist types and the micaceous schists containing much granitic material. The widespread intrusions of granite in portions of the micaceous formations rendered the rock harder and more stable than would otherwise have been the case.

Excavation Costs

Information pertaining to the cost of excavation in the several rock formations is shown in Table 8. Partial information relating to this particular item has been published[15] previously, although not in the form presented herein. The values given are the costs for excavating to approximate line and grade only. Before lining, the contractors were required to remove rock which projected beyond the arbitrary limits on the side-walls and the arch, and also to shape the tunnel invert to grade. The cost of this operation is not included in Table 8.

The much lower cost indicated in Column (10), Table 8(*b*), is due mostly to the use of second-hand equipment, purchased from the contractors who constructed the easterly portion. This equipment, which had been maintained in excellent condition, was obtained at greatly reduced prices, compared to the original costs. Comparison of costs in the easterly tunnel portion (Table 8(*a*)) with those in the westerly portion (Table 8(*b*)) indicate striking differences

* Taken from *Information Circular*, entitled "Construction of the Wachusetts-Coldbrook Tunnel", U. S. Bureau of Mines. † Cost data for one shaft only. ‡ Labor costs of excavation after development of dragline excavator and after passing through a section that required timbering. § More approximate than other cost data.

of excavation costs in formations of similar rock character and behavior. This may be partly accounted for, as follows:

(1) The easterly tunnel portion was excavated during 1928–30, and the westerly portion during the period, 1931–33. During the latter period, the wage scale of the several classes of labor was from 5% to 25% lower than during the former years.

(2) Better progress as a whole was made in the westerly portion, where the full-face method of excavation was used entirely, than in the easterly portion, where only one-third of the headings were excavated by the full-face method and two-thirds by the slower top-heading and bench method.

(3) The number of man-hours per day, in the easterly portion, was generally from 10% to 20% greater than those in the westerly portion.

(4) Micaceous schist formations extended through longer stretches of the westerly tunnel portion than of the easterly portion. In addition, these schists were considerably softer than their counterparts farther east. These two conditions are partly responsible for the better progress throughout the westerly portion.

(5) Disregarding the single heading at Shaft 12, better progress was made in the granite formations of the westerly portion as compared to that made in granite of similar quality in the easterly portion. This advantage was largely the result of longer advances per shot, which, in turn, were due to an improved type of explosive, and deeper, and possibly better directed, drill holes.

Rock Breakage.—High and wide over-breakage at several places was caused by closely spaced and intersecting joints. This condition had some effect upon the actual volume of rock excavated as compared to the volume within the theoretical payment lines. The payment line for excavation was fixed arbitrarily 12 in. outside the *A*-line, the mimimum required line of excavation in the side-walls and arch. As excavated, the average rock breakage beyond the *A*-line, considering the total length of tunnel, was about $10\frac{1}{2}$ in.

Conclusions

An attempt has been made in this paper, to correlate data of a geologic nature with that related to engineering and construction problems. Construction of the Quabbin Aqueduct, without encountering serious difficulties, may be attributed partly to the sound character of the rock formations through which the tunnel extends. It can be emphasized, however, that many of the difficulties that might have been encountered were eliminated by careful geologic investigations, which reduced construction uncertainties to a minimum, and conversely determined the favorable geologic factors.

Several items of interest may be emphasized in conclusion, as follows:

1.—The kind of geological investigations described herein are also applicable to the study of similar problems in tunnel location in other sections of the United States. Valleys which have been deeply buried by glacial drift deposits are not new topographic features to the engineer. Numerous accounts of the crossing of such valleys by tunnels may be found in engineering literature. In presenting details concerning the surface geologic features of the

Quabbin Aqueduct the writer wishes to suggest that an understanding of the genetic relation of correspondingly formed valleys may prove helpful elsewhere in the study of similar location problems.

2.—The engineer may obtain valuable data from published geological reports. These reports are generally of a scientific nature, but often contain information that can be used in a practical manner. They are related generally to the geology of a large area, and because of this may be helpful to the engineer in obtaining a broad perspective of the geology of a region, in some particular section of which an engineering project is proposed. The engineer must rely upon his own investigations for the geological information required within and adjacent to the construction lines of a structure.

3.—The data on excavation progress are important mainly in their manner of presentation. Because the geology of this project was followed so closely it was possible to draw an accurate geologic section covering the entire 24.6 miles of the tunnel. This fact, together with other related construction data and costs, correlates the geology with construction in considerable detail.

Acknowledgments

Some parts of this paper have been taken from reports to the Chief Engineer prepared jointly by Charles P. Berkey, M. Am. Soc. C. E., and the writer. Dr. Berkey was Consulting Geologist on the work. The writer also wishes to express his indebtedness to the Chief Engineer of the Metropolitan District Water Supply Commission, Frank E. Winsor, M. Am. Soc. C. E., who has shown a keen interest in the application of geology to engineering works of this kind.

DISCUSSION

BAYARD F. SNOW,[18] M. AM. SOC. C. E. (by letter).—The operations preliminary to the construction of the Quabbin Dam and Dike afforded an excellent opportunity for the collection and study of many data relating to the exhaustive pumping of ground-water. Such data are of intense interest to many engineers whose work concerns the flow of ground-water, and Mr. Dore deserves much credit for the manner in which he has collected and presented the facts. Undoubtedly, the problem of estimating the expected leakage through the earth over-burden under a dam is nearer a rational and reasonable solution as a result of this paper. There is a question, however, as to whether the data and study are of most value in connection with estimating the flow under proposed dams. It is true that, in the case of the Quabbin works, the bore-holes were made and some of the pumping was done prior to the actual beginning of core-wall construction even if such holes may not have preceded the decision to construct such a water-stop. There is no doubt that they assisted greatly in the construction of the core-wall. However, much of the information was gathered during the sinking of the caissons and, therefore, can have had no part in reaching the decision that caissons were necessary.

It would be of considerable value to the Engineering Profession if Mr. Dore would present a modification of his study of these basic records to assist in answering a series of questions frequently met in the study of the flow of ground-waters; for example:

(*a*) What is the probable safe yield and the optimum spacing of wells under given geologic and topographic conditions?

(*b*) What portion of the pumpage is depletion of storage, what part is infiltration from within the area of the circle of influence, and what part a ground-water flow from outside that circle? and,

(*c*) With soil of a given porosity, what part of those pores is filled with water and how much of that water can be drawn as the water level is lowered by pumping?

Fig. 10 indicates that there was no change in water level at points ½ mile up stream and down stream after eighty weeks of pumping, although at the caisson it had dropped 100 ft below its original level. Pumping rates for a year had been about 3 mgd, after which they had increased so as to average slightly more than 5 mgd. One may assume that, at a point ½ mile above the dam, there was no change in the direction and velocity of the flow of ground-water and surface water as the result of the pumping. The easiest hydraulic channel for water precipitated on the uplands above this point was by surface and underground courses to the river, and this condition was unchanged by the pumping. It seems obvious, therefore, that in such materials the watershed from which a ground-water supply could be taken by wells near the site of the dam was less than a mile in diameter and that the safe yield would be

[18] Pres., X. Henry Goodnough, Inc., Boston, Mass.

not more than one-tenth the rate of pumping actually used in dewatering the soil, and even that only by excessive draw-down. It is probable that with a slight change in average size of grain, the radius of influence would be extended greatly. The real question is whether a circle of influence or area contributing to the yield of a ground-water supply can be predicted by analysis of soil samples. If Mr. Dore can utilize his data to this end and give the Engineering Profession a workable means of determining yield of wells under given geologic conditions, a noteworthy contribution to water supply engineering will have been made.

The determination of permeability by borings is certain to be, in a large measure, a matter of luck. Mr. Dore calls attention to the random nature of the deposits and refers to the connection of the coarser deposits by links of relatively small cross-section, but which serve very effectively in conducting the flow from one coarse lens to another. In seeking a suitable site for an additional ground-water supply, the writer has had the experience of finding what appeared to be a pocket of coarse material completely surrounded by a very fine sand. As far as borings could reveal any information, an acre or two of coarse sand was available, which would serve as a collecting and storing reservoir, surrounded by material through which water would flow at very slow rates. The area between the old well field and the new site was apparently an almost impervious barrier. On a pumping test, however, it was shown that hydraulic communication between the two areas was free and that each well field responded promptly to pumping from the other. It would appear, therefore, that the zone of influence was much larger than would have been indicated by computations based on examination of boring samples.

In this area the writer saw an interesting demonstration of the transmission of pressure through ground-water. On one well a stroke of a hand-pump caused an immediate temporary drop of an inch or more in the water level at the other well, 80 ft, or more, away. This calls attention to the fact that ground-water flow is affected not only by the permeability of the water-bearing strata, but also by the resistance to transmission of air through the overlying material. If the water-bearing material adjacent to the first well had been freely open to atmospheric pressure, there would have been little discernible effect of the vacuum a few feet away from the well. Many test wells in the writer's experience have disclosed nothing which would indicate a potential water supply, all the material above ledge being nearly impervious. Frequently, however, a thin stratum of coarse material lies at the rock surface and serves to form a channel through which the water flows freely and perhaps, by reason of the nature of the overlying material, transmits a differential pressure for considerable distances to points where the over-burden is less in amount or more pervious. When deposits of coarser material are connected by such devious channels the total effective water-shed to a well may be much greater than study of the most carefully selected boring samples would indicate was possible

The ratio of permeability between the material of such a very thin coarse stratum and the overlying fine deposit may be 100 to 1 so that it would appear to be important to measure the water-bearing stratum with extreme care. The ordinary methods of wash-boring and sampling do not permit of such refinement, even if by luck the boring penetrates a representative section of such a stratum. This being so, although the writer agrees that water tends to open passages of flow between pockets of coarser materials and feels that such passages may have a carrying capacity equal to that of the deposits of coarse sand they connect, nevertheless, the determination of the average permeability of a cross-section by boring samples is subject to great errors, especially where the borings miss the larger masses of relatively coarse material and may or may not penetrate a typical cross-section of the connecting channel. It is not more simple and more accurate to utilize the test borings that would be necessary for soil sampling, pumping from some and observing the slope of the water surface at others, rather than to depend upon samples obtained by more or less blind groping?

OLE SINGSTAD,[17] M. AM. SOC. C. E. (by letter).—Being especially well prepared the valuable paper by Mr. Fahlquist presents an excellent picture of the geologic features of an extensive project and their relation to its construction operations and cost. The most impressive aspect of the paper is the manner in which the geologic features have been taken into consideration in the planning of the tunnel project. It illustrates the importance and value of the co-operation between the engineer and the geologist in the proper planning of an underground project of this magnitude. It is quite evident that this thorough and scientific consideration of the geological features in the planning was in large measure responsible for the successful construction operations carried on without untoward happenings. This complete preliminary information undoubtedly removed from the project much of the uncertainty attached to the bidding on underground projects where the preliminary exploratory work is less thorough, resulting in economy to the owner and a greater degree of certainty that the contractor can complete the work within the bid price and the stipulated time.

The paper also presents in convenient tabular form much valuable information as to cost and progress, and shows the variation of these items in relation to the geologic conditions. It should be of great value to engineers dealing with underground construction work, in stimulating more attention to the geologic features and more thorough exploratory work than has sometimes been the case in the past.

VERNE GONGWER,[18] M. AM. SOC. C. E. (by letter).—In the "Synopsis" of Mr. Dore's very interesting and valuable paper, two general sources of information for use in determining the permeability of earth over-burden are mentioned: (1) Dry samples from bore-hole investigations; and (2) the effect of pumping upon the ground-water conditions in the over-burden.

[17] Chf. Engr., New York City Tunnel Authority, New York, N. Y.
[18] Project Engr., Guntersville Dam, TVA, Guntersville Dam, Ala.

Mr. Dore has described a very careful and almost exhaustive application of these methods to the study of conditions at Quabbin Reservoir, and is to be commended for so thoroughly presenting it in his paper, because the characteristics of the underlying formations, where a dam is to be built on earth foundations, warrants the gravest study. This phase of the problem is too often given little or only perfunctory attention, usually being confined to the drilling of a few holes, sinking of a few test pits, and possibly doing a little perfunctory pumping from them; or confined to the application of some well known formula to a conjectural distance for seepage or "creep" by means of an effective size determined in the laboratory from a greater or less number of usually questionable samples recovered from the explorations. The formulas seldom have been developed for the conditions prevailing at the site under investigation, and the results of laboratory analyses and tests can be no better than the samples submitted to the technicians; in fact, the usual unwitting inaccuracies in the recovering of samples, even where great care is intended, often render the laboratory results seriously misleading.

The writer fully agrees with Mr. Dore's "Conclusions," and desires, for emphasis, to quote from them:

"There seems to be a scarcity of data concerning the permeable characteristics of soils and there are few, if any, definite methods in common use for making satisfactory determinations of the permeability of an overburden. In many cases permeable qualities of foundations have been a matter of extremely rough estimate, of guess, or merely of conjecture."

Very pertinent also is a comment made to the writer by E. W. Lane, M. Am. Soc. C. E., that engineers have advanced greatly in their study of soils and the development of methods for building excellent and water-tight earth-fill dams; but that too little attention is paid to the materials and foundations upon which such structures are built and that they are woefully lacking in means and methods of attack.

The writer has found attempts to determine the permeability of most soils (other than uniform silts, clay, and fine sand), from samples, to be very unsatisfactory and misleading. In fact, they can be said to be almost invariably misleading, due to the difficulty of recovering, in place, truly representative samples of streamers, lenses, or veins of the more open gravels without admixture from adjoining layers of materials, above or below. This condition vitiates the accuracy of either mechanical analysis curves or direct testing of "so-called dry samples" for permeability.

Observations of the variations in, and effect on, the ground-water levels from pumping from open test pits, casings, or well-points is believed to furnish much more illuminating and dependable data in regard to permeability; however, the writer has never been able to arrive by this method at anything very tangible, other than a general indication of relative water-tightness. There have been certain surprising results, in that test pits in areas previously considered quite tight from borings and mechanical analyses of samples, have produced water under the pumping test almost as freely as other pits that have been expected from mechanical analyses of samples

to produce water freely. In this connection, the writer's experience coincides remarkably with certain conclusions by Mr. Dore; for example, in the making of certain calculations of the quantity of water which would flow horizontally under a given head through a vertical 1-ft slice of the materials found in a test pit from surface to bed-rock, it was found that, theoretically, on the basis of flow constants corresponding to results of mechanical analyses, from 90% to 95% of the total water passing will be transmitted through, or by, the coarsest stratum penetrated by the test pit, even if that stratum is relatively insignificant in thickness and the "effective size" of the particles is not particularly, or startlingly, large. This lends considerable importance to a conclusion by Mr. Dore, which is also heartily concurred in by the writer, that although the coarser materials are found or are usually considered as lying in random assortment or lenses, they are usually in glacial soils—and almost invariably in alluvial soils—either connected or continuous in the general direction of the valley, or should be considered continuous for safety.

When a dam is proposed to rest on earth foundations, with or without underlying rock at shallow or greater depths, two main questions arise, which must be answered in advance:

(1) Will the volume of the total leakage through the sub-strata be excessive from the standpoint of loss of water, unsightliness, possible damage to property, or for any of a number of possible reasons, other than as affecting the safety of the dam itself?

(2) Are the materials, or disposition of the sub-strata, such as to render at all possible the disastrous phenomenon resulting from concentrated flow at one or more points, at high velocity, known as "piping"?

A positive answer to Question (1) or to both questions, of course, will call for a positive cut-off. This may apply either to the over-burden or to the underlying rock, where it is cavernous or seamy. In some few cases it may be permissible to "take a chance" and determine the answer to Question (2) by constructing the dam and awaiting results, trusting that correction will be then possible, but in the vast majority of cases too much is at stake.

From Mr. Dore's paper it is assumed that, at the Quabbin Dams, the preliminary data and investigation somewhat indicated the need of a positive cut-off, and that the first caissons constructed, although located and designed for possible incorporation in a cut-off wall, were by way of pioneering for positive proof that the completion of such a cut-off was actually necessary. The analysis of results of subsequent pumping from these caissons and sumps furnished a definite answer to Question (1) but not necessarily to Question (2), upon which the need of a cut-off could be decided. It is usually difficult to provide such an ideal pumping arrangement as that described by Mr. Dore except where caissons have been installed as at Quabbin, and large capacity pumps are usually necessary.

With the cut-off once decided upon, and assuming that it will be tight in itself, tightly sealed upon the rock, and that the rock itself

is tight, an answer to Question (2) is not essential. However, since extreme difficulty of construction or other previously unknown hazards sometimes leaves doubt as to the existence of possible flaws in the cut-off, or in the seal to the rock, and due to the difficulty or cost of detection and correction, an answer to Question (2) is very desirable, both before and after the construction of the cut-off. This would scarcely be necessary with the type of cut-off adopted at Quabbin, but it is sometimes the case where a steel sheet-pile cut-off is adopted, or even more positive and seemingly thorough means are used, as is attested by comparatively recent occurrences at the Ontelaunee Dam, at Reading, Pa.

As stated, although the writer, like Mr. Dore, considers the observations and data obtained as the results of pumping in pits and test wells of considerable value in determining the average effective permeable quality of the over-burden as a whole, where this factor is desired, he does not consider the average permeability of an over-burden (which is to become the foundation material of a dam) of any great value. It may even be disastrously misleading, if considered alone, in determining the safety of the dam from "piping" or other phenomena of undermining, because calculations of velocities of flow of under-seepage from average permeability will result, ordinarily, in a very re-assuring figure for velocity. The maximum rate of flow through the coarsest stratum, lense, or vein of material existing at the site, will indicate the possible danger from piping and if determinable will be vastly greater and considerably less re-assuring. Such conditions will seldom be discovered by pumping tests or by any known method of sampling, except from test pits, which are usually much too far apart for this purpose. Let it be assumed that the vein in question has no actual direct connection to the river or watercourse, or to the ground surface under the proposed reservoir by any of a large variety of possible means. Then, under full reservoir conditions, all other materials of the valley floor or flood plain are acting, or will act, as a vast filter admitting water to the vein rather freely and in considerable quantities, producing a high velocity. Should the vein lie relatively close to the surface of the reservoir floor, or have connections close to it, the so-called piping distance necessary to protect against failure is reduced from a comfortably long distance greater than the base width of the dam, to substantially no more than the vertical depth of the over-burden above the seam. In most cases the distance is reduced to the thickness of a fairly thin stratum of comparatively impervious material, which cannot usually be proved to be continuous or without fault or opening. It is immaterial, of course, whether the pervious stratum is of coarse gravel or whether it is an open and uncorrected seam or solution channel in the underlying bed-rock. In either case the relative conducting capacity is so great under the increased head of the reservoir as to warrant deducting practically the entire width of the base of the dam from any calculation of safety from "piping."

Whether or not one or more sink-holes form in the bottom of the reservoir, the area of the filter bed will usually be such that water will be supplied to any open vein or stratum with so little loss of head that although the "blanket" below the dam is thick and comparatively impermeable, the hydraulic gradient of the seeping water, under the conditions, is likely to be well above the ground surface at one or more points. In some cases a pressure can be calculated readily to exist, which is sufficient actually to lift the overlying blanket, particularly if only one of several permeable veins should chance to end, or be substantially reduced in carrying capacity near the down-stream toe of the embankment. However, some spring or other natural "seep" will probably be present to encourage escape and to start "piping" action. The phenomenon of flotation of the finer particles, of course, will render the thickness and tightness of the down-stream blanket of little value, whereas the gravel seam or solution channel in the rock (the chances being that there will be a number of one or the other), will usually have ample unfilled voids to accommodate the displacement of the relatively small quantity of the "fines" from the up-stream blanket necessary to begin the action of piping at that end. The next step is the formation of sink-holes, and then, possibly, disaster.

The foregoing may seem a pessimistic view, but that such results are very possible is attested by the comparatively recent partial failure of the Ontelaunee Dam at Reading, Pa., previously referred to and recently described in engineering periodicals. The writer has often had opportunity to verify suspicion by excavating in foundations, and finding seams of large, perfectly clean gravel located in apparently quite impervious fine sand and silt, which seams were producing water copiously. He also has discovered numerous partly filled and water-bearing solution channels in limestone where few were indicated by the customary spacing of exploratory drill holes. Some "chimneys" were actually found leading into the latter, and subsequent pumping from the seams proved the presence of other "chimneys."

Fortunately, in the case of most important projects, some means of investigating the possible under-flow has been undertaken, and although not usually conducted with the thoroughness of that described by Mr. Dore, has resulted in a cut-off wall or other positive element being incorporated in the structure as a safeguard. Such action is seldom too conservative; in effect, it corresponds to the usual safety factor against uplift, sliding, etc., for concrete dams. The relative proportion of the cost of safety against under-failure of earth dams to total cost seldom, if ever, approaches that of the usual practice in utilizing three or four times the theoretically necessary material in wood, steel, or concrete structures.

Dam failures of recent years are believed to indicate that, through continued success, the profession is in danger of becoming somewhat too optimistic in regard to factors of safety, particularly in foundations with respect to the elements herein discussed.

The determination of permeabilities by laboratory analyses of bore samples is of value only in the case of the finer and more cohesive materials, as the result depends entirely upon whether a representative actual sample is furnished to the laboratory. Wash-boring samples are practically valueless. Samples of fine cohesive materials may be taken from the ends of drill casings by various methods, which will be suitable for mechanical analysis, but seldom in natural unconsolidated, or unbroken, state for direct permeability tests. True samples of the coarser veins, accidentally encountered, cannot be taken by any means or tool known to the writer, without the probability of mixing in it at least 10% or 15% of the finer strata above or below it, which admixture will control the "effective size" and render worse than valueless any calculations made from it. Such calculations may lead to serious errors in resulting decisions, always tending to the unsafe side.

This admixture of fines is almost certain to occur in sampling where thin strata of very open materials are encountered, even in open test pits, and particularly with running ground-water, unless a competent observer is present in the pit at all times. to take true samples. Samples from the bottoms of casings, below ground-water level, or where wash-boring methods are used, are always subject to question. In all cases where pumping has been resorted to in a casing or pit, samples of coarser materials may have fines washed into or out of them before the casing or pit has quite reached such a stratum. Furthermore, it is extremely unlikely that the coarsest stratum or other opening has been discovered unless bore-holes or test pits are prohibitive in number (at least as close as 10-ft centers over the entire area under investigation) and more unlikely that it has been identified and a true sample taken.

It is noted that Mr. Dore dissents from the use of the coarsest particle of the finest 10% of the sample or the term, "effective size," in making permeability computations, by means of the Slichter formula. After discarding certain extreme variations, such as 5% and 26%, however, he finds that the permeability is controlled in most cases by sizes within the fairly close range of from 8% to 15%, with a reasonable mean of all results at 12%, which he uses in connection with the Slichter formula. The writer agrees with his conclusion that all such methods are subject to errors of from 50% to 100%, and, therefore, such a small difference in practice in the selection of the controlling size seems unimportant. For that reason no close decision as to the need of a cut-off wall should ever be decided in the negative, on the basis of pumping tests or permeability calculations from samples, but a factor should be used, on the side of safety, considerably greater than the possible error inherent in the methods of investigation.

The belief and hope that the methods developed and used at Quabbin may find application elsewhere, has been expressed by Mr. Dore, and his paper adds greatly to the practical application of the meager methods and tools that are available for predicting under-seepage in order to determine the necessity of cut-off provisions. Where, as at Quabbin, pump-

ing was done on such a scale, and for a period long enough so that the ground-water was considerably lowered along the axis of the dam from one abutment to the other, many valuable data and determinations are possible, particularly as to general permeability. However, high productivity in the caissons used as wells would seem to leave little doubt as to the need for cut-off provisions, as without such provisions it would seem probable that under full reservoir head the leakage would be at least as much as, or several times, the total rate of pumping.

In his investigations, Mr. Dore represented the variation of the ground-water table by means of contours. The use of ground-water contours is worthy and capable of wide general application to the study of sub-strata with respect to permeability and the writer has used this tool with satisfactory results at several locations in both glacial and alluvial soils. In general, the method involved a system or grid of a greater or lesser number of observation wells, consisting of auger holes, perforated pipes, supplemented by such test pits, existing dug wells, or ponds, depending on which were available With the latter, of course, care should be exercised to determine that the free water surface does not represent a perched water-table, as frequently happens in the case of ponds, ditches, and even rivers at certain locations. Periodic readings of the elevation of the water in such wells are taken very conveniently and accurately with a 50-ft or a 100-ft steel tape (with 0.01-ft graduations) on a compact reel, and fitted with a cupped lead weight.

By taking observations of all wells and plotting ground-water contour maps at 1-day, 5-day, or 10-day intervals, during variations in the water-table, much may be deduced in regard to the direction of flow of the underground water. Occasionally, different elevations will be registered in pairs of pipes driven to different depths, where the ground-water is moving rapidly in some stratum. The variation in the water-table may be due to the natural rise and fall of the adjacent reservoir or river; or it may be produced by "gunning" the river by means of discharge from the outlet valves or spillway of some dam, or by pumping from various pits or wells. The time lag and the response of the wells to fluctuations in river or reservoir level, will give a general indication of the relative general permeability of the materials. It is very enlightening to plat time graphs of a group of wells, superimposed upon a time graph of the river-gage readings.

Certain general information may be derived from the displacement of the ground-water table in a given time, over a given area, due to a rise or fall of the river; but usually a calculation from the amount of upward displacement of the water-table is of no value on account of the impracticability of calculating the quantity of ground-water escaping from the area in question. Valleys in the water-table contour maps will often indicate this condition and the direction of escape.

The ground-water contour maps would be closely analogous to contour maps of the free water surface of a flowing river were it not for the varying

resistance of the materials through which the ground-water is moving. A steep slope or a nearly flat slope in the water-table may indicate various rates of flow, depending upon the characteristics of the materials. The difficulties in determining the characteristics of the more open materials by sampling has been discussed. For a complete and dependable determination of conditions, therefore, it is necessary to have a means for determining directly the actual rate of flow in the soil at definite locations and depths. Such a means was happily suggested to the writer by chancing upon a reference to the electrical ground-water timing apparatus devised by Professor Charles Slichter.[19] Such an apparatus was constructed for use at one dam site, with the exception that the timing and recording were done by attaching a commutator to the shaft of a recording ammeter of the type used on power-house switchboards.

The configurations of the water-table contours will usually indicate valleys where, presumably, the rate of underground flow is greatest. In the first two such locations selected, in a terrain previously considered quite impervious, rates of flow approximating 400 ft per day were observed. Sal ammoniac was used as the electrolyte, and the direction of flow checked that assumed from the contours. At one place it was at right angles to the river and at the other location approximately parallel to the river, both being caused by the same rise in the river level. The direction was corroborated further by the fact that the only electrode affected in each case being brass, was found upon removal to have been discolored to a deep purple, whereas the other electrodes were still bright. The discoloration was easily removed by sand paper after each test. Calculating backward from the measured rate of flow indicated an effective size of the particular gravel vein approximately ten times larger than that obtained from the coarsest samples recovered from 24-in. casings driven to rock at several places relatively near-by.

With a few determinations made in critical or representative locations, and with the slope of the water-table accurately determined by precise measurements in the wells used with the Slichter apparatus, and roughly checked from the contour map, a much more complete understanding of conditions is had than may be determined by any other method known to the writer. If the hydraulic gradient found between the test wells differs materially from the general slope taken from the contour map, the latter should be disregarded in calculating the flow constant.

Remembering that even where the materials do not differ greatly in gradation (approximately 90% of the total water movement will be found to occur in the one coarsest layer), the pipes for the Slichter test may be perforated for only 2 ft or 3 ft at the bottom and driven directly to this stratum when its location is known. Where the locations of suspected coarse strata are unknown, the pipes may be perforated for the entire depth of the over-burden if desired, to permit a maximum flow rate being recorded on the first trial. On the other hand, 2 ft or 3 ft may be per-

[19] *Ground-Water Paper No. 140*, U. S. Geological Survey.

forated, and the pervious strata located, by surveying the entire depth of over-burden by successive tests, driving the pipes deeper each time by a distance equal to the length of perforations. The pipes may be driven by hand for shallow depths, but where the over-burden is deep or gravelly, a drill rig of the usual type will be found to expedite the work greatly.

If successive tests are to be made at the same set-up of pipes, it will usually be found necessary to allow from one to several days between tests for the sal ammoniac or salt from the previous test to become dissipated or washed away.

This direct method of measuring the flow through the actual materials in place, at sites selected by means of the ground-water maps, seems far superior to calculations from soil samples. It is not particularly necessary to compute the effective size of grains from the Slichter test, as this apparatus provides a direct measurement of rate of flow under a known hydraulic gradient, and the possibility of piping under increased gradients may be calculated directly from it.

A word of warning may be in order in regard to the use of this equipment in locations where solution cavities or other water passages or faults are possible in the underlying bed-rock. Assuming that the pipes have been properly cleaned, and unless the materials are entirely clay or fine silt, should the apparatus fail to register a positive test after a reasonable time interval, it is entirely possible that the flow may be straight downward or in an inclined direction beneath the receiving electrodes. The ground-water map, if constructed from a sufficient number of test wells, should be examined carefully for the presence of a depression or pot-hole, marked by a closed contour over a small area, which may not have been recognized in the interpolation of the contours. This condition would indicate a "chimney" in the rock, into which, under certain conditions, the ground-water may be flowing. It is often desirable to drive additional test wells to assist in solving peculiar conditions.

To avoid disappointment, and to attain satisfactory results in the use of driven perforated pipes for observing ground-water fluctuations and for use with the Slichter apparatus, the following suggestions are offered. The writer has found that the commercial type of screened well-points are not sturdy enough to stand the hard driving necessary in deep, sandy, or gravelly over-burden. The most satisfactory and economical points were devised by blowing four rows of holes at 90° in extra heavy pipe, the holes being spaced 4 to 6 in. in the rows, with the oxy-acetylene torch, and pointing and welding the ends of the pipes in the same manner, or by employing a blacksmith. The pipes should be 2 in. or larger, as desired or required.

After driving, the pipes are frequently found to be plugged with sand or silt forced through the holes, even if the water level may seem to stand at approximately the correct height. The pipes should be washed by inserting a $\frac{1}{2}$-in. or $\frac{3}{4}$-in. pipe used as a water-jet, rather than by attempting to blow or jet them clear with air. After the air pressure has been turned off the inrushing water usually plugs the pipes again with silt and

sand, and serious error and lost records result in assuming that they are clean. The writer has seen pipes stand inactive for days after several attempts to clean them with air, and later register freely after washing them with a water-jet. The pipe lengths should be measured as driven, and the sounding lead used to ascertain whether they are clear for the full length after the completion of driving. After driving and cleaning, if necessary, each pipe should be tested by pouring a bucket or two of water into it and observing with sounding lead whether the water level subsequently subsides at a reasonable rate. Only if the perforations are in contact with very dense silt or clay will the water level remain stationary. When tested with the bucket, all stationary or sluggish pipe should be regarded with suspicion.

In driving, all pipes should be threaded so that, with application of considerable force, the ends can be made to abut firmly in the couplings. Ordinarily, extra heavy pipe should be used, with recessed couplings.

Driven pipes are seldom exactly plumb and may deviate several feet. For this reason, pipes driven for the Slichter apparatus should be spaced well apart to reduce the percentage of possible error in spacing between the perforated parts, and the corresponding error in the apparent timing of passage of the electrolyte. A spacing of 20 ft to 25 ft from the salted well to the receiving wells is desirable, although this will require more time for the observations, and additional receiving pipes and electrodes may also be required.

Considerable difficulty and annoyance will be avoided if the perforated basket for lowering the dry sal ammoniac, the insulators for the electrodes, and sounding leads used on steel tapes are all made sufficiently small to avoid catching on the burrs on the ends of the pipes in the couplings.

Clothes-line ropes and electrical wires should be very securely attached to the electrodes, and the wires protected from injury, at such connections, by electrician's tape. Measuring marks should be established on the ropes or wires to ascertain that the electrodes reach the bottom of the well. The electrodes should be lowered slowly and carefully to place, and thereafter should not be pumped up and down as the pumping action of the insulators has been found to draw sand into the pipes, which usually means jammed and lost electrodes and a useless pipe.

Apparently, for the purpose of being able to utilize a recording instrument, the Slichter apparatus is arranged for the use of dry cells, the measured variations in the induced current, when connected to the several circuits, furnishing the desired information as to the passage and arrival of the electrolyte. If the automatic-recording feature is not desired or essential, the process may be reversed and the varying resistance in the several circuits measured at regular intervals by means of an electrical "megger" or ground tester. At one time the writer utilized this principle with fair success between observation wells spaced approximately on 100-ft centers but without electrodes, having previously charged an up-stream well with common salt. The "megger" has certain advantages over the record-

ing ammeter since difficulties are frequently experienced with the latter in poor commutator contacts and in adjusting the number of dry cells so that the record will stay on the scale of the paper. Since the resistance is very low between the electrodes and their respective pipes after the electrolyte has entered the pipes, it is probable that two or three dry cells and a small, comparatively insensitive ammeter, carried from pipe to pipe, would give satisfactory results, and much wiring and labor in setting up would be obviated. With this method, after the electrolyte has definitely reached one of the electrodes, the observations could be taken more frequently if desired, and observations on the other wells omitted, which is not practicable where the commutator clock is used, and the observations timed to 10-min or 15-min intervals, since there are eight different circuits in the regular set-up.

Where a grid or system of observation pipes has been driven for the study of a site, all pipes possible should be preserved in order to continue the program of periodic readings throughout the filling stage of the reservoir and for some time thereafter. Should it not be convenient (as in the case of a rolled fill) to extend certain of the pipes up through the fill to the crest of the dam, it is believed to be a justifiable expense, particularly where a cut-off has been constructed, subsequently, to drive a sufficient number of pipes through the completed fill into the more pervious strata of the foundation, closely up stream and down stream of the axis, in order to observe the hydraulic gradient at different locations after the filling of the reservoir, and to check the efficiency of the cut-off provisions.

In addition to the Slichter apparatus, valuable data have sometimes been obtained by the introduction of fluorescein dye into the perforated test walls and timing its arrival in test pits and excavations in which pumping is being done. In one case a rate of flow of approximately 200 ft in 2 hr was observed on a moderate gradient, in a limestone seam, with the probability that the greater part of the 2 hr was consumed by the fluorescein finding its way from the well into the chimney leading into the seam.

Stanley M. Dore,[30] M. Am. Soc. C. E. (by letter).—The discussion by Mr. Snow calls attention to the "more or less blind groping" that occurs in the investigation of the permeable qualities of an over-burden which depends solely upon analyses of bore-hole samples. The writer agrees that the pumping of ground-water from one of many measuring wells is decidedly, and by far, the superior means of estimating the permeability, and should preferably be used wherever such means are available. However, in many cases, the determination might be made after the bore-hole casings have been pulled. For such cases the usefulness of results obtained by analyses of bore-hole samples depends upon the number of samples available and the manner in which the volume of the over-burden has been investigated with bore holes. To take samples from a relatively small number of bore holes for the determination of the permeability of an over-burden as a whole is practically use-

[30] Associate Civ. Engr., Massachusetts Met. Dist. Water Supply Comm., Boston, Mass.

less, as the result obtained may be correct or it may be absurd, and in such a case the groping is decidedly blind. However, with a large number of samples from an adequate number of well-placed bore holes, the law of averages operates to reduce the guesswork and materially to increase the probability that the result is a reasonable one.

For free-draining glacial materials, similar to those at the sites of the Quabbin Dam and Dike, it was estimated that about 90% of the water in the pores was obtained quickly from storage by pumping. Probably, having been under water for years, the pores of these materials were entirely filled with water. Part of the remaining 10% would trickle slowly down to the lowered ground-water surface, and part would be held in the corners of the pores and would never travel toward the pumps.

The division of the quantity pumped into that obtained from depletion of storage, that obtained from infiltration within the circle of influence, and that obtained from flow into the circle from without, can not be precisely made for any site for all periods of time, as it depends upon variable conditions, such as rainfall, temperature, run-off, vegetation, etc. The quantity flowing underground into the circle from without is usually relatively very small; and, for a valley-shaped over-burden, it is the quantity that ordinarily flows down the valley underground. For instance, for the relatively pervious over-burden at the Quabbin Dike such quantity was estimated to be about 100 gal per min. The quantity flowing on the surface into the circle from without depends on local conditions, and the quantity that reaches the areas affected by the pumping operations depends upon the slope and water-tightness of the stream bed. At Quabbin Dike nearly all the surface drainage up stream (drainage area, 1.4 sq miles), flowed indirectly into the circle of influence, sank into the ground, and was pumped. Practically, then, the water pumped is nearly all infiltration within the circle of influence and depletion of storage. The quantity of pumpage remaining constant, the quantity depleted from storage, depends directly upon the infiltration, which, in turn, is large or small as affected by recent rains or other conditions. At the Quabbin Dike the percentage of the total pumpage coming from depletion of storage varied generally from about 10 to 90.

Mr. Snow expressed a desire that the determinations of permeability might be used as means of estimating the yield of ground-water wells. It was the writer's intention that such would be the case although he presented the investigations in connection with unwatering and seepage problems. In both cases the permeability of the over-burden would be estimated in a like manner, the data in case of a water-supply development being obtained, if possible, by test pumping from one bore hole and observing the drop in water level in others.

Once this average permeability is obtained, circles of influence can be estimated, and the ground-water maximum draw-down curves plotted in profile for wells at various depths. The maximum continuous yield of any well, after the ground-water curve is drawn down to its maximum and there is no further reduction of storage available, depends upon the infiltration portion

of the pumpage, which in turn depends upon local conditions of rainfall and run-off and of surface and sub-surface flow into the circle of influence. This part of the yield as a continuous water supply is comparable to the prime power of a hydro-electric development, and in case of an extended and continuous excessive demand, the yield of the well will be limited to this quantity. However, the demand upon a well as a water supply is seldom constant and continuous. The volume of the pores between this maximum draw-down curve and the original ground-water surface, in such a case, can be utilized as a storage reservoir, to be filled in wet periods and drawn upon in dry periods.

Thus, the underground supply can be treated in a manner similar to the surface supply, the infiltration being the source and the volume of pores above the maximum draw-down curve being the storage reservoir, upon which certain demands can be made, limited by the capacity of the pumps and the permeability of the over-burden. For estimating the maximum draw-down curve and the rate at which water can be drawn from the over-burden for other positions of the draw-down curve, the same formulas for pumpage as were described in the paper apply when the permeability is known.

After the local factors affecting the infiltration, the volume of underground storage, and the rates of pumpage permissible at various depths have been determined, the probable capacity of any well to meet certain demands can then be estimated. The spacing of wells is most advantageous if the circles of influence do not interfere, but, in such cases, although more complicated, the yields may be similarly estimated.

Mr. Gongwer evidently feels that, although the methods described in the paper are useful in obtaining the average permeability of an earth over-burden, such a value does not necessarily indicate the lack of a need for a cut-off in case this result is a relatively small one, as the average permeability is not indicative of what the largest permeability of some of the materials may be. Of course, if the total quantity of percolation indicated by the average permeability determinations is large enough to warrant the construction of a cut-off (which was the case at the Quabbin Dams), the distribution of this percolation throughout the over-burden is not important, except in cases where the cut-off provisions considered are partial or not positive. The writer agrees with Mr. Gongwer that, for the partial or non-positive cut-off provisions, and for the case in which the total quantity of percolation in itself is not large enough to warrant a cut-off, the final decision on omitting the complete cut-off provisions should not be made until investigations and studies indicate that there is no serious concentration of the total percolation (although small) in one or more veins, channels, or strata, which might jeopardize the safety of the dam through "piping." For such cases, the presence of a concentrated flow condition would be definitely indicated in a pumping program with an adequate number of observation wells, because the loss of head in the wells through or near the coarse veins or strata would be comparatively much less than elsewhere at the site where the wells were in the tighter materials. The writer, however, wishes to thank Mr. Gongwer for describing methods used in determining

the location and size of concentrated flows in over-burdens. These constitute a valuable addition to the paper as they can be utilized, if desired, in connection with a pumping program or with bore-hole investigations for locating and measuring concentrated flow conditions or for demonstrating the lack of any such flow.

Mr. Gongwer indicates that it is practically impossible to obtain satisfactory bore-hole samples that contain the proper quantity and quality of coarse materials to indicate the existence of the coarser veins and strata in the over-burden. For certain types of soils, such as alluvial deposits, the writer agrees that this is the case, but in many soils, such as random glacial deposits, reasonably good, so-called, dry samples are obtainable from bore holes which are fairly representative of the materials from which they are taken, the coarse materials usually occurring in thick veins, pockets, lenses, and strata. If the number of samples taken is large enough to be indicative, the chances of appreciable distortion in the estimate are not large, although the writer agrees that, as in the case of the pumping program, the possible existence of any coarse "piping" channel should be investigated before definite conclusions are reached regarding the omission of the cut-off.

The writer notes particularly that Mr. Gongwer concurs with him in the opinion that in over-burdens the coarser veins or pockets are usually interconnected, because the study of permeable qualities of an over-burden, especially from bore-hole samples, cannot be made reasonably, if it is assumed that the coarser portions are segregated and insulated from each other by the finer parts.

It is believed that, although the pumping arrangements at Quabbin are fairly ideal, because of the caisson pumping intakes, it would not be difficult to obtain a good pumping program elsewhere using well-points and pumps installed in the bottom of small pipe wells sunk to the desired depths at suitable locations.

Mr. Gongwer's comparison of the expense of cut-off provisions with the cost of the materials used to obtain the factor of safety in structural work is particularly well made; but sufficient and proper investigations in some cases will reveal that considerable saving can be made instead of spending money for cut-off insurance, and, in other cases, will eliminate the practice too often followed of deciding not to build a cut-off, risking the unknown consequences.

The point that the writer wishes to emphasize is not that the 12% size was a reasonable means to be used in making permeability computations by means of the Slichter formula for materials at Quabbin Dams, but that it might be some size other than the 10% size commonly used for the materials found at some other location, say, the 2%, the 5% or the 15% size; and that in using the common method the permeability results might be distorted so seriously as to be extremely misleading if not useless.

ADMINISTRATIVE CONTROL OF UNDERGROUND WATER: PHYSICAL AND LEGAL ASPECTS

By Harold Conkling,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Joseph Jacobs, W. D. Faucette and J. E. Willoughby, R. E. Savage, H. J. F. Gourley, O. J. Baldwin, G. E. P. Smith, David G. Thompson, Wells A. Hutchins, John E. Field, George S. Knapp, Chandler Davis, L. Standish Hall, and Harold Conkling.

Synopsis

Wells may be drilled in almost all valley areas of the United States with the expectation of securing sufficient water for household purposes and stock watering. Such supplies are of first importance in pioneer and farming communities, but are not of commercial importance. Neither legislative nor Court control of them has often been attempted. Usually it is only when supplies sufficient for irrigation, municipal, and industrial uses exist that engineering and law are involved. This paper deals only with the larger supplies.

A large percentage of the major cities of the United States is supplied with water produced from wells and probably most of the smaller ones are similarly supplied. Irrigation from wells exclusively increased 55.1% and, from wells as a supplemental supply, 177.5% in the 1919–1929 decade, whereas irrigation from surface streams decreased 6.3 per cent. This growing use of underground water has brought about much study of underground supplies throughout the United States and is causing changes in underground-water law. An important question that arises is whether the underground supplies should be placed under administrative control and the nature of legislative enactments creating such control.

Note.—Published in April, 1936, *Proceedings*.

[1] Deputy State Engr., Sacramento, Calif.

This paper opens a discussion of the laws of underground waters, their consistency with those of surface waters, the possibility of enacting statutes for their administrative control, the form of such statutes, and the drawbacks and benefits of such control. The paper is not a treatise on underground-water law. This subject has been treated many times by minds much better qualified for the task than that of the writer. It is rather at attempt to reach a practical solution of a problem which, unlike most engineering problems, does not rest on physical laws alone, but on the laws of physics as interpreted by legal minds, and also on the fundamental law of property as applied to water. The foundation combines the legal with the material. Were this paper concerned with the design of a bridge the writer would not think of introducing into it the foundation concepts of elementary mechanics, but since it treats of the use of water, it is deemed necessary and advisable to outline the growth and development of water law so that the foundation for the conclusions will be apparent.

For those who may wish to go further into the subject, reference is made to Kinney on "Irrigation and Water Rights"; Wiel on "Water Rights in the Western States"; "Corpus Juris"; "American Law Reports"; and the great body of decisions of the Federal and State Courts.

Introduction

The usual physical situations in which ground-water of commercial importance is found, are as follows: (1) Definite underground channels; (2) percolating through basins; (3) underflow which may support a surface stream; (4) artesian areas or basins; and (5) alluvium or glacial till supplied by (*a*) irrigation; and (*b*) rainfall. These different physical situations are not clearly delimited and merge one into another. Underground supplies derived wholly from surface rainfall on valley floors are found in humid areas, but rarely, if at all, in arid areas. No essential difference exists between deep percolation from irrigation and that from rainfall. A description of typical instances would clarify the subject more than general descriptions.

Definite Underground Channels

If the underflow of a stream passing through bottom-lands several miles wide, bounded by bluffs, hills, or mountains, is regarded as a definite underground stream, it may be said that such streams, usable for irrigation, often occur in the West. The attitude of the Courts is not entirely clear as to the status of this supplementary flow, but in one case the Court of Arizona has defined it, definitely, as an underground stream. In most such streams in Arizona there is not perennial surface flow. The law covering such waters generally is the same as the law of surface waters, but nevertheless the subject is treated herein because such occurrences of underground water are important.

Percolation Through Basins

The San Gabriel Basin[3] lies immediately east of Los Angeles, Calif. In it are large areas devoted to citrus groves and walnut orchards and many towns and cities, including such famous municipalities as Long Beach and Pasadena. The basin consists of a mountain drainage area of 294 sq miles, an upper valley of 278 sq miles, called San Gabriel Valley, and a lower valley, known as the Coastal Plain, supplied by several streams of which the San Gabriel River is the largest. Of the entire area of San Gabriel Valley, 151 sq miles are using water for irrigation or for domestic and municipal purposes, and the Coastal Plain is likewise well developed. These are structural valleys filled with detritus from the mountains and surrounding hills.

A range of hills separates San Gabriel Valley and the Coastal Plain and through this barrier the San Gabriel River has cut a pass about two miles wide. Another range of hills almost faces the ocean and through this obstruction the stream has also cut two passes several miles wide. The alluvial plain below these hills faces directly on the ocean and is a true coastal plain as distinguished from the area above the lower range of hills which, although known as the Coastal Plain, is really a structural valley.

The summers are rainless and most of the precipitation occurs in the four months, December to March, inclusive. The annual rainfall in the San Gabriel Valley varies from about 26 in. near the mountains to 17 in. at the lower or southern side of the valley. In the Coastal Plain it is about 12 in. Rainfall is heavy at times and, although most of it is absorbed in the valleys, the steep impervious mountain slopes rising to elevations of about 7 000 ft and as high as 10 000 ft above sea level, shed the rain rapidly and cause large flashy floods. In such floods all the streams cross the pervious valley fill and flow into the ocean, but during most of the year the flows from the mountains are entirely absorbed if not used close to the mountains.

The stream beds in the valley are dry sandy washes during most of the year, but at the gap between the San Gabriel Valley and the Coastal Plain and, again, at the gap in the hills near the ocean, the underflow comes to the surface, creating a perennial stream of rising water, much larger at the upper gap than at the lower one.

The average slope of the surface of the San Gabriel Valley from the mountains to the outlet is about 50 ft to the mile and that of the Coastal Plain is about 12 ft to the mile. The water-table is 200 to 300 ft, and even 400 ft, below the surface in places near the mountains; it is at the surface through the outlet and is again 30 to 50 ft beneath the surface immediately below the gap. A few miles below the hills separating the San Gabriel Valley and the Coastal Plain artesian conditions begin and the piezometric level is above the surface between this point and the lower range of hills. Down stream from the latter point the water-table is again below the surface. The small summer flows from the mountains and the rising water are the only gravity supplies available for irrigation. All other supplies are from wells which, in general, have good yields.

---

[3] "San Gabriel Investigations", by Harold Conkling, *Bulletin No. 7*, Div. of Water Rights, Dept. of Public Works, State of California.

The climate is subject to long cyclic fluctuations of rainfall. In 1934, the average water-table in the San Gabriel Valley was about 60 ft lower than in 1916, when the highest was recorded. In small basins partly cut off from the main area by underground formations the recessions have been much larger, whereas in the Coastal Plain and near the gap in the San Gabriel Valley they have been smaller. The area using water has increased from 32 000 acres in 1904 to 97 000 acres in 1934. The recession of the water-table is due partly to the increased draft to supply this demand, but mainly to lack of rainfall during the period, 1916 to 1934, and cumulative overdraft is not indicated. Likewise, rising water at the outlet from the San Gabriel Valley has decreased from an estimated average of 164 cu ft per sec in 1916 to 38 cu ft per sec in 1934. Opportunity for percolation from the San Gabriel River is probably two to three times as much with the lowered water-table of 1934 as it was with the conditions of 1916, because of the greater distance the stream travels over an area beneath which the water-table is far below the surface. Opportunity for percolation of rainfall on the valley floor to the water-table is likewise greater than it was in 1916.

The particularly noteworthy points to bear in mind in a discussion of an underground-water law, is the decrease in rising water, the recession in the water-table, and the steadily increased use of water during the period when the water-table was dropping.

The characteristics of the San Gabriel Basin are typical of most of the coastal valleys of California south of San Francisco, and of the valleys or basins in which ground-water is found throughout the Great Basin which embraces parts of California, Oregon, Idaho, Nevada, Utah, and Wyoming. The major differences between Great Basin conditions and the San Gabriel Basin and others in California is the greater aridity in the Great Basin. As a consequence run-off is less, stream channels are often not cut through barriers down to the level now necessary to discharge water, and the water reaching the water-table is disposed of at the lower side of the basins by evaporation from lakes either ephemeral or constant, playas, and moist areas, instead of by the surface streams of rising water.

Underflow Which May Support a Surface Stream

The South Platte River has its source in South Park, Colo., on the eastern slope of the Continental Divide. After reaching the plain it flows northward through Denver, Colo., not far from the toe of the mountain and is joined by numerous tributaries, the last of importance being the Cache La Poudre. Then it flows eastward into Nebraska, is joined by the North Platte, and empties its waters into the Missouri River, near Omaha, Nebr.

Most of the area irrigated in Colorado from the South Platte is near the mountains in the high plains which begin their rise at the Missouri River and slope gradually upward to an elevation of 5 000 or 6 000 ft at the mountain toe where the precipitation is about 12 in. This rainfall increases, with distance eastward, to 30 in. at Omaha, occurring mainly in the growing season. Irrigation is practiced west of the 98th Meridian. The crops are practically the same throughout the irrigated area, consisting of grain, alfalfa,

and a hoed crop which is corn in the eastern part, giving way to sugar-beets toward the west.

The South Platte River furnishes a supply for 1 233 000 irrigated acres in Colorado and 45 000 acres in Nebraska, a total of 1 268 000 acres. Of the area irrigated in Colorado about 8 000 acres are supplied from pumped wells. Of the 457 wells used for irrigation, 294 are in minor tributary valleys and only 4 in the valley of the main river. There are three wells in the valley in Nebraska.

Below the Cache La Poudre influx the river flows in a broad valley, generally ten miles or more wide, but sometimes narrowing to about two miles. The bottom-lands are only slightly above the water surface of the stream. The valley has been carved through the plain and the bottom refilled with porous detritus carried by the stream. The uplands are fertile, and their topography is suitable for irrigation, but as they rise from 150 to 350 ft above the river, it is not feasible either to pump for them or to reach them by gravity canals below the point where the river turns east. Wells drilled in the uplands do not reach sufficient porous water-bearing material to furnish more than domestic or stock supplies. The wells in the valley generally find porous aquifers from which irrigation supplies can be produced. Although reservoir development for impounding the floods of the South Platte System is exceptionally large, considerable water escapes into the more humid eastern area in flood times. More pumping in the river bottom would provide storage space into which the floods would percolate and greater development could be made. At the same time, supplies to existing gravity diversions below would be reduced and the people dependent on them would also be forced to pump to secure their quota of water.

The principal points to bear in mind in the foregoing discussion are the possibilities of greater development by pumping in the river valleys and the greater expense to secure a water supply, which would be incurred by all interests below the pumping plants.

Artesian Areas or Basins

The Roswell Basin[3] is situated in Southeastern New Mexico and is a narrow strip about 65 miles along the Pecos River, a tributary of the Rio Grande from the north. The original area of artesian flow was 663 sq miles, but by the winter of 1926–27 it had shrunk to 425 sq miles because of heavy draft. Under a considerably larger area to the west ground-water is under pressure but development is not economically feasible. The principal intake area lies still to the west and water for it is supplied by run-off from the Sacramento Mountains which are parallel to the river, the crest being about 80 miles distant. The streams from the mountains percolate into their beds in crossing this area, and the water finds its way to the artesian aquifers. This is the principal supply but there is an additional supply from deep percolation of rainfall on the intake area.

The Roswell Basin is not a structural basin, but is more nearly an artesian slope with the strata dipping from west to east. The permeable artesian strata

[3] "Geology and Ground Water Resources of the Roswell Artesian Basin, New Mexico", by Albert G. Fiedler and S. Spencer Nye, *Water Supply Paper 639*, U. S. Geological Survey.

consist of honeycombed and cavernous limestone, but moderate quantities of water are produced from sand strata and sandstone. Water is found also in the surface alluvium or valley fill derived from surface drainage, local precipitation, irrigation return, and upward leakage from the artesian strata. The Pecos River acts as a drain to the valley and its waters are diverted for irrigation in, and at points below, the artesian area.

The principal crops are cotton, alfalfa, orchard products, and corn. The annual precipitation is 12 to 14 in. in the agricultural area, and the climate may be classed as semi-arid. The annual average temperature is from 59° to 63°, depending on the altitude which is from 3 100 to 3 600 ft above sea level.

The draft on the artesian basin evidently has been greater than the recharge, as the continuous loss of head on the artesian wells and the shrinkage in area of artesian flow testify. The safe annual yield is thought to be somewhat greater than 165 000 acre-ft, but the annual draft is now (1936) about 200 000 acre-ft, of which more than 100 000 acre-ft are required for the irrigation of crops now supplied from artesian wells. Various non-beneficial natural disposals of water are in process which, together with leakage from wells, account for the remainder of the 200 000 acre-ft. The non-beneficial disposals are decreasing as the pressure lowers.

Originally, large springs flowed in the vicinity of Roswell, but these no longer exist as the water formerly issuing from them is now diverted underground to the artesian wells because of the depressed piezometric head. The area formerly irrigated by gravity by means of ditches is reduced to that which can be irrigated from "return from irrigation" and other minor sources. It is probable that other adjustments in the area irrigated by gravity from the river and tributaries will be made if the excess demands on the artesian basin continue.

The principal points for attention in the foregoing is the probable present overdraft, with consequent past and future decrease in surface flows, along a river formerly available for irrigation.

Alluvium Supplied by Deep Percolation from Irrigation

The Boise River has its source in the Sawtooth Range, in Idaho, and flows west into Snake River, a tributary of the Columbia River. At an early date, diversions were made on both sides of the river but principally on the south side. The normal flow in late summer is not sufficient to supply all water rights. In 1907, the United States Bureau of Reclamation started the Boise Project on the south side of the river paralleling older irrigated areas but at a higher elevation, and completed Arrowrock Reservoir about 1914. The rising water-table caused by deep percolation from irrigation on the Boise Project threatened ruin to some of the land on the Project and to a considerable area of the older irrigated lands along the lower river and on the south side of it. Surface drains to the river were installed and the land was thus protected. The discharge from the drains is used by rights diverting from the river below them during the irrigation season and water formerly allowed to flow down river from the head-waters is now diverted

farther up stream by other rights. During the winter the drainage water wastes into the Snake River.

Some, but no great quantity, of underground water has been pumped for irrigation from this area of high water-table, but water shortages in recent years have forced the consideration of greater development of this source. If a sufficient quantity were pumped, the ground-water would be lowered and the waste from drains in the winter would decrease, or perhaps cease entirely. The rights down stream might not have a full supply from drains in such a case and, if so, would have to be supplied with discharge direct from the head-waters.

The principal point to observe in this situation is that a greater area could have been developed or a better supply to the present area could have been given if, instead of building surface drains, wells and pumping plants had been installed to accomplish the same thing (assuming the existence of the necessary porous aquifers). The cost to the farmer of using this water would have been greater also, due largely to the subsidy on capital costs given in the financing of Federal irrigation projects, but the additional cost would have been spread over a large area. Under the appropriative doctrine if the proprietors of any land not now irrigated, or to be irrigated as a part of the Boise Project, should attempt to use this water, they might find the cost excessive because of the upset to the existing situation. As a supplemental supply to existing projects either over-lying the underground basin, or near-by, this water might prove very valuable, and might be secured without great legal difficulty.

Alluvium or Glacial Till Supplied by Rainfall.—In New York State, Long Island is marked by a range of hills from east to west forming the backbone of the Island and rising about 100 to 200 ft above sea level[4]. From these hills streams drain both north and south into the ocean. The surface soils are of glacial origin of particularly porous nature on the south side of the Island. The rainfall averages about 45 in. annually and, except when the ground is frozen, most of it is absorbed by the soil. Perhaps 40% or 50% reaches the water-table which, in most of the area, is below the root zone. The water-table slopes toward the sea and probably most of the underground water reaches the sea without coming to the surface. Near the stream channels, carved deeply by large ancient glacial streams, the water-table slopes toward the valleys and they act as drains. Other surface disposals are by evaporation from ponds and swamps where the water-table intercepts the surface.

As shown by the water development of the Borough of Brooklyn, N. Y., on the western end of Long Island, wells yield heavily. As irrigation is not practiced, except perhaps in a very limited way, there is little draft on the underground water except in the western end, to supply Brooklyn. If average annual deep percolation from rain averages about 20 in., as estimated, the yield from the approximate 500 sq miles of Southern Long Island would be very large and suited to the requirements of a large municipal center

[4] "Long Island Sources", Rept. of the Board of Water Supply of the City of New York, 1912.

which requirement is the only one of magnitude for consumptive use in humid climates.

The Long Island situation is of interest because, aside from the western end used by the Borough of Brooklyn, the underground water resources are practically undeveloped, although they have been thoroughly explored as a supply to New York City. This is an unusual situation since in most cases knowledge comes only after development.

Exploitation of the supply would lower the water-table and thus create additional storage space underground for the wet years. Movement toward the ocean would decrease and salt water from the ocean would move farther under the land as pressure was removed. The discharge of streams fed from ground-water would decrease and ponds and swampy areas would diminish in size. If, instead of the ocean, a stream flowed along the southern shore its flow would be decreased.

The area is typical of those in humid regions suitable for large development except that some are tributary to a stream of magnitude instead of to the ocean.

Underground Water in General

Aside from the flood flows of a stream, its discharge is the result of precipitation on the tributary water-shed which has percolated below the root zone of vegetation and moved underground in the direction of the slope, to the stream (or other body of surface water). Underground flow is merely an evidence of water on its way to the surface. It may be used either directly from underground or after it has found a stream. It is the same water in either case, but in the one it has been brought to the surface by Nature, and in the other, by Man; but if Man had not interfered, Nature would have done the job at some lower elevation.

Any withdrawal of water from the aquifers causes a decrease in the water reaching the stream. It may be the floods that are decreased, inasmuch as the withdrawals will provide additional space into which the rainfall may percolate. On the other hand, the underflow may be decreased and thus the low water of the stream diminished. Water moves very slowly underground, its rate depending on slope and on porosity and thickness of the aquifers. If pumping withdrawal occurs at a sufficient distance from the surface outlet it may be that several rains, or even annual rainy seasons, may occur before the depressed water-table caused by pumping reaches the outlet; and, in such cases, sufficient replenishment may occur to restore the former underground supply completely. Such replenishment is unlikely in arid regions, but in humid regions the longer the period the more likely that the depletion will be made up by percolation which would not have occurred if the withdrawal had not been made. Likewise, the smaller the quantity of water pumped the more likely it is that it will be replenished. Pumping from the underflow of a surface stream would undoubtedly decrease the surface flow for a distance below the pumps, but might have no effect on it farther down stream.

Natural disposal of underground water must be in equilibrium with the recharge over a term of years, but the water-table constantly fluctuates with

the wetness of the season, or cycle of seasons, because disposal is more uniform than recharge. For a time, perhaps many years after pumping draft begins, disposal continues as before, and the water-table in the general vicinity of the pumping lowers with comparative rapidity until natural disposal is decreased by the quantity of water pumped unless, as may occur (especially in humid regions), the draft is made good by additional recharge. If the new draft is not greater than natural disposal the water-table assumes equilibrium at this new lower level. If it is greater, pumping draft must eventually decrease to equal recharge and again equilibrium will be established. In any event the stream below would be decreased.

In arid regions, especially, evaporation may be so great and the supply so small that disposal is accomplished from wet areas in the lower levels of the valley, and no surface stream issues from it. In such cases the lowered water-table caused by pumping merely decreases the evaporation.

In considering the different physical situations heretofore described in which ground-water of commercial importance is found, it is discovered that there are no essential differences. In some cases (such as that of Long Island and closed valleys in arid regions where the disposal is, in the one case mainly into the sea and, in the other, into an evaporating area) pumping would produce no general effect on a stream system but would nevertheless upset local conditions by lowering the water-table. In humid regions, where water-courses are more frequent than in arid regions, the distance between the recharge area and the point of disposal may be small and the effect on stream flow felt more immediately. On the other hand, greater probability of additional recharge below the pumped area exists in humid regions. Each situation is a separate study which must be exhaustive and widespread to reach reliable conclusions.

Ordinarily, the exploitation of an underground source has proceeded without supervision or knowledge on the part of those using the water. Such knowledge comes usually after a series of lawsuits to enjoin exploitation, or when alarm is caused by the receding water-table. A notable exception is the survey of the underground supply of Long Island previously mentioned. Presumably similar surveys have been made by other large organizations in seeking a water supply. The United States Geological Survey has done, and is doing, much work throughout the United States on investigations largely in co-operation with States or local entities, but because of paucity of funds its work is naturally most intensive in those areas where exploitation has caused alarm. Probably State supervisory boards are doing similar work in many States. In California, the State Division of Water Resources is doing considerable investigational work, but as the use of underground water in California far exceeds that in all the other States of the Union its work is likewise being done in regions already overdrawn, or where alarm has been caused by lowered water-table.

Extent of Underground Water Use

In this paper it is implicit that use of underground water for ordinary domestic or stock supplies is not considered. This draft is insignificant and

has never, to any extent, been a matter of legislative or Court control. In humid regions (that is, in regions of the United States east of the 98th Meridian) underground water is exploited to the point where far-reaching effects are produced only to secure supplies for metropolitan areas and information as to the extent of such exploitation has not been found. West of the 98th Meridian the climate in the regions where agriculture is developed is arid, semi-arid, or sub-humid, and irrigation is required. It is in part of this region that the possibilities, proportionately to those of the East, are highly exploited, and in some cases over-exploited.

There are more statistical data in available form for the West than for the remainder of the United States, and these data are summarized herein in tabular form. Table 1 contains data on irrigation for the years 1919 and 1929 for each of the nineteen States in which it is practiced.

This information is selected from a *Bulletin* of the U. S. Bureau of the Census, published in 1930[5]. In addition, the *Bulletin* reports an item under "Supplements from Pumped Streams, Pumped Wells, and Flowing Wells." The total shown for pumped wells[6] is 293 026 acres, of which 287 136 acres are in California and the remainder scattered through the other States. The same information is not given for 1919 and, therefore, it is not considered in Table 1. If it were added, the total for California, irrigated partly from wells, would be 1 070 318 acres in 1928, whereas the total for other States would be only slightly affected.

The total area irrigated is given by the Census as 19 191 761 acres in 1919 and 19 547 544 acres in 1929. The area in Table 1 covering three different classes of irrigation is 17 745 182 and 18 189 425 acres, or 92.5 and 93.0% of the total, respectively. The remainder not covered by Table 1 is irrigated from springs, lakes, etc., and from supplementary well supplies not owned by the owners of the surface rights. Table 1 gives: (1) The area receiving its entire supply from streams; (2) the area receiving its entire supply from wells; and (3) the area receiving a supply from streams supplemented by wells. The total shows for the decade a decrease of 6.3% in the first class and increases of 55.1% and 177.5% in the second and third classes. When California is excluded the increase in irrigation from wells becomes much less impressive. The decrease in the area irrigated from streams exclusively is then 2.6%; the increase in the area irrigated from wells exclusively is only 18.0%; and the areas with a supplemental supply from wells shows an increase of only 20.0 instead of 177.5 per cent.

Even this increase indicates a vitality in the growth of the use of underground water which does not exist in the case of irrigation from streams, or gravity irrigation, as it is commonly called. The use of underground water has gone forward in spite of conditions adverse to agricultural development which existed during the decade. The causes for this increase are probably: (1) Pressure for new development in certain areas in spite of over-development of agriculture in the United States and even in the State in which the

* Exclusive of California.

new development is made; (2) failure of gravity supplies due to drought, or to additional use of the stream at higher elevations; (3) increased efficiency of pumps; and (4) lower power cost.

A clearer picture of the whole may be made by roughly grouping the arid States in accord with difference in economic, physical, and climatic conditions to determine in what general areas the increase has taken place and to lay the basis of an estimate for the future.

Group 1 consists of Louisiana, Arkansas, and Texas (southeastern part). Although Western Texas is arid, the eastern part, with all of Arkansas and Louisiana, is humid. Irrigation by pumping from wells is practiced for rice even in the most humid portions of each of these States, as this crop should be partly submerged after a certain stage of its growth. Rice is grown on leveled land on which water may be ponded by dikes surrounding or going through the fields. In the section of this group of States where rice is grown, the terrain is so flat that gravity irrigation is impracticable in most cases and recourse must be had to wells or to pumping from streams. The ground-water supply is not sufficient to maintain the present draft in certain of the areas. The acreage in rice depends on the rice market. Future increase in the acreage irrigated from wells may not be large as it is unlikely that there will be any considerable failure of stream supplies making it necessary to substitute wells.

Group 2 consists of Montana, Wyoming, North Dakota, and South Dakota. In all four States only 1 912 acres were irrigated from wells exclusively in 1929. Although this is 196% increase from the 647 acres thus irrigated in 1919, the total is insignificant. The climate of these States is not conducive to crops which can stand the comparatively large annual expenditure required for pumping from wells, and it is believed improbable that the total cost will ever be so large as to cause it to be a problem.

Group 3 consists of Colorado, Kansas, and Nebraska. Colorado east of the Rocky Mountains is an area of high plains with an eastern gradient which continues through Kansas and Nebraska to the Missouri and Mississippi Rivers. The eastern limit of irrigation is at about Longitude 98° W, west of which lies about three-fourths of the length of Nebraska and two-thirds the length of Kansas. The principal streams from the eastern slope of the Rockies in Colorado flow on through Nebraska and Kansas. Precipitation occurs principally in the growing season. Both temperature and precipitation increase to the east and south. Crops raised by irrigation are quite similar over the entire area, but corn—the hoed crop in the eastern part of the area—gives way to sugar-beets as one goes west. Such irrigation from wells as occurs is practiced entirely in the broad bottom-lands of the streams. It is not feasible for the bordering plains. The cost of securing water in the bottom-lands is small, as the water-table is high and other conditions are favorable. Physical conditions are favorable to an increase in the area watered from wells. Surface supplies from the principal stream are unreliable especially as the distance from the mountains increases and until the humid section is reached, but there should be ample underground water for any demand that is likely to be made upon it.

Group 4 consists of Idaho, Utah, and Nevada. Except as to Northern Idaho these States are arid. The climate in a considerable area of each State is conducive to high crop values. Underground water is found: (1) In isolated basins from which the water that enters them is dissipated without surface outflow; (2) in larger basins, more prolifically supplied, from which issue streams originating in the ground-water; and (3) along river bottoms and under irrigation projects. Physical conditions are favorable to an increase in the area supplied from wells, and in some basins of Utah the demand is said now to exceed replenishment. In 1919, the area thus supplied in this group was 15 000 acres and the increase by 1929 was 90 per cent.

Group 5 consists of New Mexico and Arizona. The southern part of these States is characterized by an intensely hot and arid climate. Irrigation from wells in New Mexico is largely in the great artesian areas. In Arizona, to a large extent it is along the Salt River and other tributaries of the Gila where irrigation has increased the ground-water supplies. Water is pumped, however, from the bottom-lands and valleys formed by the principal streams and from closed basins. The physical conditions are favorable to the extension of the area irrigated from wells.

Group 6 consists of Oregon and Washington. West of the Cascade Mountains irrigation is not practiced, but east of these mountains both States are arid. The climate decreases in aridity east from the Columbia River, in Washington. Some development of well irrigation exclusively is occurring in Eastern Oregon from basins, but in Washington little extension is being made.

Group 7 consists of California alone. Almost 75% of the total area in the United States irrigated from wells exclusively, and 66% of that which uses wells for a supplemental supply is found in California. To a limited extent the areas in which ground-water exists are found along the flood-plains of the

TABLE 2.—AREA IRRIGATED EXCLUSIVELY FROM WELLS, BY GROUPS OF STATES

Group No.	State	Remarks	Area, in Acres 1919	Area, in Acres 1929	Percentage increase
1	Louisiana........ Arkansas......... Texas.........	Humid climate; water used for rice growing.	335 301	381 389	13.7
2	Montana......... Wyoming......... North Dakota..... South Dakota.....	Cold climate; expensive pumping impossible.	647	1 912	196.0
3	Colorado......... Kansas......... Nebraska.........	Well suited to pumping from wells along streams. Much additional development possible.	28 221	51 032	80.9
4	Idaho......... Utah......... Nevada.........	Well suited to pumping in parts of this group. Considerable development possible.	15 110	28 650	89.6
5	New Mexico....... Arizona.........	Climate suitable to expensive development. Water naturally available is limited.	94 105	164 117	57.3
6	Oregon......... Washington.......	Climate favorable over great part, but ground-water conditions not suitable for large development.	23 070	24 886	8.0
7	California.......	Ground-water over exploited in parts and must be replenished by importation if present development maintained.	828 060	1 464 960	68.8

streams, but most of the ground-water supply is found in the coastal valleys and in the great central valley. These valleys are filled with detritus and are supplied by percolation from streams crossing them and rainfall on the valley floor. Some areas are now over-developed. It is to be expected that only a small percentage of increase will take place in the future in the area of the State irrigated from wells, because most of the development possible has occurred unless (as is proposed for some areas) water is imported for artificial recharge.

Table 2 shows the comparison of area in each group irrigated from wells exclusively in 1919 and 1929. It is in Groups 3, 4, and 5, and possibly in Group 6, that climate and physical conditions point to further development with possibilities of over-development and attendant legal conflicts, such as have occurred already in some States, and particularly in California.

Water Law in General

Any legislative acts concerning underground water would presumably follow closely any existing legislation as to surface waters in the jurisdiction wherein the enactment is made, and it is desirable, therefore, to inquire into the law of surface waters in the various States before discussing that of underground water, in order to discover something of its nature. The law of underground waters, as now developed, is less than a century old, whereas the law of surface waters of the United States had its antecedents and development in the Roman Empire; hence for intelligent discussion reference must first be had to the law of surface waters. The civil law of the Romans is the foundation for the common law of England, which was adopted by each of the jurisdictions of the United States that came in after the original Thirteen Colonies where not incompatible with economic conditions prevailing in the new country. It appears probable, however, that the common law of England on water was taken from early American decisions which were derived from the Code Napoleon, which, in turn, was derived from the Roman law.

The doctrine of surface water originally made it the common property of the public, just as air and fish in the water—economically a "free good"; but because private ownership of land came to exist, it follows that the public is excluded from the use of the water except in the case of navigable streams and lakes, or the sea, and, consequently, the stream and the lake are the common property only of those who own lands bordering them. As a final outgrowth (in this country, at least) the common law doctrine of riparian rights permits each owner of riparian lands to use the natural flow of the stream on his riparian land in any reasonable way. In other words each riparian owner has a right correlative with, and equal to (proportionate to his holdings of riparian land), that of every other riparian owner. Riparian rights do not attach to all land in the water-shed, but only to the extent of the holding (which has never been severed) of lands bordering the stream, and even then not past the water-shed boundary. Priority of right does not exist; nor does the right exist to store water for use in a later season. Use must be made of the stream in its natural regimen if at all.

Water may be appropriated for use, however, on distant non-riparian lands in all jurisdictions. This is at the sufferance of the riparian owner where the riparian right is recognized and, if he insists, after compensation for any damage he may suffer if he makes his claim before the period of limitation forecloses it. If no damage is suffered no claim can be made, as the riparian right, similar to the appropriative right, is the right to use, but not to hold, unused water against others who may have use for it. The definition of the use for riparian rights varies with the jurisdiction and is probably very broad in some States. Appropriations could be made under the civil law of Rome and can also be made under the legal systems of all countries the laws of which derive from the civil law. Undoubtedly, this was the case also under all legal systems foreign to the Roman system, which were developed under civilizations where irrigation was necessary. Mexico does not seem to have recognized the riparian doctrine and from reading its water codes it is concluded that its officials exercised a free hand in granting appropriations. Most of the arid States of the United States have rejected the riparian doctrine and have substituted for it an appropriative procedure entirely, based on Mexican procedure probably, but adhering strictly to the doctrine of priority of right obtained with an appropriation.

In the arid States water is more important than land, since it is the limiting natural resource in development. Under the appropriative doctrine it is conceived that water is public property, but that the State owns it in trust for all the people, and it is not the property of only those who have access to it because of riparian holdings. These States have ruled that the right to use water should be exclusive instead of correlative. A water right is a property right and the exclusive appropriative doctrine is somewhat more akin to the law of real property than the riparian doctrine of water law. In the appropriative doctrine, as it now prevails in the States, he who is first in time is first in right and can insist on his full right as long as reasonably needed even if it takes all the water in the stream except that necessary for domestic and stock use in most cases. In sequence of priority all users take their full right as long as the water in the stream will yield it without infringing on prior rights.

Wyoming, Nevada, Utah, Colorado, Arizona, and New Mexico, which are wholly arid States, and Idaho, which is partly arid, abrogated the riparian doctrine and adopted the appropriative doctrine either by constitutional provision or by statute at an early date in their history. Montana by a Court decision uttered in 1921 appears to have joined this same category. In the States immediately east of the Rocky Mountains (that is, North Dakota, South Dakota, Nebraska, Kansas, Oklahoma, and Texas) irrigation is necessary or desirable only west of about the 98th Meridian; that is, in only about three-fourths or less of their area, and is, therefore, not so important as in the aforementioned States. Both the riparian and the appropriative doctrines exist in these States, although incompatible in theory; and yet, because the riparian right in the arid parts has been limited to reasonable use consonant to the definition of reasonable use in connection with appropriative rights, or has been limited in some other way, the conflict is not important. In Oregon,

riparian rights as defined herein have been virtually abrogated and, in Washington, they still exist but are no longer of importance. In California, the basic doctrine is strongly riparian but an appropriative procedure has been superimposed on it. Riparian rights have been limited by constitutional amendment (1928) to that reasonably required for beneficial use comparable to beneficial use under appropriative rights. This was upheld and interpreted by the Court in 1935 (Peabody, *et al. v.* City of Vallejo, 2 Cal. 2d 351).

The appropriative doctrine lends itself to administrative control more fully than the riparian doctrine. In all the aforementioned States, where the most arid conditions prevail, an elaborate procedure as to surface waters has been set up for receiving filings for appropriation, granting permits and licenses, adjudicating water rights by stream systems, patrolling streams, regulating head-gates, and, in general, seeing that each water user gets the water to which he is entitled. In the less arid Western States the procedure is not so much elaborated.

One point in surface-water law, especially important to this discussion, needs to be considered: "Is the diverter from the stream protected in his means of diversion?" Under the common law doctrine the riparian owner has a right correlative with that of every other riparian owner to the use of surface water; he possesses nothing exclusive. If one suffers from water shortage all must suffer. Under the appropriative doctrine, the user of surface water has an exclusive right, which may be exercised when sufficient water is in the stream no matter what may happen to those having rights junior to him except that, under certain conditions, stock water and domestic supplies for the junior rights take precedence over every other kind of use by the senior rights.

Does this correlativity and this exclusiveness extend to the means of diversion? In other words, can the riparian diverter claim that an undue burden has been placed upon him if other up-stream riparians, after his works are completed, take from the stream sufficient to make his diversion works useless and to require him to incur additional expense if he wishes to continue to use the water? Furthermore, can the appropriator using surface waters claim estoppel on projects up stream which, while not depriving the stream of sufficient water for his right, cause him additional expense to divert?

It is patent that all degrees of deprivation might be incurred in such a case from the most minor to one in which the cost of changing diversion methods would be so expensive as to be complete confiscation of property. Actually, this latter would rarely be the case, and it would seem just that protection be given against such contingency. Most cases are not so serious but nevertheless any additional expense would be partial confiscation unless recompense were made. On the other hand the "hurdle" faced by the individual who proposes to divert at an up-stream point would indeed be high if he had to compensate all down-stream riparians whose diversion works would have to be reconstructed because of his act. Development would be seriously curtailed.

It would seem that a right to an exclusive method of diversion would be incompatible with the riparian doctrine. The riparian doctrine is such that

any owner up stream or down stream can take a part of the supply of the original riparian diverter and deprive him of his use. As compared to this, the benefits of a certain method of diversion would be of comparatively small moment. As there are only a small number of riparian rights being exercised in the United States in locations where water is important, it is probable that the matter has never come to the attention of the Courts. At least, "Corpus Juris" does not list any cases exactly in point.

When it comes to appropriative rights it is found that two cases were decided at a comparatively early date—Shodde *v.* Twin Falls Land and Water Company (161 F. 43) Idaho, and Natoma W. and M. Co. *v.* Hancock (101 Cal. 42) California—which held that the appropriative right did not include a further right to insist on a certain means of diversion. In the first case, the force of the current turned the plaintiff's water-wheel, which, in revolving, lifted water in buckets attached to the wheel. The water in these buckets was dumped into a canal and reached the land of the plaintiff. The Court held that the plaintiff had appropriated water for irrigation, had made no appropriation for power, and denied injunction when a dam below caused backwater at this wheel. The Natoma case is exactly in point and declared flatly that the plaintiff must change his diversion system when up-stream takings interfered with his ability to obtain water by means of existing works. No other cases have been found.

Legislative enactments or "water codes" of the various States contain nothing on protection of means of diversion. It would seem from this fact, and from the foregoing cases, that short of absolute or a very great degree of confiscation, protection is not given to means of diversion. Protection of the water right seems to be regarded as important in the "water codes", but not protection of the other phases of the property right. Constitutional provisions regarding confiscation of property as interpreted by the Courts are the protection in such cases.

Comparison—Appropriative and Riparian Doctrines

Both the appropriative doctrine and the riparian doctrine have faults and both have advantages. The appropriative doctrine, particularly is an attempt to give the closest approximation possible of the law of real property; but land is fixed in position and stable in area, whereas running water is evanescent and its quantity varies from day to day, from season to season, from year to year, and from cycle to cycle. Manifestly, with such an unstable natural resource, no such security of possession can be given as is the case with land; but the appropriative doctrine attempts to approximate it as closely as the nature of flowing streams and vagaries of climate permit. In times of normal flow the difficulties are not such as to be serious, but in cycles of unusual drought the deficiencies of the doctrine become apparent and these defects result from this very attempt to give stability. A preferred class of first users exists and all junior appropriators can be deprived of even partial supplies (except domestic and stock necessities under certain limitations) to give a full supply to the preferred class. This result of the doctrine has been masked on many streams by the reservoirs con-

structed by the U. S. Reclamation Bureau which in many cases although originally built for the new projects of the Bureau, have been found large enough to supplement such of the prior rights as were deficient.

The riparian doctrine recognizes the variability of water supply and prorates it to the riparian owners; and thus, in times of deficiency, all riparian users suffer equally just as in humid areas all suffer during drought. Nevertheless, the riparian owners are a preferred class, as is the early appropriator. The base is somewhat broader, however, and the preference much more limited. Since it deals only with streams in their natural regimen, reservoir development is impossible under it and recourse must be had to the doctrine of appropriation. The riparian doctrine creates uncertainty as to water rights and encourages resistance to non-riparian diversions; but where limited to reasonable use (as rights under this doctrine now have been in all arid areas of America), the resistance is not serious.

As interpreted by the Courts neither doctrine has been entirely satisfactory for present complex conditions and there is a tendency toward modification. Compacts between States have been consummated, or are in process of consummation, which allocate certain shares of water in the stream system to the different States regardless of priority. The Colorado River Compact is a notable example. In California, the terms of the act creating the Water Project Authority which relates to the Central Valley Project, introduces another new phase in water law in that priority of an entire water-shed is given. In California, also, streams have been adjudicated by zones in which the relation of the water rights of one zone to those in another has not been observed. Such an adjudication is very similar to the Colorado River Compact.

In the water conflicts between States the Supreme Court of the United States is the only judicial body having power to assume jurisdiction no matter what doctrine of water rights prevails in them. The Court has assumed this power and has shown a tendency toward making an "equitable" allocation of the unused water where the appropriative doctrine is not in force in both or in all of the contesting States, leaving present uses untouched. It has also shown a tendency to continue to hold such situations under its control with the apparent expectation of revising its allocation as development proceeds.

It seems probable that whatever system now exists will continue to exist for the smaller stream systems, in all jurisdictions, but that construction of reservoirs and modification of interpretation will finally occur by which a more uniform and flexible distribution of the unstable water supply will be secured. For the larger stream systems, special laws (either legislative or judicial) framed to meet the situation, are probable. In other words, the two doctrines will continue to meet the requirements of minor matters, but modifications of both are being made for the large developments.

Underground Water Law in General

Only in comparatively recent times has underground water become important. The first case used as a precedent by the Courts of the United States

was decided in England in 1843 and the controlling case in 1857. In these decisions, underground water was considered as a mineral which could be extracted by the owner of land at his will without recourse on the part of others who might be damaged by such extraction. All American Courts followed this rule for a time, but in 1862 the New Hampshire Court departed from it and promulgated the rule that the use of underground water must not be greater than reasonably necessary for the tract of land in which the water is produced. Under the former rule exportation of water could be made even if it damaged others dependent on the underground water either directly or indirectly, but in the newer rule such exportation was not allowed if damage resulted. This is termed the "doctrine of reasonable use", or the "American rule"; it is applied in a considerable number of the States in the humid sections of the United States whereas in the others the former doctrine of what may be termed "unreasonable use", or the English rule, still prevails. All Western jurisdictions, also, followed the English rule at first, but when greater knowledge of physical conditions came about through the use of underground water for irrigation, especially in California, the California Court (Katz *v.* Walkinshaw, 74 Pac. 766) introduced another doctrine which abrogated the English rule and expressly adopted a further and entirely logical development of the doctrine of reasonable use. This rule holds that each land owner overlying a basin has a right to the underground water co-equal and correlative with that of all other land owners overlying the same basin. In contradistinction to the doctrine of reasonable use this means that one land owner can not extract more than his proportion of the underground water even for use on land overlying the source when by so doing he encroaches on the right of another owner to do the same; nor can water be exported if injury to the overlying land owners results.

This places underground waters in California under the same doctrine as surface waters on riparian lands; that is, under the doctrine of correlative right. By later decisions, all the waters of a stream system, whether percolating and diffused underground; flowing underground in contact with a surface stream; flowing underground in a definite channel; or flowing as a surface stream or ponded in a lake, were treated in the same way, and the use of underground water was made correlative with the use of the surface stream.

The rule of underground water as promulgated in Katz *v.* Walkinshaw was adopted by the Courts in some Western jurisdictions in spite of the fundamental appropriative doctrine which exists in many of them. This rule is compatible with the riparian doctrine of surface streams, but is not compatible with the doctrine of exclusive appropriation of surface waters prevailing in the strictly arid States. Some other Western States still adhere to the English rule; thus, in many Western States, there are Court rulings which define the law for underground water either on the reasonable or the unreasonable use basis, and an entirely different legislative doctrine for the surface stream which may be fed by the underground basin, a condition that is certain to cause legal confusion where economic conditions permit the development of underground water.

A digest of Court decisions made in 1928 (55 A. L. R. 1390) lists thirty-one States (including the District of Columbia), mostly in the humid region, but including five in the arid region, in which former decisions are favorable to the common law rule of absolute ownership of underground waters. This doctrine, as heretofore stated, was first challenged in 1862 in New Hampshire, and the doctrine of reasonable use was introduced. Not until 1900 did any other State concur, but in that year the Court of New York adopted the same rule and, in 1909, the Court of New Jersey followed. Of the States listed in the foregoing digest a total of six had reversed themselves and eight have not recorded decisions since 1900. Twelve States not listed in the digest have adopted the doctrine of reasonable use (Neb. L. B. 12; 191–6N, 1933). It appears that the trend in humid States is toward the American rule, but that many jurisdictions still hold to the English rule.

The status of the law as to underground waters in the various Western States (there are statutes in many States prohibiting the waste of artesian water, but this phase is not considered in this paper), is as follows:

Arizona.—There are no statutes on underground water in Arizona. The Court has ruled that such water is not subject to appropriation (Maricopa County Municipal Water District *v.* Southwest Cotton Co., 1931, 4 P. 2d 369), and, at first, reserved decision as to whether the English rule or the correlative doctrine which originated in California should prevail; but in 1934 (Fouryan *v.* Curtis, 29 P. 2d. 722), it decided in favor of the American doctrine of reasonable use—that is, that the water belongs to the land under which it is found and could be taken to distant lands if injury did not result to another on the stream system. In the case of Pima Farms *v.* Proctor (245 P. 369, 1926), the underground water in a stream valley several miles wide was in question. No surface flow exists except in flood times. The Court ruled that this was a definite underground channel (the litigants stipulated at the outset that the water involved was the immediate underflow of the river), that the prior user of underground water had a vested right to the maintenance of the water level, and that subsequent users must deliver water to him at no greater cost than had been incurred prior to the new use. This is similar to declaring that a prior appropriator of surface waters had a vested right in the means of diversion; in fact, the Court states that this is the law, but cites no decisions to that effect.

California.—There are no statutes on underground water in this State, but it may be appropriated by taking on sufferance of the overlying land owners. These appropriations ripen into a right after five years of open taking and are so recognized by the Courts.

No exclusive rights are permitted in underground waters except the appropriations previously noted. Cities and other municipal organizations are regarded as appropriators even if they are located directly above the underground basin. All overlying lands, and lands riparian to a stream where the percolating waters feed a surface stream, have correlative and equal rights to the stream system whether water is on the surface or underground (that is, percolating). A diversion from a surface stream made prior to 1914 may be an appropriation even if on riparian land, and, as such, prescription obtains

against an underground water user below, who may be supplied wholly or in part by percolation from the surface stream.

The law of waters in California, both surface and underground, is highly developed and rests on reasonable use and the correlative doctrine of equal rights.

Colorado.—Underground water is not mentioned in Colorado statutes as subject to appropriation. The Courts have held that it is subject to appropriation, however, and subject to the same regulation as surface water. Rights under appropriation are in order of priority of filing on the stream in question. The Courts seem to be tending to the rule that in Colorado all waters, whether surface or underground, are presumably tributary to a surface channel, and that their taking is thus subject to prior appropriation of the surface stream.

In Colorado the taking by an underground user is stopped if it decreases the surface flow available to the down-stream user even if the down-stream user could sink pumps to the underflow and get a full supply. This amounts to a guaranty of the method of diversion previously discussed.

The theory of underground water law in Colorado is consistent with that of surface streams, but the application varies in the aforementioned particular. The waters of an entire stream system are treated as one.

Idaho.—Underground water is not specifically mentioned in statutes in Idaho. The Court concurs in the doctrine of appropriation of underground waters and states that it may be by the procedure of the water code, or by taking (Silkey *v.* Trego, 5 P. 2d, 1049, 1931). The subsequent appropriator of underground water must not lower the water-table from which the prior appropriator pumped (Noli *v.* Stonen, 26 P. 1112, 1933). In other words, the prior appropriator is protected in his means of diversion when underground water is in question.

Kansas.—All underground waters in the northwest quarter of the State are, by statute, subject to appropriation. Disputes on underground water have not been before the Court to any great extent, but so far decisions appear to be based on the English rule.

Montana.—There are no statutory provisions for the appropriation of underground water in Montana. Conflicts involving underground water have not been frequent. A case decided in 1912 followed the English rule (Ryan *v.* Quinlan, 124 P. 512).

Nebraska.—There is no legislation concerning underground water in this State, but in 1933 the Court declared in favor of the doctrine of reasonable use (Olson *v.* City of Wahoo, 124 Neb. 802).

Nevada.—The statutes provide that all water within the State, whether above or below the ground surface, belongs to the public and may be appropriated for beneficial use as provided in the act and in no other way; but it specifically eliminates percolating water, the course and boundaries of which are incapable of determination. Use of underground water is not great and details of administration have not been established by State authorities. There have been no recent Court decisions on the matter.

New Mexico.—In 1927, a statute as to appropriation of underground waters was passed in New Mexico, but was declared unconstitutional in 1929 because of faulty title. In 1931, a new act, designed to satisfy the Court's objections to the first, was passed by the Legislature.

The statute applies to waters of underground streams, channels, artesian basins, reservoirs, or lakes having reasonably ascertainable boundaries; and declares them to be public waters and subject to appropriation. As a result of the definition, waters diffused and percolating toward a stream in the manner customary in humid countries, may not be included.

As a result of investigation the State Engineer has declared three basins as coming within the scope of the law. Two of these are basins in which the water is not under pressure, but in a condition such as that defined previously under the heading, "Percolation Through Basins." The other is the famous Roswell artesian basin previously mentioned.

The degree of co-ordination between procedure in the case of underground water and surface water in the same stream system is not apparent in the statute or the procedure outlined by rulings of the State Engineer. Apparently, the State Engineer proposes to accept filings only in those basins which have been examined and which have been declared to come within the purview of the statute. The Court has declared that adjudications should embrace both ground and surface water in one proceeding (El Paso and R. I. Ry. *v.* District Ct. 8 P. 2d. 1064, 1932).

North Dakota.—The statutes of North Dakota declare underground waters to be in the same ownership as the land on which they are found. No Court decisions have been made.

Oklahoma.—The statutes of this State make no mention of underground water and Court decisions on the question have not been found.

Oregon.—All waters, according to the Oregon statute of 1909, may be appropriated for beneficial use. In 1927, underground water east of the Cascades was declared subject to appropriation when it occurred in basins the boundaries of which could be defined with reasonable certainty. As finally amended in 1932 the statute as to underground waters still limits appropriation to the areas east of the Cascades and conforms to the law of New Mexico. Applicants for appropriations follow the general procedure outlined for surface waters. Development is proceeding east of the Cascades. There are no recent Court decisions as to the status of the underground water in Oregon.

South Dakota.—The statutes in force in South Dakota are "silent" on underground water. All Court decisions uphold the common law doctrine of absolute ownership and unreasonable use.

Texas.—There are no statutory enactments as to underground water in Texas. All Court decisions uphold the doctrine of absolute ownership of underground water.

Utah.—By a number of decisions, the Utah Court has held that owners of overlying land have co-equal and correlative rights in underground water (Katz *v.* Walkinshaw, *supra*) and also that such owner may export his *pro rata* share to distant points. The controlling case is Glover *v.* Utah Oil Refining Co.

(218 Pac. 955, 1923). In the case of Wrathall *v.* Johnson (1935), the Court —in a peculiarly divided opinion—held that the use of underground water is by appropriation even if on overlying land and is subject to the same restrictions as prevail for appropriations of surface water. This was a decision on demurrer and cannot be regarded as conclusive.

The Legislature of 1935 enacted a statute placing underground water in the same status as surface water; that is, as a right secured only by application for appropriation to the office of the State Engineer. This act follows a model recommended by the Association of Western State Engineers and is similar to the New Mexico statutes.

Washington.—All water in the State of Washington is declared to be subject to appropriation which would include underground water, but State officials consider that no authority is conferred on the State over such waters. One Court decision on underground water adopts the doctrine of reasonable use on overlying lands; another that underground water may not be taken to the injury of surface water diverters from the stream. The doctrine of the Courts is not well defined.

Wyoming.—No mention is made of underground water in the statutes of the State; nor are there recent Court decisions to clarify the law.

All Other States.—The only attempt at statutory control coming to the notice of the writer is in New York State where wells on Long Island drawing more than 100 000 gal per day are placed under the jurisdiction of the State Conservation Commission.

Summary.—Summing up the results of the foregoing examination, there are found to be four doctrines of law in the United States on which use of underground water is based: (1) Absolute ownership of water because of the ownership of the land beneath which the water is found, with no obligation to respect the rights of others, is herein termed the "doctrine of unreasonable use" or the English rule; (2) absolute ownership of water to the extent of reasonable use on the land beneath which the water is found, but with no right to export to distant land if by so doing damage is caused to another, is herein termed the "doctrine of reasonable use", or the American rule; (3) ownership, co-equal and correlative with that of every other land owner, of water lying over the basin, or riparian to a stream fed by water rising from the basin, is herein termed the California doctrine; and (4) entire lack of ownership on the part of the proprietor of the land, but ownership by the State instead—which allows use by appropriation under a procedure set by the State, or otherwise, and which is subject to prior rights of other users whether from the surface stream or from underground sources tributary to the stream—that is, the doctrine of prior appropriation. These differences are successive and cumulative impositions of control or, broadly speaking, the police power as found desirable because of the growing use of underground water, and as found possible because of increased knowledge of groundwater hydrology.

Unless analyzed these diverse doctrines would seem to entail endless confusion, but when it is remembered that there is also great diversity of climate

in the United States and also great variation in the present stage of development and possibilities of future development, the probable confusion appears not to be very great as a whole although potentially bad enough in limited areas. The worst legal confusion could result from lack of consistency between surface-water law and underground water law in the same general region; but even where these laws are inconsistent, the climate may be such that costly development is impossible and, if so, the conflict may be more apparent than real.

Administration

Surface Streams.—From a stream of any extent, in arid regions, there are numerous diversions made for irrigation and it is obvious, in view of fluctuations of stream flow, that if use is large as compared to flow, chaos would result if these diversions were not controlled. In times when the flow is not sufficiently greater than the rights so that control is not needed, the administrative official allows to each diversion its right as determined by the law, Court decisions interpreting the law, Court decrees dealing with water rights in the stream, custom, and his own interpretation of the law. The decrees or the law not only determines the priority, but the amount of diversion. This administration is possible under both riparian and appropriative systems of law. Under the appropriative doctrine the administrator goes further and permits or denies new rights (if the law gives authority to deny), depending on his determination of the existence or non-existence of unappropriated water. In many States authority to deny is not given but control rests on the water master. So far as known no administrator denies a permit or in his policing of the stream closes a diversion because of difficulty which may be, or is, caused to a lower diverter as long as the water required by the right of the lower diverter will reach his point of diversion on the surface; but accompanying almost every surface stream is underflow which is legally a part of the stream system, and where this exists, it can be diverted by pumping so that even if the surface stream is all diverted at a point up stream, the lower user is not necessarily deprived of water. So far as known, however, administrators take no cognizance of this in their administration. This custom is based on Court decisions.

The Courts in all jurisdictions, in so far as can be found, have enjoined surface diversions which would have made it necessary for a prior and lower diverter of surface water to pump to secure water. It seems probable that this is the outgrowth of custom antedating the use of underground water, or it may be that a change from surface diversion to pumping diversion is unconsciously regarded as a rough dividing line between complete confiscation and endurable confiscation, discussed previously, in connection with surface water; or, it may be that, because the appropriation of surface water was made, it is regarded as necessary that surface water be preserved to the right. It is only recently that connection between surface water and underground water has been recognized legally. Formerly, the two were treated in separate and distinct doctrines of law, and still are, to a great extent. This matter has an important bearing on the development of underground water because

it is probable that once control of the use of underground water is attempted, both classes of water will be brought under the system which prevails as to surface water in those situations where both are involved but most statutes so far enacted for control seem to ignore this probability.
